The CHAIRMAN said: Gentlemen, I have sent you a circular which to a certain extent illustrates our present position, and you have all before you the report of the Directors. These two documents together place you in full possession of all the facts bearing upon the present position and interests of the Company. I shall therefore address you very briefly, and if I omit from my remarks any point in which you feel interested I shall be glad to answer afterwards any question you may choose to put to me. I think that the most important point for your consideration is that there is a great contrast between your position now and two years ago. Then you were entangled in a series of law suits which, in all probability, would have exhausted not only the capital then called up but all the uncalled capital. I do not know that I can give you a better idea of what those legal charges might have been than to state that there has already been expended in legal proceedings, which the Company has had to pay, £4,500. You may therefore imagine what would have been the result to the Company if the various actions had been pressed to their utmost extremity in the courts, and if the losing parties, as would undoubtedly have been the case, had appealed to the higher courts. I am happy to be able to inform you that we have succeeded by compromises which I consider advantageous to the Company—the circumstances connected with which you are already aware of—in getting rid of the risk of the frightful legal expenses to which I have just referred. And I may briefly point out to you what the effect of the compromises has been. In the first instance the capital of the Company was 91,732 shares upon which 12s. 6d. a share was paid, and 78,500 shares that we issued fully paid up, making the total capital of the Company £170,232. Under an arrangement with the litigants 41,131 of the 12s. 6d. shares were surren-

Digitized by Google

dered, and under an arrangement sanctioned by you on the 13th of April, 1884, 50,350 fully paid-up shares were surrendered, making together 91,381 shares, leaving the capital of the Company, instead of £170,232, only £78,851. Upon the 50,701 ordinary shares remaining, £31,869 has been paid up, which with the 28,150 fully paid-up shares, leaves the capital of the Company entitled to a dividend at this time, if we could pay a dividend, at £60,019. Now, a most important compromise which has been made is this. You are aware that the fully paid-up shares held a preferential position, and suppose you had liquidated the Company when 78,500 of them existed, their preferential position of 7s. 6d. a share would have amounted to £29,437. The 50,350 shares that have been cancelled accounted for £18,881, and the preferential position occupied by the paid-up shareholders at present is only £10,566. Now, had the paid-up shareholders remained in their old position, and you had decided to liquidate the Company, the extra amount that you would have had to pay in, owing to the preferential position of those shareholders, would have been £18,881, or 7s. 5d. per share on all the ordinary shares of the Company. The difference is equivalent to all the uncalled capital of the Company, and it must be a great relief to you to feel that you have got rid of a grave and overwhelming incubus. You will be glad to hear that during the current half year the results at the Polmadie works have been very much more satisfactory than hitherto. There is a loss, but it is a very small one. The patents possessed by the Company have produced most satisfactory returns. Relatively large returns have been derived from the waggon-cover fastener, and there is still a prospect of our obtaining a considerable revenue from that small patent. The compensator, invented by Mr. Henry Williams, is likely to be of great importance to the Company hereafter. It has been tried by most of the principal railways. Several of them have given second, and one or two of them third orders for it, and Major Marindin, of the Board of Trade, has expressed his great approval of the invention, and has given Mr. Henry Williams permission to state that he does think well of it; so that I trust hereafter that we may get something towards providing a dividend for the Company out of the compensator. You are aware that trade has been for some time past in an extremely unsatisfactory and unprofitable condition, and companies like this, relying on the out turn of their works for a dividend, have necessarily been in a disadvantageous position. But we hope that the long continuance of bad trade will soon come to an end, and that there will be brighter prospects before us at no remote date. If that be so, I should hope, with the improvement in our ordinary trade, the success of our patents would help us towards putting the Company, with its reduced capital, into a more prosperous and satisfactory state. Looking to the report, there is just one feature in it to which I wish to ask your attention. It is that in the statement of the loss at Polmadie Works two of the items have been entered as affecting last year which have told against us, and yet had not resulted from the actual working of the establishment. The first is that £420 was paid to the old manager of the Company. His services were dispensed with. He was receiving an extremely high salary, and it was thought judicious on the part of the Directors to pay him up to the period of the termination of his engagement, and to dispense with his services, in order that new arrangements for placing the works on a better basis should be carried out forthwith, so that the losses of the year have been debited with £420 for which the Company have derived no direct advantage. There has been a reduction in the valuation of the stock of £700. That reduction ought properly to have fallen into the losses of the previous year. It should have been made at the beginning of that year. If it had been, the loss in the works last year would have been extremely small. You are aware that £2,000 is put down for Directors' remuneration. The Directors had no intention of receiving the full amount of remuneration put into the accounts which they are entitled to under the Articles of Association. But it turned out that, in order to get through with the important compromises to which I have referred, by which we got rid of 50,350 fully paid-up shares, it was necessary to come to an arrangement with the party who was blocking our action; and his arrangement was that certain expenses should be paid by the Directors, instead of being paid as authorised by the Company. The Directors have therefore paid £1,151, which the Company by your sanction would have paid, and which was a fair charge against the assets of the Company. That £1,151, therefore, must be regarded as a diminution of the loss put to profit and loss account. That is all the explanation which I have to give you on the report, and I trust that hereafter we shall be able to meet you in circumstances more favourable than those which are before us now. He concluded by formally moving the adoption of the report and accounts.

Sir George R. Prescott, Bart., seconded the resolution, which was carried unanimously without discussion.

On the motion of the Chairman, seconded by Mr. Alexander Smith, Lieut.-Colonel G. A. Elliot was re-elected to his seat at the Board. The auditor having been re-appointed,

The Chairman explained that Mr. Archibald Arrol had not offered himself for re election as a Director. Those who had co-operated with that gentleman had experienced the greatest satisfaction in all their relations with him, and regretted that he now ceased to be one of their number. Mr. Arrol, however, was resident in Glasgow, and it was difficult for him to attend regularly the meetings of the Board, and he felt it was his duty to retire.

A vote of thanks to the Chairman, proposed by Mr. Herbige and seconded by Mr. Arrol, was cordially carried, the latter gentleman expressing his regret that his sense of duty compelled him to sever his connection with the directorate, and an earnest hope for the future success of the Company.

The Chairman briefly acknowledged the vote, and the proceedings terminated.

Submarine Telegraph Company.

Report of the Directors to be submitted at the meeting of the proprietors of the Submarine Telegraph Company, to be held at the offices of the Company, 2, Throgmorton-avenue, London-wall, E.C., on Tuesday, 4th August, 1885, at one o'clock p.m.

The accounts for the six months ending 30th June, 1885, show the gross receipts to have amounted to £66,795. 16s. 11½d., and a net result which enables the Directors to add £8,334. 6s. 5d. to the reserve fund, and to recommend a dividend at the rate of 15 per cent. per annum, leaving a balance of £889. 4s. 2d. to be carried to the next account. The receipts for the six months exceed those for the corresponding months of the year 1884 by £4,038. 5s. 0½d. This increase arises principally from the general traffic, although there has also been an increase in the receipts from the special traffic transmitted by the Indo-European Company over the wire in the Norderney cable, which they lease from the Post Office. The average length of the messages, however, in the six months has been shorter, being 11·72 words against 12·04 words in 1884. On the other hand, the number of messages transmitted has been 85,011 more than in 1884. Besides the increase in the receipts, there has been a decrease of £1,229. 5s. 1½d. in the total expenses. The cost of repairs to cables has been £1,858. 8s. 4d. less than in 1884, but the other items of expenditure show together an increase of £629. 3s. 2½d., which sum includes £139. 9s. 10d., a part of the extraordinary expenses referred to in the last report as having been incurred in overhauling and repairing the steamer in the half year ending December, 1884. The decreased cost of repairs to cables is due chiefly to the two Government cables to Holland having been, the one completely, the other partially, renewed by the Post Office, and, consequently, being better able to bear the strain of fishing gear and anchors coming in contact with them. In 1884 these cables were interrupted for 252 days, and in 1885 one of them was not interrupted at all, while the other was interrupted only for a period of 81 days, in the course of which a new length of about 32 miles was inserted in it. The Company's cables in the Channel have also been remarkably free from interruptions, and at the present time all the cables worked by the Company are in good working order. The term of the agreement under which the Indo-European Company worked a wire in the Government cable to Norderney expired on the 24th December, 1884, and fresh arrangements have been made with that Company for continuing the working of the Norderney wire, and also for a wire in the cable of the German Union Telegraph Company, under which the Company will receive a small increase of income.

THE INTERNATIONAL INVENTIONS EXHIBITION.

Dynamo-Electric Machinery.

BY W. M. MORDEY.

The Thomson-Houston Dynamo.—In considering a dynamo machine it is convenient, in the first place, to classify it, to define its type, and then to proceed to examine its details in order to find in what particulars it is an improvement on its predecessors. In most cases this task is a very simple one. A glance at almost any dynamo is usually sufficient to enable its class to be determined. Just as nearly all the early generators were of the Pixii-Saxton class, so now the great majority of successful continuous current machines are of the types with which the names of Pacinotti and Gramme, or of Siemens and Alteneck are connected. But in the very interesting machine now under our notice this usually easy task of general classification is found to present the first of a series of difficulties. In fact, it may be said that in every part of this dynamo, in its mechanical construction as well as in its electrical action, we have something unusual. Peculiarity has marked it for her own. The general form of armature, the construction of the armature core, the winding, the commutator, the general magnetic system, the collection of the current, and the method of regulation—all these matters present points of interest which well deserve study.

The feeling produced by a study of this machine is one of surprise that it should work well. There are so many things about it that are not in accordance with accepted ideas of what is best in dynamo construction, that the writer believes that a consideration of its details and action, in the absence of a knowledge that it worked satisfactorily, would be sufficient to cause most electrical engineers unhesitatingly to come to the conclusion that it would not answer, especially as a high tension dynamo.

The Thomson-Houston armature belongs to the drum, or Siemens-Alteneck type, but is distinguished from its prototype by having the form of a hollow sphere instead of a cylinder —the difference is not one of principle. This spherical form is almost peculiar to this dynamo, the only other instance known to the writer of the employment of a spherical armature being the electromotor of Bürgin, shown at the Paris Electrical Exhibition of 1881. But the Bürgin motor armature resembled the Thomson-Houston armature in no other point than in its external spherical form; its internal construction, as well as its mode of action, being quite distinct from the latter. The iron core of the Thomson-Houston armature, as will be seen from the description given in last week's article, is a hollow shell constructed of cast-iron plates and bridge-pieces or ribs, overwound with iron wire. It would be interesting to know why the inventors left so large a space vacant in the interior of the core. We know that Edison employed a hollow drum in his dynamo—for the Edison armature, as made with the large core of wood, is magnetically hollow—and that other makers, Heinrichs and Gülcher for instance, have made armatures with large inoperative spaces in them; but in no other case is the writer aware of the existence of a dynamo having so large a magnetic vacancy as the machine under consideration. An examination of the distribution of the iron of the core shows that the main portion of the lines of force within the armature probably pass by the iron wire. The cast-iron portions of the core consist of two concave plates, as shown in Fig. 3 in the last Supplement, and of a number of cross ribs. We say that the iron wire plays the most important part in magnetically connecting one pole of the field-magnet with the other, because it will be evident that the ribs, being placed at right angles to the lines of force, can assist but slightly in this action, their position inside the shell formed by the iron wire also to some extent relieving them of any great share in an action which would necessarily render them liable to inconvenient heating by eddy currents. The end plates are further from the pole pieces than the iron wire is, and on this account must be to some extent withdrawn from an action which in their case also would be deleterious.

The field-magnet system need not be explained. It will be understood from the description already given. In the field-magnet of the Thomson-Houston dynamo every consideration which would weigh with English electricians seems to have been set at defiance. The magnets are mainly of cast iron, and, like the armatures, are mere shells. Although the poles present a large surface to the armature a reference to a sectional view shows that the directly magnetised cylinder is continued into a polar prolongation through an acute angle, the whole being of cast-iron, and that a considerable portion of the centre of the pole-piece is cut away altogether for purposes of ventilation. Again, the yoke joining the ends of the hollow cylindrical cores is necessarily very long and thin, and passes dangerously near to the poles, so that a "leakage" or "short-circuiting" of lines of force would appear to be unavoidable. On the other hand, the field has some distinct advantages. The yoke, as well as the cores, is magnetised directly by the solenoid, thus, to some extent, compensating for its extreme length. The armature is well enclosed by the pole pieces, and presents a large surface to them; and, in addition, the armature core itself is brought within the direct magnetising influence of the solenoids. The machine would no doubt give a considerable E.M.F., even if it had no iron in the field-magnets. Then, again, the magnetic system is self-enclosed. The yoke bars, although they may afford facilities for magnetic short-circuiting, act as guards to the armature, and prevent the straying of lines of force outside of the machine. It is probable that watches are not seriously affected by these dynamos.

But probably the feature of this machine which strikes those accustomed to the more conventional forms as being more than anything else likely to give trouble is the small number of coils on the armature and of plates in the commutator. Professors Thomson and Houston have, however, not been daunted by any difficulties which might result from short-circuiting or open-circuiting coils of large inductive capacity. They have not only met and overcome these difficulties, they have gone further, and for regulating purposes have introduced momentary short-circuiting of the whole armature, with the necessary accompaniment of violent pulsating changes of current through the whole circuit.

The current is "redressed" by means of a 3-part commutator. The ordinary 2-part Pixii commutator, which has been so largely used in the Wilde and other early forms of generators, has the disadvantage that it yields a discontinuous current whether in the external circuit of a generator or in the internal circuit of a motor, as it either breaks the circuit or short-circuits twice in each revolution. By combining several of these commutators in one, Brush succeeded in maintaining continuity, and Thomson and Houston accomplish the same object by their arrangement of the three coils with the three commutator plates; although in some phases of the commutation this advantage of continuity is abandoned. With this arrangement, as with all true commutators, the diameter of collection is at right angles with the diameter of commutation. In fact, there is not strictly a "diameter" of collection at all. In the Pacinotti-Gramme collector the diameters of commutation and of collection coincide, and there the brushes are placed, being connected with the active coils only through the junctions of the idle coils; but with true commutators the brushes are connected with the ends of the working coils during the whole time that these are active. In this commutator only three plates are used, the coils being connected at one extremity, thus dispensing with three commutator plates which would otherwise be required. The effect of this, and the point in which it differs from other commutators of the same class, is that when a coil is thrown out of connection its circuit is opened at one end only instead of at both ends, as is usual. It is interesting to note that in the earlier Brush dynamos, many of which are still working, a rather similar arrangement obtained, the "idle" coils being put out of connection with the brush at one end only, the other end remaining in contact with another brush.

Digitized by Google

The series of arrangements of the three coils under normal circumstances need not detain us. Each coil is twice out of circuit in each revolution, during which the other two coils are in series with each other. Twice in each revolution two of the coils are parallel, and the third coil is in series with them.

One point is, perhaps, worth alluding to in connection with the parallel working of two coils. As they are, in this case, separated by 120° it will be evident that they are not traversing regions of the field of equal intensity, and on that account their E.M.F.'s are not equal, and the output is something less than that which would be produced by the sum of the E.M.F. of the highest of the parallel coils and the E.M.F of the series coil.

In connection with this question of the construction of commutators it is noteworthy that the two dynamos which have been most successful, and have been most extensively applied as high tension generators, possess certain distinctive qualities in common. The armatures are wound with a small number of large coils, part of which are cut entirely out of the circuit, while some are in series with others, which latter are connected parallel. The effect of this is that with a given winding a greater difference of potential is obtained at the terminals for the same E.M.F. in the armature than would be possible were the Pacinotti-Gramme collector used, which, as it places the two sides of the ring parallel, reduces the E.M.F. available to one-half of the total. Comparing this with the Thomson-Houston armature we see that even when one-third of the wire is removed from the circuit, the remaining two-thirds are in series. Similarly, the Brush armature, with its eight coils, two of which are always out of circuit, may be looked upon as having six working coils, and may be compared with a Gramme 8-coil armature with brushes, each always touching two segments; four of the six coils are always in series. A Gramme collector, of course, could only place three of them in series.

It will be evident that for the purpose of obtaining the greatest difference of potential with any given winding these commutators with the series connections are more suitable than the ordinary continuous connections used with collectors.

The brushes of the Thomson-Houston dynamo are four in number, but as the two brushes on each side of the commutator are directly connected, each pair may for all practical purposes be regarded as forming one wide or thick brush. This arrangement was used in the Siemens dynamos some years ago, and is now employed in the Hochhausen machines, in each case with the apparent object of diminishing the armature resistance by removing coils from the circuit when they were passing through the portions of the field where the direction of the E.M.F. changes. This plan has been abandoned in the case of the Siemens dynamos, and, the writer believes, also in some of the recent Hochhausen machines, probably because the "neutral" region was found to be very small, and that, although the coils so treated had not sufficient E.M.F. to be of much use as a source of current to the line, they generated wasteful and injurious currents when short-circuited through the brushes. A short-circuiting device similar in principle and effect was also used for a considerable time in the Weston dynamos, and may even now be seen in one of these dynamos, of an old design, working in the electric lighting shed—viz., the placing of the plates obliquely on the commutator, thus causing the ordinary single brushes to bear on and connect a greater number of plates than they would if the plates were straight and parallel with the axis.

The application of the wide or double brushes in the Thomson-Houston dynamo differs in some essential points from the foregoing instances, in which the connections of the armature coils were on the continuous or Pacinotti system. As the commutator plates are arranged around the commutator one after the other, each subtending an angle of nearly 120°, and not side by side, brushes enclosing a considerable angle are required in order that the two commutator plates connected respectively with the ends of the adjacent coils may be brought into contact with one brush when they are required to be placed in parallel connection. The same, or a very similar object, is accomplished in the Brush commutator—with which this invites comparison, there being more than a distant resemblance between them—by using a single brush, and arranging the commutator plates side by side through the proper angular distance. A plan very similar to that used in the Brush dynamo appears to have been used in this machine during the earlier stages of its growth, but given up in the recent forms, no doubt in order to meet the requirements of the very striking regulation system.

It may be useful, before considering the peculiar Thomson-Houston regulating system, to glance briefly at some general conditions of the question of regulation, and to ascertain in what directions inventors have mainly worked in their efforts to control the output of the dynamo to meet the requirements of the circuit. Alike in the constant current system of working, which is by far the most practical one for arc lighting, and in the constant E.M.F. system, which, in one form or another, best lends itself to incandescent lighting, a most important point is the automatic regulation of the dynamo to meet the requirements of the circuit. Of these two systems the difficulties of the former almost entirely present themselves at the generator, where they may be met and overcome. The external circuit requires only a constant current. The latter system, on the other hand, presents difficulties not only at the generator, but also in the external circuit, where a constant potential difference is called for at perhaps many points—a constancy which is not perfectly attainable.

The problem of the regulation of dynamos, either automatically or by hand, to give constant current or E.M.F., has been in almost every case approached in one of two ways, other than effecting this by the method of winding or "compounding." Either the strength of the field has been varied, or the brushes have been moved on the commutator till the required result has been obtained.

Maxim, and more recently Hochhausen and others, have employed devices whereby the object was attained by means of rather complicated electrically-controlled mechanism, which moved the brushes to suit the requirements of the varying circuit, or to compensate for irregularities of speed. The collectors in these cases were of the Pacinotti type. There are several objections to such methods. The field expenditure is as great for a small output as for a large one; the loss from eddy currents is greatest when the least amount of work is being done; and the collection of the current, especially in constant current systems, is attended with difficulties arising from the necessity for placing the brushes in position more or less remote from the neutral line in the case of collectors, or the maximum line in the case of commutators.

The other and more usual method of effecting regulation is by varying the strength of the field, making it sufficient to generate the required constant current or maintain the required constant potential difference at the dynamo terminals or elsewhere, and no more. In series dynamos this is best accomplished by employing a variable shunt placed across the terminals of the field-magnet coils; in shunt dynamos by the interposition of resistance capable of variation. In both of these cases the resistance should be capable of perfectly gradual variations, such as may be obtained by the compression of carbon, or by the use of a liquid resistance with movable electrodes. It should not be variable by a step-by-step arrangement, as this produces a jerky and irregular effect in the circuit.

This principle of field regulation was at one time sought to be carried into effect—in the first instance, we think, being proposed by Brush in connection with series dynamos—by dividing the field winding into several parts, one or more of which could be removed from the circuit as required, thus varying the excitation of the magnets. Unless the divisions are very numerous—even if there were no other drawback—this method would not give good results.

There is another plan, one which has found several advocates, amongst them Edison. According to this it has been proposed to vary the field, not by alteration of the magnetising current, but by having a non-magnetic gap in some part of the magnet, usually the yoke, which gap could be filled to the required extent by a movable iron plug playing the part of a variable "magnetic resistance;" or by placing a "keeper" on the poles which acted as a magnetic shunt on the armature, in the manner familiar to us in the magneto-electric shocking or

Digitized by Google

"medical" coils, to vary the useful power of the field magnets. A combination of the two methods of brush-movement and shunt-current-alteration was proposed by Edison, viz., to use an additional brush, to which one end of the field shunt was connected, the other end of the shunt being joined in the usual way to one of the ordinary brushes or terminals. This additional brush was to be moved on the commutator, between the two main brushes, to the position which was necessary to obtain the proper current for the shunt. As any difference of potential, up to that maintained between the main brushes, could in this way be obtained for the field circuit, the shunt current could be varied without the use of additional resistance coils, or the employment of divided field windings. Perhaps the difficulties connected with the construction of incombustible and infusible brushes prevented the extensive application of this very ingenious idea.

The Thomson-Houston regulating system is a most novel and interesting one. The problem of obtaining constant current has certainly been attacked in a very novel manner, the method employed being made to yield results of a character far above what might have been expected. It is not necessary to enter into any examination of the ingenious apparatus by which these results are obtained; it has already been described. Suffice it to say that the apparatus appears to be very sensitive, and to respond promptly to all calls made upon it. By watching the action of the regulating devices it can be seen that they are in a state of constant movement, correcting slight changes in the current caused by variations of speed or resistance. The method is based on the first one mentioned above, viz., the movement of the brushes, but the brushes are moved in a peculiar manner. Bearing in mind what may be called the normal position of the brushes it will be seen that they correspond with the line of maximum effect, one coil being cut out of circuit when it is in a position incapable of adding greatly to the E.M.F. of the other two coils, which are in series with each other, and being brought into circuit again only when its E.M.F. is of value in the reversed direction. When the external resistance is reduced each double brush is made to enclose an increased amount of the commutator, the forward brush of each pair being brought forward, thus lengthening the time during which the coil about to traverse or traversing the "neutral" portion of the field is kept in circuit; the back or rear brush at the same time being made to retreat, thus, at an earlier stage, enabling it to place the coil which is emerging from the neutral region in parallel with one of the active coils. The movement backwards of the rear brush is only one-third as much as the forward movement of the leading brush.

Thus commutation is delayed, the "idle" coil, instead of being removed from the circuit, being kept parallel with another coil when it is producing no E.M.F., or is producing one in a contrary direction. And the reintroduction into the circuit of this "idle" coil is made to occur before it has got over its idleness, and when it is only capable of short-circuiting a coil which is trying to be useful.

And not only is this done, but the brushes are still further widened until the forward brush of one pair is actually made to touch the segment on which the rear brush of the opposite pair still rests, thus short-circuiting the whole armature through that segment. This is done six times in each revolution. The effect of it can only be to successively withdraw the current from the fields and external circuit, as each segment in turn is made to connect the brushes. The boldness of this method is very striking. The effect on the economy of the generator and on the steadiness of the current must be serious. The writer imagined that the movements of the brushes did not actually effect short-circuiting, except when the external resistance was very small —that it was only rendered necessary by extreme requirements of regulation—but he is assured by Mr. Cudder, the courteous American engineer in charge of the installation, that this is not the case, and that short-circuiting commences at a comparatively early stage, when only a small reduction has been made in the resistance of the circuit, and therefore when a high E.M.F. is being produced. That it should be possible to reduce the E.M.F. of a high-tension generator by means of what is really a rapid short-circuiting make-and-break across the armature is certainly what few electricians would have believed.

Another feature of the Thomson-Houston dynamo, and a very ingenious one, is the air blast used in connection with the commutator and brushes, by which the formation of dangerous arcs at the brushes is prevented. The jet of air is directed against the commutator immediately facing the leading brush of each pair, and as there is a clear air passage between the segments of the commutator, the formation or the continuance, of arcs across this space is prevented. This air blast must act in another useful way also. It is no doubt well known that sparks occur at a heated brush much more readily than at a cool one. The reason for this is that combustion, melting, or volatilisation of particles of the metal, by the slight arcs at the contact points, takes place with the greatest facility when the brushes are hot. The air blast will do much to keep the brushes cool, and in this way to prevent destructive wear. It is only in connection with the leading brushes that the air blast is used, because it is at these points only that any rupture of the circuit takes place. At the rear brushes, the coil which has passed through its "idle" phase is placed in parallel with one of the active coils—an operation not accompanied by any spark beyond that due to the passage of current through a rubbing contact. It will be gathered from what has been already said that one effect of placing the "idle" coil too soon, or keeping it too late, in parallel with its active neighbour is a considerable back-flow of current through it. A confirmation of this is found at the brushes, Mr. Cudder informing the writer that when sparking takes place at the rear brush it is always of a more destructive character than at the leading brushes, a result doubtless to be traced to the passage of large back currents.

The air blast is a most important and admirable feature in this machine, the very breath of its nostrils, and it is no doubt mainly by its assistance that the inventors have been able so succesfully to overcome the apparently insuperable difficulties of dealing with the large and violent changes at the commutator.

W. H. Allen and Co., Lambeth, exhibit two Kapp dynamos, one for arc and the other for incandescent lamps. The latter is coupled direct to a high speed twin engine of the Allen type. The two cranks are placed at opposite angles in order to obtain a perfect balance of the working parts. With most makers of direct driven dynamos the tendency has been to accommodate the prime mover to the dynamo by designing special engines which might run at 1,000 revolutions a minute, or even faster, if possible. Now it cannot be said that these so-called rotary engines are as yet perfect, and free from the two objections of using too much steam and of breaking down occasionally. Messrs. Allen have wisely, therefore, determined not to spoil a good engine by trying to make it run fast enough for the usual commercial dynamo, but to build a dynamo of their own which shall run slow enough for driving direct by a substantial and economical engine. We illustrate the plant as exhibited in the electric light shed at the Inventions Exhibition in the annexed perspective view. Engine and dynamos are placed upon the same cast-iron bed, and the engine shaft is coupled direct to the dynamo-spindle. At a speed of 340 revolutions a minute the external electromotive force is 110 volts, and the current 150 amperes. The machine is self-regulating, but slightly overcompounded, so as to maintain, when governed by a centrifugal governor of the Pickering type, a constant electromotive force at the end of its main circuit.

As will be seen from our illustration, and from the annexed diagram (Fig. 2), the field magnets are semicircular, by which arrangement a maximum length of surface for the application of the exciting coils is obtained with a maximum length of, and therefore a minimum resistance in, the magnetic circuit. The core of the magnet is 3½in. by 20in., or 70 square inches in cross section, and the exciting coils are wound on cast-iron formers, which can be slided over the magnets very much in the same way as a scabbard over a sword. The shunt coils are wound with ·083 wire, and the main coils with ·160

Digitized by Google

wire, six of these being coupled parallel. The resistance of the shunt is 22 ohms, that of the main ·023 ohms, and the total exciting power on one half of the machine is 12,000 ampere turns. The construction of the armature will be seen by our Figs. 3, 4, and 5; it is of the Gramme type, but of exceptionally large diameter and very heavy, so that at the low speed of 340 revolutions the required E.M.F. of 110 volts shall be obtained. The armature is 16in. in diameter and 24in. long. The core consists of soft charcoal iron wire wound upon a supporting cylinder of gun metal, which in its turn is keyed to the spindle by two sets of arms as shown in Figs. 2 and 3. The surface of the supporting cylinder is perforated, and presents, when opened out into a plan (Fig. 5), the appearance of a grid with alternating bars. The object of this arrangement is partly to lighten the cylinder and partly to admit air to the interior of the core. The cylinder is stiffened by having four flanges, F, cast on, which in contour

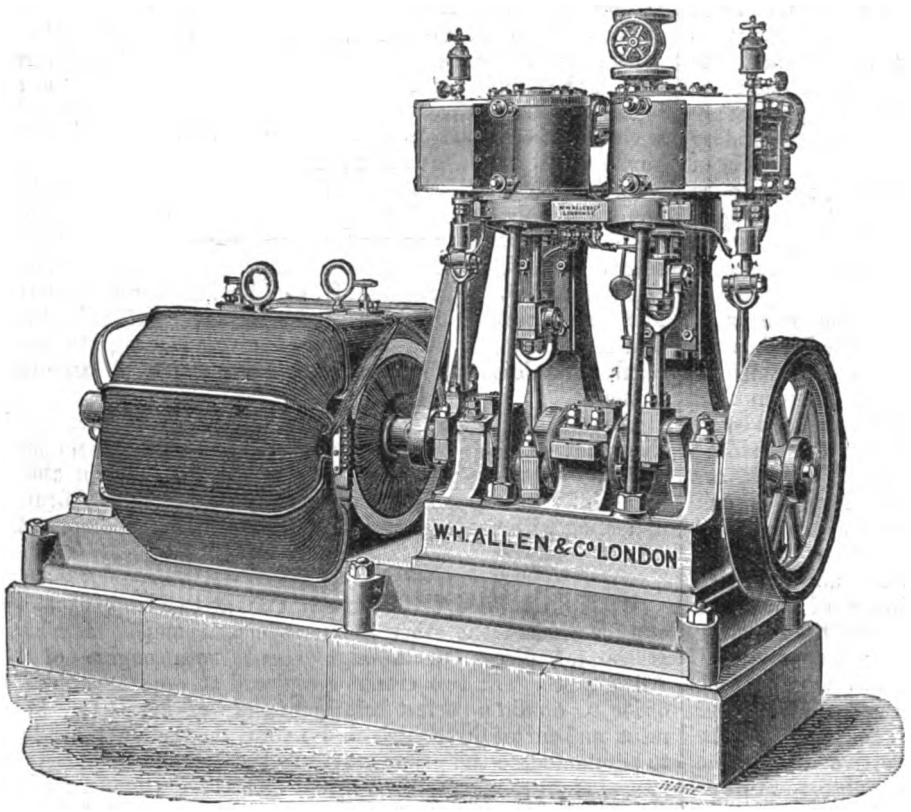

FIG. 1.

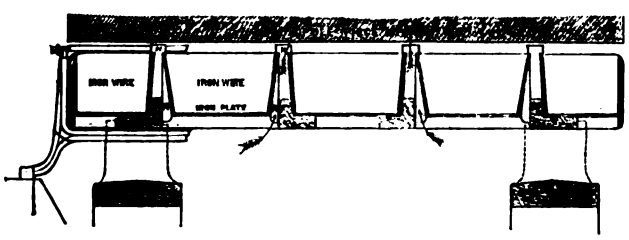

FIG. 4.—Longitudinal Section through Armature.

are not circular, but provided with radial extensions or driving horns, H, for the purpose of transmitting the driving power in a positive manner to the copper conductor, which does the work. With so strong a field as that employed in the Kapp dynamo it is absolutely necessary to make some provision by which the wire shall be prevented from slipping on the surface of the core. In many machines the friction produced by the external binding is alone relied on for carrying the coils through the field, but experience has shown this to be insufficient. Even if the wires are not bodily torn off the armature by the magnetic resistance of the fields, they shift and work on the surface of the core, and it is only a question of time when the insulation will be destroyed and the machine break down. The driving horns are provided with narrow ribs, R, which keep the core a slight distance off the horns, and air is thus allowed to enter between them and escape between the outer coils of the armature winding, which does not completely cover the surface. The driving horns are tipped with fibre ferrules, and distance pieces of the same material are inserted between the wires at stated intervals, so as to subdivide them and hold them firmly in place. Before commencing to coil the iron wire on to the supporting cylinder, a thin band of iron is lapped round it so as to cover the openings in the grating, and thin iron washers (in halves) are placed against the flanges, and are held in place by the driving horns. These washers are insulated with asbestos paper to prevent direct continuity of the metal throughout the length of the armature. The armature is wound with 200 turns of ·165 square conductor; resistance from brush to brush, ·07 ohms; total weight of copper on armature, 90lb. The weight of copper on field magnets is 410lb.; therefore, total weight of copper on the machine 500lb. The weight of engine and dynamo com-

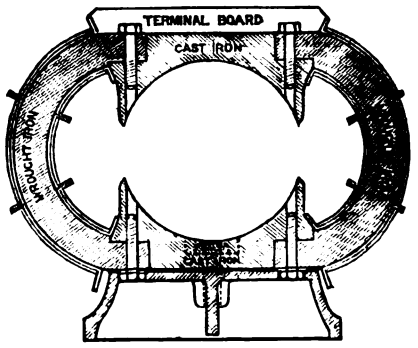

FIG. 2—Transverse Section through Field Magnets.

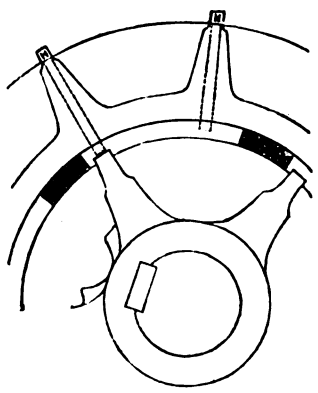

FIG. 3.—Transverse Section through Armature.

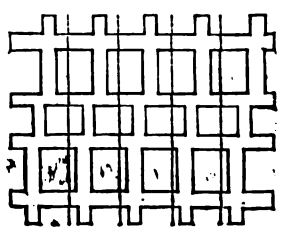

FIG. 5.—Supporting Cylinder, cut parallel to Spindle and opened out. Arms on dotted lines.

bined is nearly three tons. The current through shunt is five amperes, which gives a density of 925 amperes per square inch. The usual working current through the armature is 155 amperes, being at the rate of 2,840 amperes per square inch.

The arc light dynamo exhibited by Messrs. Allen and Co. has an armature similar to that just described, but is much smaller. The armature is 8½in. diameter by 11½in. long, and is wound with thirty-six coils, each coil consisting of sixteen turns ·057 wire. The field magnets are placed vertically, and are straight slabs of iron 2in. by 8in. in cross section. The machine is driven by belt, and at a speed of 1,150 revolutions gives a current of 15 amperes and an E.M.F. at terminals of 300 volts, feeding six Slatter arc lamps. The total length of conductor wound on the armature is 415 yards, which corresponds to about 1·4 yards per volt in the external circuit.

NOTES.

NEW TELEGRAPH LINE.—A new telegraph line has been established between Wolfeborough and Alton Bay, *vid* Dover, N.H.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 31st July were £2,652.

THE TELEPHONE IN BELGIUM.—On the 3rd inst. telephonic service was opened between Ostend and the exchanges at Brussels and Mons.

THE TELEGRAPH TO MERV.—Intelligence from Merv reports that the Russian authorities intend continuing the telegraph line from Merv to Bokhara.

STRUCK BY LIGHTNING.—During a violent thunderstorm at Northampton on Wednesday a young man named Soden, assistant to Mr. Cockerell, fruiterer, was struck by lightning, his sight being injured.

THE ELECTRIC LIGHT IN NEW YORK CITY.—The quarterly report of the Commissioner of Public Works shows that at the close of the quarter ended 30th June 703 arc lamps were in use in the city.

THE COLONIES AND THE TELEGRAPH TREATY.—According to the *Norddeutsche*, the Australian Colonies of New South Wales and Tasmania have announced their entrance into the International Telegraph Treaty.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st July are £2,560, as compared with £2,791 in the corresponding period of 1884.

ELECTRIC LIGHT FOR STEAMSHIPS.—The new Chinese war ships are provided with excellent arc lamps. The "Chin-Yuen" and the "Ting-Yuen" have search lights of 40,000 carcels. The third, the "Tae-Yeen," has only electric side-lights.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending the 31st ult. were £2,124, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

A CURIOUS ACCIDENT.—The cover of a manhole on the underground electric wire conduit in Beekman-street, in New York City, became charged with electricity one day last week, and gave severe shocks to several horses. One animal was thrown down.

CITY AND GUILDS EXAMINATION.—We understand that Mr. James Crombie, Eastern Telegraph Company, Glasgow, has taken second class honours in "Telegraphy," under Principal Jamieson, at the College of Science and Arts, Glasgow, during the past session.

TIME INDICATING BY TELEPHONE.—One of the most useful adjuncts to the telephonic service in America is an arrangement whereby any subscriber is enabled to ascertain the exact time at any minute of the day by simply placing his telephone receiver to his ear.

NEW FRENCH CABLES.—The projected establishment of telegraphic cable communication between the French colonies of Rio Nunez, Grand Bassam, Porto Novo and the Gabon, was adopted by the *Sénat* at the sitting of the 31st ult. The West African Telegraph Company have the concessions.

THE TELEPHONE IN FRANCE.—By decree of the President of the Republic, subscribers to private telephone companies are now permitted to extend their communications through any of the public offices upon payment of an annual tax of 40 francs per annum in Paris, and 30 francs per annum in the provinces.

THE "PYLADES."—The Admiralty have decided to arm the "Pylades" with 14 5-in. steel long range breechloading guns, mounted on the Vavasseur system of carriages. She is fitted with the electrical machinery for discharging the spar torpedoes, and when completed for active service she will be the strongest vessel of her class afloat.

THE ELECTRIC LIGHT IN THE LEEDS MUNICIPAL BUILDINGS.—We understand that, to avoid further litigation, the contractors have offered to make certain changes in this installation, an offer which has been accepted by the Corporation as very satisfactory. The electric light will therefore be at work again in two or three weeks' time.

EXTENSION OF THE INDIAN TELEGRAPH SYSTEM.—A telegram, dated Allahabad, Wednesday night, says so much inconvenience was experienced by the Indian Government during the recent agitated period in obtaining information beyond the Indo-Afghan frontier, that it is being seriously advocated that the Indian telegraph system shall be extended to Candahar and Herat.

AN INTERESTING EXCURSION.—On Saturday the Royal Historical and Archæological Association of Ireland brought its annual meetings and excursions to a termination. During the proceedings interesting papers were read upon various subjects, and several excursions were made, one of which was to Dunluce electric generating station in connection with the electric tramway at River Bush, and the residence of Dr. Traill, F.T.C.D.

NOT PROGRESS.—A Daddsville woman is about to patent an electrical device having for its object the abolition of flirting in the conjugal domicile—that is to say, to prevent any flirting on the part of the husband during the absence of his better or worse half. This is not progress. We don't want things of this sort, and if our efforts on behalf of domestic lighting are to be only productive of ingratitude, the sooner we revert to chaos the better.

TRIAL OF AN INSTALLATION.—The official trial of the installation at Messrs. J. Bell and Sons, erected by the Electrical Power Storage Company, has just been completed. The conditions were that a proportion of the lights were to be supplied by the accumulators for sixteen hours; that the cells were to be recharged in eight hours, and were then to supply the lights for another sixteen hours. The dynamo was driven by means of countershafting from the air compressor engines, and the conditions of the trial were amply fulfilled throughout.

THUNDERSTORM IN LONDON.—On Wednesday evening, shortly after six o'clock, a thunderstorm, light at first, but gradually becoming violent, burst over the metropolis. The peals appeared at the outset to come from the eastward, but the later and louder ones burst forth from the south-east; and they were accompanied with very heavy showers of rain. The last peal of thunder was of extraordinary force and power, and literally shook the windows in many houses in the south-eastern district. Rain continued to fall until dusk, and the atmosphere appeared to be still charged with electricity.

ELECTRIC LIGHTING AT BUCKINGHAM PALACE.—At the last State ball the various rooms were lighted by electric light. The arrangement, which was carried out by the Electrical Power Storage Company, and which was on a larger scale than any previous attempt of the kind, was very successful, and gave

Digitized by Google

much satisfaction. The total number of lamps fixed was 340, of which 280 were of 20 candle-power and 60 were of 10 candle-power. The whole current for the lamps was supplied from accumulators placed in a tent in the garden, the cells having been brought, ready charged, from the works of the company at Millwall.

CONCESSIONS TO INDIAN TELEGRAPH OFFICIALS.—It is notified that officers of the telegraph department who attain the rank of superintendent 4th grade, and serve in that rank for a period of three years, are eligible for the special additional pension of 1,000 rs. per annum admissible to directors of construction and traffic under paragraph 4 of the resolution of January 23 last. Officers whose cases Government was said to be prepared to consider favourably in paragraph 3 of the resolution will now be those who may attain to the rank of superintendent 1st grade. The orders will have effect from May 1 last.

TRANSMISSION OF POWER AT THE ANTWERP EXHIBITION.—Amongst the most interesting of the installations at the Antwerp Exhibition, that of the Compagnie Générale d'Electricité, for raising the sea water to supply the aquarium in the Belgian section, may be mentioned. This installation comprises two Gramme dynamos, the generating machine being placed in the Galerie des Machines, and the receiver near the aquarium. The water is elevated to a height of 7 metres. The same generator also actuates a second dynamo situated at the exhibit of the Société l'Electro-Métallurgique de Geneve, at the opposite end of the Galerie des Machines.

CONSOLIDATION OF ELECTRIC LIGHTING COMPANIES IN AMERICA.—The consolidation of the Brush, the New England Weston, and the Merchants' Electric Light Companies of Boston was effected July 11. The new company is to be named the Union Electric Light and Power Company, and will have a capital stock of $700,000. Of this the Brush Company receives $250,000, each of the other $225,000. The consolidated company will assume the debts of the old companies, putting them into fifteen-year bonds. The lighting capacity of the three united companies is 1,900 lights, with steam-power at the stations sufficient for 500 lights additional.

THE ELECTRIC LIGHT IN TURIN.—The Municipal Council of Turin have finally decided to light certain streets in the town by electricity. The installation, which will be completed and in working order by the 1st of January, 1886, will be divided into two sections. In the first of these the lamps will be supplied direct from the dynamos; but in the other the secondary generators of Gaulard and Gibbs will be employed. The lamps will be arcs of from 800 to 5,000 candle-power and incandescents of 50 candle-power. The cost of the lighting is estimated at about £5,200 per annum, whilst the cost of gas lighting is only £3,200. There will, however, be a total increase of more than 70,000 candles over the present system, or about eight times the light now afforded by gas.

THE EARTHQUAKES.—A Reuter's telegram, dated St. Petersburg, Aug. 3, says:—Despatches from Tashkend and Verny announce that there has been a severe earthquake at Pishpek (? Bish-uzek), damaging all the houses at that place. The shock extended to the settlements of Sukuluk and Belovodsk, which were laid in ruins. At Belovodsk a church fell in, many of the congregation assembled in it at the time being killed. Numerous fissures appeared in the ground. A later telegram from Verny reports that altogether fifty-four people were killed and sixty-four injured by the earthquake at Belovodsk and Karabolty. The shocks continue, and the people are terror-stricken. The earthquakes in Spain continue to occur. A telegram from Malaga states that a shock occurred at Motril on the afternoon of the 30th ult.

THE RUSSIAN TELEGRAPHS IN CENTRAL ASIA.—St. Petersburg is connected with Bami, between Kizil Arvat and Askabad, by two separate lines of telegraph. A cable laid in the Caspian joins the Russian telegraph network at Baku to Krasnovodsk, which is in communication with Bami by a land line passing through Michaelovski and Kizil Arvat. On the other hand, the Russian telegraph line is connected with the Persian at Julfa on the Arax, whence, passing *viâ* Tabreez and Teheran, it is rejoined to the Russian wire on the frontier of Askabad, and thence is continued through Tchikislar to Bami. From here a single line is carried to Askabad, the place of residence of the Governor of the Transcaspian province, and thence latterly to Merv and Sarakhs. Thus the Russians are in comunication by two separate telegraph lines with their lately acquired and outlying province in Central Asia.

THE LIPPMANN GALVANOMETER.—A mercury manometer is placed between the poles of a fixed magnet, which lie right and left of its horizontal arm. The current traverses the latter in a vertical direction parallel to the axis of the tube, by which the mercury rises in one limb. If i is the strength of the current, H the strength of the magnetic field, l the length of a small rectangular parallelopipedon in the direction of the current, ϵ its thickness in the direction of the lines of force, the force which displaces the parallelopipedon is Hli, and the pressure $p = \frac{Hli}{l\epsilon} = \frac{Hi}{\epsilon}$. Hence the sensitiveness increases with the strength of the magnetic field and the thinness of the column of mercury. Accordingly the lower bend of the manometer is replaced by a chamber filled with mercury at right angles to the current, and only $\frac{1}{10}$ millim. in thickness.

THE ELECTRIC LIGHT IN BALLYMENA.—A trial of the electric light was recently made at the end of Harryville Bridge and Waveney-road, Ballymena, where one of the Belfast arc lamps was raised by the Belfast Electric Light Appliance Company, and the electric light produced under the superintendence of Mr. W. H. Drennan. The driving power was supplied at the Braid Water Foundry, and the dynamo machine was one of Newton's patent. The light, which was said to be equal to about 2,000 candle-power, was exceedingly brilliant, and whilst it illuminated portions of the town for a considerable distance in various directions it was witnessed by thousands of spectators who congregated in the streets. The introduction of the light to Ballymena was freely discussed among the assemblage, and many appeared in favour of the project, whilst others shook their heads in doubt and dissent. Later a portion of the town was lighted up with incandescent lamps.

MR. GLADSTONE AND ELECTRICITY.—On the occasion of his recent visit to the International Inventions Exhibition Mr. Gladstone remained for some time in Sir Francis Bolton's chamber in the tower. Mr., Mrs., and Miss Gladstone tried their hands at directing the illuminations of the fountains by touching several keys, which brought forth certain colours in the water display. Mr. Gladstone made some pretty contrasts, but Miss Gladstone's combinations of colours were most satisfactory. Mr. Gladstone had the several plans of electric lighting of the gardens explained to him, and there was not a little fear lest he should by some mistake touch the wrong key and switch off the lights and leave the whole of the gardens in darkness. The fountains display gave the whole party great interest, and after spending over 20 minutes in Sir Francis Bolton's machinery room, a move was made to Old London, where the party remained some time, admiring

Digitized by Google

the workmanship, the electric machinery room, and the grand entrance gallery.

CITY AND GUILDS OF LONDON INSTITUTE.—The report of the seventh annual examination in technology, which took place in May last under the direction of this institute, has been issued. The number of candidates examined, 3,968, was more by over 300 than in the previous year, while the number of passes increased from 1,829 to 2,168. Two new subjects, boot and shoe manufacture and framework knitting, were last year added to the list of subjects in which examinations are held. The percentage of failures on the results of the examination in all subjects decreased from 49·7 in 1884 to 45·3 in 1885. This, the report states, is still a very large proportion, showing the necessity of better instruction on the part of the teachers, and of more careful and sustained work on the part of the students. This year Manchester heads the list of provincial centres from which the largest number of students have passed, and it may be added that during the year 6,396 persons have received technical instruction in connection with these examinations, at a cost per student of less than 11s. for the session.

ELECTRICITY AT THE MECHANICAL ENGINEERS' MEETING, LINCOLN.—At the opening meeting, on Tuesday last, during the discussion on Mr. Ruston's paper on the Dunbar and Ruston Steam Navvy, Mr. Sydney Walker expressed the opinion that it might be worked by electrical current transmitted from a fixed and permanent source of supply; and Mr. Ruston replied that if power could be transmitted by electricity, so as to be more economical than steam, he would be glad to adopt it. In a paper on recent adaptations of the Robey semi-portable engine, Mr. John Richardson observed that this engine is admirably suited for electric lighting, being fitted with an electric speed regulator instead of the ordinary centrifugal governor. One of its incidental advantages, particularly in connection with compound engines, in which any wide variation in the duty results in loss, is that with its aid such an engine may be made to develop 5 horse-power as economically as 50 horse-power, while making the same number of revolutions per minute. This governor is fully described in Mr. R. H. C. Nevile's paper on private installations of electric lighting, read on the following day, which is commenced in our present issue.

SMALL CONTRIBUTIONS THANKFULLY ——.—The *New York World*, in its wonderful feat of collecting its 96,000 dollars from 100,000 patriotic Americans, has given evidence of the power and influence of the Press, and also of the willingness of the American people at large to respond to any call upon their patriotism. There remain yet a few thousands to be subscribed to the Pedestal Fund. The *Newark* (U.S.A.) *Journal* has on exhibition at its office an exact reproduction of Bartholdi's great work, in bronze, which stands upon a handsome mahogany case, containing an electric attachment. When a quarter of a dollar is dropped into the aperture at the base of the statue a "cam" inside revolves, depositing the coin in a locked draw below. At the same moment the cam presses a spring, which completes an electric circuit between a set of Bunsen cells beneath, and a small Edison incandescent lamp, which Miss Liberty holds aloft in lieu of a torch. The torch flashes its tiny light for a moment at every coin that enters the drawer. The apparatus is so adjusted as to operate only with a quarter of a dollar, but, a contemporary considerately adds, those desiring to put in larger contributions can drop them in in quarters.

THE SALTERS' COMPANY AND TECHNICAL EDUCATION.—The following resolution was passed at a meeting of the Court of the Salters' Company, held on July 31, 1885:—"That the Court of the Salters' Company being informed of the need of increased funds to enable the City and Guilds of London Institute to maintain in efficiency the various branches of work for the advancement of technical education to which the confederated companies are pledged, hereby agrees to raise its annual subscription to the institute from £525 to £1,000, payable in moieties during the pleasure of the court in the months of May and November, and that the Right Hon. the Lord Mayor, as Master, be requested to signify the same to the late Lord Chancellor Selborne, and Sir Frederick Bramwell, vice-presidents, chairman of the Council and chairman of the Executive Committee respectively, adding an expression of the gratitude which the Salters' Company feel for the signal services which they have rendered to the interests of technical education, and of the Livery Companies in helping and directing the combined efforts of the City and Guilds of London in associating art and science with the furtherance of industrial progress."

THE MUTHEL INCANDESCENT LAMP.—Mr. Max Muthel's incandescent lamp requires no vacuum in the globe. He has also very ingeniously overcome the fusion of the incandescent wire. The wire used by him consists of a mixture of bodies that are conductors and non-conductors of electricity. He takes magnesia, silicate of magnesia, &c., and porcelain clay, and forms a fine thread of them, which he heats to incandescence and saturates with a solution of platino-iridium salts, and afterwards raises several times to incandescence in order to reduce the absorbed salts to a metallic state. Instead of the foregoing mixture, filaments of clay may be taken and saturated with a solution of a metallic salt, which is then reduced to a metallic state through incandescence and the use of oil of lavender or some other organic substance, or through an electric current. With wires thus prepared fusion is absolutely overcome, the presence of the non-conducting substances preventing the metallic parts from melting. Mr. Muthel supposes that the electric spark jumps, so to speak, from one particle to another, and in this way causes a heating of the other substances, which, brought to incandescence, emit a more intense light. In order to make the filaments stronger, they may be covered with chrome, the melting point of which is still higher than that of platinum. To effect this, the filament is placed as the anode in a bath of chloride of chromium.

COMMUNICATION WITH AFGHANISTAN.—An Allahabad paper thinks that the answer to the telegraph extension in the Herat direction should be the laying of the wire from Jamrud to Cabul. Abdul Rahman's authority is so fully recognised by the tribesmen along the route that working parties would, it is said, be safe from molestation if guarded by a small Afghan escort, and once the wire was laid it would probably be left intact if the various local headmen were made responsible to the Ameer for its safety. The Afghan traders who visit India use the telegraph freely, and they would not be slow to welcome it in their own country. Thus it would serve both political and trade purposes, and would exert a civilising influence in Northern Afghanistan. Cabul is only 160 miles from our frontier, and couriers easily cover the distance in three days, but direct telegraphic communication between the Ameer and the Government of India is highly necessary, as even a few days' delay might in the near future be of serious moment. Our alliance with Afghanistan is patent now, after the Rawul Pindi durbar, to all the world; and another outward and visible sign of its existence, in the shape of a telegraph line to Cabul, would not offend the delicate susceptibilities of Abdul Rahman's subjects. That the line should be made without delay is the opinion

Digitized by Google

certainly of the majority of those who are best acquainted with the complex Central Asian Question.

THE INTERNATIONAL TELEGRAPH CONFERENCE AT BERLIN.—The opening sitting of the International Telegraph Conference has, with the Emperor's sanction, been fixed to take place at noon on the 10th inst. The chief matter to be dealt with by the Conference on the opening day will be a proposal on the part of Germany for the introduction of an international European tariff of a reduced and uniform kind. For the European network of telegraphs Germany proposes that this tariff should be fixed at 20 centimes a word, with a telegram tax of 50 centimes, while for those messages that have to pass over a submarine cable a supplementary *maximum* tax of 10 centimes a word might be charged. Such is the proposal with regard to conterminous countries, while extra transit dues on messages to "nonlimitrophe" countries, such as Belgium, Bosnia and Herzegovina, Bulgaria, Denmark, Greece, Luxemburg, Montenegro, Norway, the Netherlands, Portugal, Roumania, Servia, and Switzerland would be imposed at the rate of two centimes a word, and four centimes a word for Germany, Austria, Spain, Franco, Great Britain, Italy, Russia, Sweden, and Turkey. On cablegrams for distances under 300 nautical miles five centimes a word would be charged, and for greater distances 10 centimes. Conterminous countries might agree if they liked to reduce the tariff from 20 centimes to 10 centimes a word. MM. Frebourg, Lorin, and Brunot, the three delegates sent by France to the Congress, left Paris on Tuesday evening. The Post Office telegraph authorities of this country will be represented by Messrs. C. H. B. Patey, Secretary; H. C. Fischer, Controller of the Central Station; and Benton, of the Receiver and Accountant General's Office.

TELEGRAPHIC ADDRESSES.—A correspondent of *The Times* writes on the 6th instant as follows:—"Some months since you allowed me to offer to your readers some suggestions as to the simplification of telegraphic addresses, *à propos* of the sixpenny telegrams. They apply now in full force to the measure as accepted by the House of Commons, and it occurs to me that as a re-naming of streets and proper numeration will be a long affair, a simple method would be the numbering of all the streets, places, squares, &c., with progressive numbers. A small directory with the streets alphabetically arranged and opposed by consecutive numbers will give any address in a single group of figures of at most five characters, and the absurd custom of giving high-soundings names to individual houses would in most cases give place to numbers, so that the address might be simply given in three words—thus, Brown, 25, 5,672. The telegraph clerk, turning to this directory, will be able to write the name of the street from it instead of the number in the telegram. For the convenience of the telegraphic operators the telegraphic station which serves the street might be indicated by a letter or combination of letters in the directory. The sender of a telegram who had not provided himself with a copy of the directory would find at each station a copy from which he would get the number of the street he wishes to address to and fill it into his form, the address standing, when complete, thus, Brown, 25, 5,672 *ah*, the *ah* standing for the number of the telegraph station; or this may be given, if no confusion is likely, in plain numbers, but, being only for the guidance of the operator, should not be charged for or added to the address sent out. In this case the address would stand, Brown, 25, 5,672, 34. This leaves seven words for the message, which, supposing the *minimum* to be ten words, is very liberal. This need not prevent the rational designation of the streets of London, which would, however, be a longer process, and does not depend on the Post Office."

ELECTRICITY FOR STREET CARS.—A successful test and demonstration of the electric storage battery as a motive power for city passenger railways was made recently in America on the Union Passenger Railway from the stables on Huntingdon Avenue to Hampden, Baltimore County, and return. Eighteen persons were in the car, which, with the weight of the car, motor, &c., made a total of 5½ tons. The car moved out of the yard, passing over grades of 235ft. to the mile and around curves with 75ft. radius with ease and comfort. The batteries used on the occasion were simply the ¼ horse-power, not even made for motive power, but for incandescent light. Mr. Bauer, the electrician, however, after figuring out the subject, decided that even with these small boxes a street car could be run, as was fully demonstrated. Forty-nine of the little ¼ horse-power boxes were placed in the car and connected with the Daft electric motor. On level grades only 29 of these boxes were used, the loaded car making easily six miles an hour. On the 235ft. grade the 49 boxes were used, equal to $8\frac{4}{10}$ horse-power. A storage battery especially constructed for street-car purposes would consist of one hor e-power boxes instead of one-quarter, and about 65 would be required. The Storage Company on the day of trial placed their small boxes in the motor car used by the Daft Company. In practical usage these boxes will be put under the seats of the ordinary passenger car. The car will be started or stopped by simply turning a switch. An ordinary hand-brake was used, though this in future will be done by electricity. The first advent of the storage battery in America was on the steamship "Labrador," in November, 1882, at which time the rights under the patents for Maryland, District of Columbia and West Virginia, were purchased by Mr. A. G. Davis. The factory of that gentleman, the Viaduct, is said to be the only concern in America which has made experiments and finally demonstrated the practical use of the storage battery. The Storage Company propose at once to arrange the storage batteries for a street-car such as is used by President Bowie's City Passenger Railway Company. When they are complete the car will be put on the tracks and run through the city from one end to the other.

THE ELECTRIC LIGHT IN MINES.—An experiment is being made by the Low Moor Coal and Iron Company to supply electric light in their mines, with a view to reducing the risk of explosion, and at the same time give a better light in their workings. The pit selected for this experiment is that known as the Lofthouse, near Wyke Station, and is a black bed working well known to our local geologists. At the bottom of the shaft a main hauling path runs to the end of the pit some hundred and eighty yards, while parallel with this another road is cut for the same length, and turning at the end at right angles for a distance of one hundred and forty yards. At right angles with these roads the working faces of the pit are reached by cuttings at a distance of about sixty yards. Along the whole of the main roads incandescent lamps are fixed, while the workings are supplied with similar lamps, but in this case the lamps are made portable by allowing sufficient slack connecting wire to enable the miners to move them as required. These portable lamps are further supplied with a switch, to enable the miner on leaving his work to turn off the light. The electricity is generated by means of a Blakey-Emmott compound wound dynamo, capable of reducing from 60 to one light without alteration of speed. On Thursday week the mine was visited by Mr. Lawrence Hardy, J.P., of the Low Moor Company, and the company's engineer, Mr. Woodhead, together with Mr. Walter Emmott, the consulting electrician to the Crossley Telephone Company, of Albany-buildings, Bradford, under whose superintendence the

Digitized by Google

lights have been fixed. Numerous experiments were made, showing the advantages of the electric light over the present form of Davy lamp employed. In point of illumination there was no comparison, as the main roadways were lit from end to end, to use the words of one of the men, "as well as any street," while the light at the working faces was even more noticeable, being distributed over a smaller area. The main point left for consideration seems to be the relative cost of the electric light and the old form of illumination, and if the former can be brought in at anything like a reasonable price, although it may be a considerable increase on the latter, we have no doubt the system will be adopted, as the loss of life and money due to an accident is a considerable item to be taken into account, and it is satisfactory to note that the Low Moor Company are the first to make the experiment in this district.

THE BLACKPOOL ELECTRIC RAILWAY.—New notoriety, says the *Blackpool Times*, will be given to this latest developed of the various Blackpool enterprises, by the refusal of the Government inspector to pass the lines laid by the Corporation. On Monday, from an early hour in the morning, crowds hung about the little piece of line running from the Foxhall down to the engine house and car sheds belonging to the Tramway Company. The reason was that there were indications of some experiments likely to be made by Mr. Holroyd Smith, the engineer for the electrical portion of the lines. The sightseers were not disappointed. Shortly before eight Mr. Smith came out with one of the cars, and ran several journeys over the short section of line mentioned above. The engine house is an extensive erection. In an apartment some 40ft. long by 28ft. wide, are two semi-portable engines, made by the celebrated firm of Marshall's, of Gainsborough. These engines are each capable of developing a power equal to 75 horses, and running at a very high rate of speed. The engines are of patent compound high pressure type, and are fitted with expansion gear. Their purpose is to drive three dynamos, two of which have been specially made for the tramway company, and they are said to be the largest in the world. They are made on the principle of Elwell and Parker's patents, with sundry modifications which Mr. Smith suggested to the patentees. These dynamos can be driven with one or both engines, as the occasion may demand. The shafting and gearing are both very ingenious, and the appliances which have been brought to bear for the obviating of possible difficulties, such as the breakdown of an engine, or the inability of a dynamo to perform its duty, are indicative of forethought and skill. Adjoining the engine house is the car shed, an erection of imposing dimensions, with a capability of housing at least a score of cars. There were nine in on Monday morning, some of which are very fine specimens of their order. These cars have been made for the company by Starbuck, of Birkenhead, and by the Lancaster Waggon Company. They are very beautifully made. If the line is not a success it will be no fault of the company, or of its engineer. Our only hope is that ere the season draws to a close they will have some chance to demonstrate to the public at large how important a scheme they have devised, and how completely they have carried it to a successful issue. We may mention that the car at the International Inventions Exhibition is one of ten built for the Electric Tramway Company of Blackpool. The generators now being fixed there will be capable of driving twice that number—sufficient, indeed, to carry 800 to 1,000 passengers. The line is over two miles in length, and will be shortly opened.

ELECTRIC LIGHTING IN MINES.—The following letter appeared recently in *The Times*:—"As I have been engaged for the past nine years in introducing electricity into the practical working of mines, and have, I believe, a closer acquaintance with them than any electrical engineer, or any one not actually engaged in their working can have, perhaps you will kindly afford me space to state my views on this subject. In the first place I would most strongly deprecate any suggestion of compulsory legislation, both as unjust to colliery owners, and unwise in the truest interests of the electric lighting industry. In my experience, no body of industrial proprietors are more ready to give a fair trial to a new apparatus, once it can be shown by practical work that it is for their advantage, and, on the other hand, it would be manifestly unfair to compel the adoption of an illuminant that might not be all that they require. For there are grave practical difficulties in the way of the use of the electric light at the working face, where it would be of most service, both from the additional light given and from the greater need of a safety lamp at that point. The working face is constantly moving, in one method of working ever receding, and the operation of getting the coal in its most marketable form entails the constant falling or shattering of huge masses, so that no fixed lamp would be of the least service or could live long. On the other hand, up to the present, so far as I am aware, no portable electric lamp has yet been produced which is of a reasonable weight and size, so that the collier can handle it and place it in position where his light is most required, and at the same time that gives a good light for the time required. By reducing the amount of light on the one hand, and its duration on the other, a few so-called mining electric lamps have been produced, but they would be useless for practical mining work, as they only last a few hours at the outside, while their cost is out of all proportion to that of the existing forms of lamp. In my opinion, the outcome of electric lighting in mines for the working face will be that supply mains will be led to convenient points near, and the collier will attach a pair of small wires to them and his lamp to the other end of his small wires and use it as he likes. Our strongest card in this direction is the rapid advances that are being made in the acquisition of the rudiments of electric science in every grade of society. I feel confident that as soon as the working collier realises the fact that he can have a good, powerful light, which he can manipulate as he pleases, by merely attaching two wires as I have suggested, and that the maintenance of the light and the continuance of his work depend upon the lamp and wires being kept out of harm's way, it may safely be left to him without fear of the result. If the electric light and other forms of electrical energy are to be utilised, as we hope, in mines, factories, and our homes, it will only be after having won their way in a fair field, and not under the wing of any grandmotherly legislation. The early progress of new inventions, more particularly electrical, is too often seriously retarded by inefficiency, arising from their promoters either not knowing or not fully appreciating the difficulties they have to contend with; and in my opinion compulsory legislation would greatly increase the chances of such inefficiency, with the result that the law would either be repealed or become a dead letter. Judging from the past, I think we need have no fear but that the electric light will make its own way in mines without extraneous assistance.—Yours very truly, SYDNEY F. WALKER, 195, Severn-road, Cardiff. P.S.—You are doubtless aware that several collieries already have their shaft bottoms and main roads lighted. We have already had two underground installations, working for two and a-half years and 18 months respectively, and are about fixing a third in a colliery belonging to the same firm who have had the installation running 18 months."

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.

BY OLIVER HEAVISIDE.

(Continued from page 172.)

Electrization and Electrification. Natural Electrets.

A dielectric, not including ether, the universal medium, when under the influence of electric force, may be said to become electrized. We must not say electrified, as that refers to something entirely different from electrization, namely, electrification, or discontinuity in the displacement. The proper measure of the intensity of electrization will appear presently; in the meantime we need only observe that electrization is the analogue of magnetization, and, like it, requires the presence of matter.

Electrization may be approximately perfectly elastic with reference to the standard zero state, as in a dielectric in which absorption does not occur, so as to disappear on the removal of the exciting cause. This must be an impressed electric force somewhere, except in a transient inductive state, when there may be none, unless we choose to consider the electric force of induction as impressed; or else there must be electrification somewhere. There may also be residual electrization, namely, when absorption occurs. This may tend naturally to wholly subside, or a part of it may remain. The body is then permanently electrized. But, apart from artificial production of permanent electrization, it exists naturally in pyro-electric crystals, if nowhere else.

A word is evidently wanted to describe a body which is naturally permanently electrized by internal causes. Noticing that "magnet" is got from "magnetism" by curtailment at the third joint from the end, it is suggested that we may get what we want by performing the same operation upon electricity. An "electric," which is what results, would be a very good name for an intrinsically electrized body, but for two reasons. First, it was once used to signify what we should now call a dielectric or an insulator; and secondly, electric is now used as an adjective, or, equivalently, electrical. The former of these objections is of hardly any weight, that use of the word as a substantive being wholly obsolete. The latter is heavier, but still of no great importance. Another word that suggests itself is electret, against which there is nothing to be said except that it sounds strange. That is, however, a mere question of habit. Choosing, at least provisionally, the second word suggested, to avoid collision with the adjective, we may then say that certain crystals, if no other bodies, are natural electrets; that solid insulating substances may be made electrets artificially, with a greater or less amount of permanency; that liquid insulators can only be electrets for a minute interval of time, if at all; whilst gases, whose particles are always vigorously wandering about, are never electrets. But all insulators can be electrized; they are only electrets when the electrization, or part of it, is intrinsic.

Let J be the intensity of intrinsic electrization anywhere, and let $J = ce/4\pi$, c being the specific capacity at the place. Then e is the intrinsic electric force, and the displacement D and actual electric force E are determinable fully by the conditions

$$D = cE/4\pi; \qquad \text{div.}D = \rho; \qquad \text{curl}(e - E) = 0;$$

supposing that there is no conductivity. Here ρ is the volume density of electrification, if there be any. Should there be conductors present, charged or uncharged, their effect is determinable by the additional conditions of there being no force in any conductor (unless there be impressed force therein), and every separate conductor to have a given total charge, zero or finite, according as the conductor is not or is electrified when placed by itself in a space previously free from electric force.

The physical explanation of electrization is of course matter of speculation, as it depends not only on the nature of molecules, but also on their relation to the ether. Weber's theory of induced magnetization obviously suggests its analogue. Accordingly, we might say that the molecules of a body are always permanent electrets; but should there be, in a very small portion of it, but still large enough to contain a very great number of molecules, an average uniformity of distribution in all directions of their axes of electrization, there will be no external signs of its being electrized, or the intensity of electrization is zero. Next, the molecules admit of rotation, so that under the influence of externally caused electric force the axes of electrization are turned to a greater or less extent towards coincidence with the direction of the electrizing force. This preponderance of electrization in one direction of the molecules in our small volume naturally causes there to be a finite intensity of evident electrization or of electric moment. Should this angular displacement of molecules be only elastically resisted, the evident electrisation will wholly disappear on the removal of the electrizing force, or the body was only inductively electrized. Should there be a slow slipping, the phenomenon of absorption will occur, there being no longer a complete return of the molecules to their original state on removal of the electrizing force. The body is then made an electret. Should the slip be permanent, the body is an artificially made permanent electret.

Such a theory is of course very empirical, and admits of considerable variation according to the hypothesis we adopt regarding the angular displacement and its tendency to subside. There is of course a maximum intensity of electrization which cannot be exceeded, viz., when all molecules are turned the same way. It is only one way of accounting for evident electrization, and may be utterly unlike the reality. Weber's theory of rotation of molecules has a great many recommendations, but I do not think they go further than to make it anything better than a working hypothesis, even with the support of Professor Hughes's experiments.

But, admitting that molecules are electrets, we may go a step further, and, in a manner, account for it. In the first place the state of electric force and displacement determined by the above equations would be identically given in another manner. Do away with e, that is, do away with J, the intrinsic electrization, and substitute for it an arrangement of closed magnetic current of density $(-\text{curl}\, e)/4\pi = G$ say. The magnetic current G and the intrinsic electric force e are equivalent, so far as the distribution of displacement is concerned. In the case of a bar uniformly electrized longitudinally, the current G will be entirely superficial, going round the bar. But by Ampère's device, we may substitute a network of currents for a current bounding the network. Thus we may get down to the molecules, and ascribe their electrization to molecular magnetic currents whose moments equal their electric moments. But I do not put this forward as being at all a physical explanation of why molecules are electrets, if they be. There is merely a mathematical equivalence.

Nor do I, in the parallel case of explaining the magnetism of a molecule by means of a molecular electric current, admit that any step towards a physical explanation of magnetism has been made. Not that I attach much importance to the common objection originating from the fact that an electric current in a conductor requires a continual supply of energy to keep it up, owing to the Joule heating that goes on. For we observe the effects of heat in mass, and ascribe heat to the kinetic energy of agitation of the molecules. Not of the parts of molecules, but of their wholes. Now, considering a molecule as an atom, for simplicity, if an atomic current generated heat as a current in a wire does, the heat would be the energy of agitation of the parts of the atom, which, though indivisible, may yet not be of unchangeable form. This communication of energy would surely alter the nature of the atom. In fact it is assuming an atom to be like a body in the ordinary sense. In brief, conduction as we know it is an affair in which molecules or atoms as wholes are involved, so far as the heat is concerned, and it would be far more wonderful if atoms had internal resistance than, as we are obliged to suppose, that atoms are perfect conductors, if we choose to have atomic currents.

My reason for not considering a molecular electric current to be a physical explanation of magnetism is, that although the more closely we look at the matter, apart from old-fashioned notions of an electric current as something going round and round, the more we are led to the conclusion that the mag-

Digitized by Google

netized molecule with its field of force and the Ampèrean current with its field of forces are really one and the same thing, yet we are brought no nearer to an understanding of either, so that explaining the former by the latter is futile, regarded physically. But let us return, for the present, to electrization.

Dismissing altogether all ideas concerning the possible electrization of single molecules, keep to evident electrization. To illustrate it with sufficient comprehensiveness, without any great complication, or difficult calculations, let the electrized body be of spherical shape, and let us perform a series of simple operations upon it.

(1.) Let there be a uniform field of electric force of strength E, and displacement D in air, of specific capacity c, practically equal to unity. Then bring into the field a perfectly neutral solid spherical dielectric of radius a and specific capacity c_1. Call those points on its surface where it is cut by a straight line through its centre parallel to the force of the undisturbed field the poles, the negative pole being that where the line of force enters, and the positive where it leaves the sphere. This line is the axis. Supposing c_1 greater than c, the lines of force will be drawn in by the sphere symmetrically with respect to the axis. The displacement is continuous, and is therefore made greater within the sphere than in the field previously. On the other hand the electric force within the sphere is weakened. Both are parallel to the axis and uniform, within the sphere. Let D_1 and E_1 be the displacement and force, then $D_1 = c_1E_1/4\pi$, and $D_1 = 3Dc_1/(2c+c_1)$. Thus it is not possible to make the displacement more than three times as great as before, and that is when $c_1 = \infty$. It is twice as great when $c_1 = 4c$. There is no real electrification, but the sphere appears electrified, to surface density D_1 at the positive pole, and elsewhere proportional to the sine of the latitude. The potential, not counting that of the undisturbed field, which increases uniformly parallel to the axis, is $\sigma r\cos\theta$ within and $\sigma a^3\cos\theta/r^2$ without the sphere, where $\sigma = E(c_1 - c)/(2c + c_1)$, at a point distant r from its centre, θ being the co-latitude. If the sphere be taken out of the field, its apparent electrification will disappear, unless absorption or conduction have occurred.

(2.) Whilst in the field, as above, let absorption occur, and go on until the displacement has become increased by D_2, such an amount as would be caused by an impressed force e_2 uniformly distributed parallel to the axis. We must not write $D_2 = c_1e_2/4\pi$; D_2 is less than this amount. For continuity in the displacement requires that when the displacement in the sphere increases from some cause in itself, there must be a corresponding change in the external displacement. The effect of the intrinsic electrization of intensity $J_2 = c_1e_2/4\pi$ is to make $D_2 = 2J_2/(2c + c_1)$ within the sphere. The apparent charge is increased in density to $(D_1 + D_2)\cos\theta$.

(3.) Next, remove the sphere from the original field of force. There is left the field due to the intrinsic electrization. The displacement within the sphere is D_2, and the apparent charge is of density $D_2\cos\theta$. The potential is $\rho r\cos\theta$ within and $\rho a^3\cos\theta/r^2$ without the sphere, where $\rho = c_1e_2/(2c + c_1)$. In fact the field is exactly similar to the magnetic field of a uniformly magnetised sphere. If the absorption gradually disappear, so will the external field.

(4.) But whilst the intrinsic electrization remains appreciably steady, let us cover the sphere with a metal coating, or in any other way produce surface conduction. There will be a current through the sphere from the negative to the positive side, and oppositely in the conducting coating. Thus the displacement within the sphere must be increased by the short circuiting; it becomes $D_3 = c_1e_2/4\pi = J_2$, the greatest displacement possible without external aid. The external field is done away with altogether. There is now a real distribution of electrification on the surface of the sphere, of density $-J_2\cos\theta$; *i.e.*, negative on the positive side and positive on the negative side. The potential is zero inside and outside. The electret is now in the state of the dielectric of a condenser in which absorption has occurred, and a first discharge taken, the remaining charge not being accompanied by difference of potential between the metal plates.

(5.) On removing the metal coating, the surface charge gives no signs of its presence.

(6.) Keeping the sphere insulated, let the intrinsic electrization subside. As it does so, an external field of the opposite character to before appears, the real surface electrification remaining constant, whilst the displacement it exactly neutralised becomes less. When the intrinsic electrization has gone, supposing it to wholly disappear, the displacement, inside and outside, is merely that due to the surface charge. Inside, the displacement is $+c_1J_2/(2c + c_1)$ and the potential is $-4\pi J_2r\cos\theta/(2c + c_1)$. Outside the potential is $-4\pi J_2a^3\cos\theta/r^2(2c + c_1)$. The apparent electrification has density $-2J_2r\cos\theta/(2c + c_1)$.

(7.) Finally we may get rid of the surface charge by again putting on the conducting coating, after which the sphere will be in its original neutral state.

The study of the theory of electrization is in some respects more important than of magnetization; on account of its greater generality it is more instructive. We have conductors and dielectrics, real and apparent electrification. The magnetic problems are less general on account of the absence of magnetic conductors, with corresponding absence of any magnetic representative of real electrification, as in (4) above, the magnetic matter or free magnetism being, except as regards a constant factor, the representative of the apparent or imaginary electricity, as in (3), where there was no real electrification.

As regards natural electrets, Sir W. Thomson's theory of pyro-electricity is (so far as is known to me) contained in a short article in "Nicol's Cyclopœdia," reprinted in Vol. I. of "Mathematical and Physical Papers," Art. 48, p. 315. Being only a few lines in length, I can scarcely be quite certain that, when fully developed, it would be exactly as I state it—that is to say, when details are gone into, similarly to the above—though, generally speaking, there is no room for ambiguity. A pyro electric crystal is a natural electret. In its neutral state, however, its external field of force has been done away with by surface conduction and convection. Disregarding eolotropy, it is then in the condition of the sphere in (5) above, the surface being charged so that its density equals the divergence of the internal displacement. Warming or cooling the electret, by altering the internal stresses, alters the intensity of electrization, whereby the surface charge no longer exactly balances it. If, for example, warming decreases the intensity of electrization, the positive end appears to acquire a negative charge, the negative end a positive, like the sphere (6) above. If it be kept at the higher temperature, and surface conduction occur, its surface charge will readjust itself to again balance the internal displacement. Evidently we cannot get rid of the surface charge as in (7), unless we can make the intensity of electrization zero.

The electret may, however, without change of temperature, produce external force by breaking it across its axis of electrization, when, evidently, the two pieces will not be neutral, unless the act of fracture should cause exactly the right amount of electrification on the fractured surfaces, which is highly improbable. But by surface conduction again the two pieces will each become neutral.

Thermodynamic principles have also been applied to the case by Sir W. Thomson, under date 1879. This is the easiest part of the matter, considered qualitatively, if we know exactly the influence of heat. Applying the principle of thermal resistance discussed in the last section, we see that moving a natural electret about in an electric field must cause thermal effects. If, for example, as above, heat decrease the intensity of electrization, by decreasing the capacity, if we suddenly put the electret in an electric field so as to increase the displacement, the increase must be resisted, and this requires the electret to be heated. If now, we suddenly invert it, so as to decrease the displacement, this decrease must be resisted, hence a cooling effect. Should e vary as well as c, the application will be more complex. The phenomenon is no doubt very insignificant, but is very curious when we consider that it must occur in neutral crystals showing no external signs of their electrization.

ON THE USE OF DANIELL'S CELL AS A STANDARD OF ELECTROMOTIVE FORCE.*

BY J. A. FLEMING, M.A., D.SC. (LOND.).

The extensive use now being made of strong currents of electricity for purposes of illumination necessitates the employment of instruments for measuring current strength and electromotive force of high values. The employment of electricity for telegraphic purposes, and especially in submarine telegraphy, compelled attention to a common accuracy in measurement of resistance and capacity; but for these purposes the measurements of electromotive force and currents are not of such importance as they are in the recent developments. This requirement has drawn the attention of electro-mechanicians to the subject, and led to the inroduction of numerous forms of electromotive force and current indicators, variously called potential galvanometers, voltmeters, pressure gauges, ampere- or am-meters.

Considering first the voltmeters, they may be classified, according to Sir W. Thomson's nomenclature, into two classes —idiostatic and heterostatic. In the second class the magnetic force at a point in the neighbourhood of a conductor conveying a current is compared with another magnetic field either of the earth or of a permanent magnet, and the difference of potential at the ends of the conductor deduced therefrom. In the first class no magnetic field is made use of other than that created by the current itself.

In the case of heterostatic instruments the readings require to be controlled by a special determination of the value of the

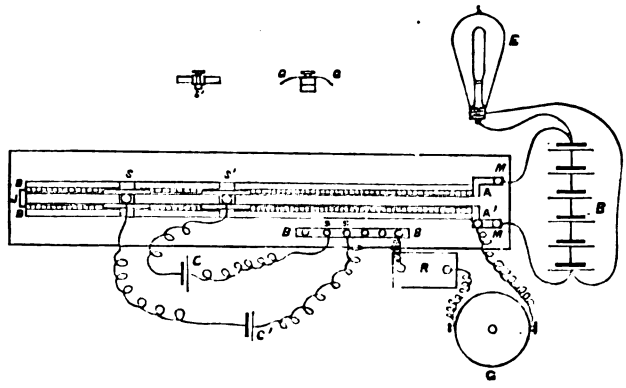

FIG. 1.

auxiliary field; and in the case of an ordinary tangent or sine-galvanometer, the determination of the earth's horizontal magnetic force is a task requiring great care and considerable precautions. In the idiostatic instruments, in many cases, springs are used to obtain a force with which to compare the magnetic force in the neighbourhood of a conductor. The elasticity of these springs is not necessarily permanent, and is liable to change by temperature as well as time. Accordingly in these instruments also the constant must from time to time be determined. Pending the appearance of the new instruments promised by Sir W. Thomson, in which no springs nor permanent magnets are used, it is necessary to fall back upon galvanic cells to establish a standard of electromotive force, and the present paper is a brief collection of facts concerning the use of Daniell's cell for this purpose, and its application in the measurement of currents of various strengths. In all the experiments and methods cited below the cell has been used only to create a difference of potential, and not allowed to send any but a very small current, the means employed for comparisons being a slight modification of Clark's potentiometer, as shown in Fig. 1. On a stout mahogany board are fastened down two boxwood scales, each 5ft. long, divided into inches and tenths; these scales are fixed about ¼in. apart and parallel, so as to form a groove between them. On these scales are stretched two fine uniform German silver wires A B, A′ B′, about ·013 inch in diameter, and having a resistance of about 1 ohm to the foot run; one end of both wires is soldered to a thick copper junction-piece, J, and the other ends respectively to copper pieces connected to terminals M M′. The wire thus forms one length of about 10 feet stretched over two scales. This forms the potentiometer wire; its length is divided by the scale into 1,200 parts, and each tenth of an inch can be divided by the eye into 10, making a possible division of 12,000. To the terminals M M′ are connected five or six large-gravity Daniell cells, and the poles of this battery are short-circuited by an Edison 16-candle lamp of 240 ohms cold resistance. This enables the battery to keep a more constant difference of potential between the terminals M M′.

A very constant E.M.F. can be obtained by using small accumulator cells in series, the poles being joined by a carbon filament lamp, and the leads to the terminals M M′ taken off from the opposite sides of the lamp.

It is easy to calculate what number of cells are required to maintain a given difference of potential, say 2 volts, at the extremities of the potentiometer-wire. For let n be the number of cells, e the E.M.F. of each, and r the internal resistance, and let R be the resistance of the lamp and potentiometer-wire combined, and v the required difference of potential desired at the terminals M, M′; then

$$v = \frac{ne\mathrm{R}}{nr + \mathrm{R}},$$

which determines n. If r is not known, it can be determined by a second experiment, in which v is observed in the case of a given number of cells.

The current along this German silver wire makes a fall in potential at about the rate of 1 volt in 5ft. On one side of the board is fastened a broad copper strap, b b, having six terminals fastened upon it. Between the last of these terminals and the end of the scale-wire A′ is inserted a reflecting-galvanometer of 5,000 ohms resistance, and an additional resistance of 50,000 ohms R.

To the other terminals, s, s on this copper strip are connected one pole (like to the pole of the battery B connected to M′) of each of the cells c, c' to be compared; and the other poles of these cells are connected with sliders S, S′ travelling over the wires. These sliders are blocks of wood sliding in the groove between the scales, and overhanging the wires. On them are German silver spring strips as shown in the figure, and which, when pressed down, make contact with the wire. The strips are backed with leather to avoid the production of thermo-electric currents. By using two or more of these sliders it is easily seen that several cells may be balanced at once on the potentiometer; and in particular two cells, $c\,c'$, can be compared in respect of electromotive force very accurately, even although the E.M.F. of the main battery is not quite constant. The introduction of the resistance R prevents any but the very smallest currents passing in the cells when the place of balance is being found on the potentiometer. The German silver strips $g\,g$ on the sliders make contact only when pressed down, so that in the normal condition the cells $c\,c'$ are insulated. With the galvanometer in a sensitive condition it is very easy to read a difference of $\frac{1}{10000}$ of a volt on the wire, and $\frac{1}{1000}$ can be read with great accuracy.

Electromotive forces are read out directly as lengths, since the E.M.F. of the cells $c\,c'$ is directly as the distance of the constant points of their respective sliders from the end A′ of the wire. Great care has to be taken in the first instance to stretch the wire uniformly, and to calibrate it if it presents any want of uniformity of resistance. Provided with this convenient means of directly comparing electromotive forces, attention was next directed to a modification of Daniell's cell suitable for the experiments required. In Dr. Alder Wright's extensive researches on the subject*, the form of cell employed was that sometimes called Raoult's form, in which two small beakers contain the two solutions, and are connected by an inverted Y-tube, the ends of which are tied over with thin bladder. This form of cell is undoubtedly convenient for

some purposes, but not for others, as when the cell has to be heated or cooled for comparison at different temperatures. Moreover, the siphon becomes filled in a very short time with a mixture of solutions by diffusion; and if the levels of the liquids are not exactly equal, a siphoning action is added to that of diffusion in carrying liquid over from one side to the other. After some numerous trials of all existing forms which have been proposed for Daniell's cell, a form was devised, which, though more bulky than others, has yet given great satisfaction, and has the great recommendation of always standing ready for use.

THE SUBMARINE TELEGRAPH CABLES BILL.

The following is the text of the Bill (as amended in committee) intituled "An Act to carry into effect an International Convention for the Protection of Submarine Telegraph Cables":—

1. This Act may be cited as the Submarine Telegraph Act, 1885.

2. The Convention of the fourteenth of March, one thousand eight hundred and eighty-four, mentioned in the schedule to this Act, as set forth in that schedule, is hereby confirmed, and subject to the provisions of this Act the articles of such Convention (referred to in this Act as the Convention) shall be of the same force as if they were enacted in the body of this Act.

3. (1.) A person shall not unlawfully and wilfully, or by culpable negligence, break or injure any submarine cable to which the Convention for the time being applies, in such manner as might interrupt or obstruct in whole or in part telegraphic communication.

(2.) Any person who acts or attempts to act in contravention of this section shall be guilty of a misdemeanour, and on conviction—

(*a.*) if he acted wilfully, shall be liable to penal servitude for a term not exceeding five years, or to imprisonment, with or without hard labour, for a term not exceeding two years and to a fine either in lieu of or in addition to such penal servitude or imprisonment; and

(*b.*) if he acted by culpable negligence, shall be liable to imprisonment for a term not exceeding three months, without hard labour, and to a fine not exceeding one hundred pounds either in lieu of or in addition to such imprisonment.

(3.) Where a person does not act with the object of preserving the life or limb of himself or of any other person, or of preserving the vessel to which he belongs or any other vessel, and takes all reasonable precautions to avoid injury to a submarine cable, such person shall not be deemed to have acted unlawfully and wilfully within the meaning of this section.

(4.) A person shall not be deemed to have unlawfully and wilfully broken or injured any submarine cable, where in the *bonâ fide* attempt to repair another submarine cable injury has been done to such first-mentioned cable, or the same has been broken; but this shall not apply so as to exempt such person from any liability under this Act, or otherwise to pay the cost of repairing such breakage or injury.

(5.) Any person who within or (being a subject of Her Majesty) without Her Majesty's dominions in any manner procures, counsels, aids, abets, or is accessory to the commission of any offence under this section, shall be guilty of a misdemeanour, and shall be liable to be tried and punished for the offence as if he had been guilty as a principal.

4. Article four of the schedule to this Act shall not apply to that part of a cable which is laid in a depth of water exceeding one hundred fathoms, but nothing in the Convention or this Act shall take away, prejudice, or affect any right or remedy to which by law any party is or may be entitled otherwise than under the provisions of the Convention or this Act.

5. (1.) It is hereby declared that the enactments of the Merchant Shipping Act, 1862, and the enactments amending the same, touching regulations as to lights and to signals and for the avoiding of collisions, shall extend to authorise regulations for carrying into effect Articles five and six of the schedule to this Act, within as well as without the territorial waters of Her Majesty's dominions, and regulations may be made, applied, altered, and revoked, and the contravention thereof punished accordingly under the said enactments, and section six of the Sea Fisheries Act, 1883, shall extend to the enforcement of the said regulations as regards sea fishing boats within the limits of that Act.

(2.) If any vessel engaged in the laying or repairing of a submarine cable to which the Convention for the time being applies, interferes contrary to the said regulations or articles with any vessel engaged in fishing, or if the operations of any vessel in connection with any such submarine cable are wilfully delayed so as to interfere with sea fishing, the master of the vessel, or the owner thereof, if it appear that he was in fault, shall be deemed guilty of a breach of the said regulations and may be punished accordingly.

6. (1.) For the purpose of carrying into effect the convention, a person commanding a ship of war of Her Majesty or of any foreign state for the time being bound by the Convention, or a ship specially commisioned for the purpose of the Convention by Her Majesty or by the government of such foreign State, may exercise and perform the powers and duties vested in and imposed on such officer by any article in the schedule to this Act.

(2.) If any person obstructs any such officer in such exercise or performance, or refuses or neglects to comply with any demand or direction lawfully made or given by him in pursuance of this Act, such person shall be liable, on summary conviction, to a fine not exceeding fifty pounds, or to be imprisoned for a term not exceeding two months, with or without hard labour.

(3.) Any action, prosecution, or proceeding against any officer for any act done in pursuance or execution or intended execution of this Act, or in respect of any alleged neglect or default in the execution of this Act, shall not lie or be instituted unless it is commenced within twelve months next after the act, neglect, or default complained of.

(4.) In any such action tender of amends before the action was commenced may, in lieu of or in addition to any other plea, be pleaded. If the action was commenced after such tender, or is proceeded with after payment into court of any money in satisfaction of the plaintiff's claim, and the plaintiff does not recover more than the sum tended or paid, he shall not recover any costs incurred after such tender or payment, and the defendants shall be entitled to costs, to be taxed as between solicitor and client, as from the time of such tender or payment.

(5.) Every such action shall be brought in one of Her Majesty's Superior Courts in the United Kingdom (which Courts shall have jurisdiction to try the same wherever the matter complained of occurred) or in a Supreme Court in India or in a Court exercising in a British possession the like authority as the High Court of Justice in England, but in no other Court whatsoever.

7. Part X. of the Merchant Shipping Act, 1854 (which relates to legal procedure), and the enactments amending the same, so far as unrepealed, shall have effect as if enacted in this Act, and offences under this Act may be tried, and fines under this Act recovered accordingly, save that nothing in the said part shall authorise the award of any punishment not authorised by this Act, or the summary prosecution of any indictable offence under this Act.

8. (1.) Any document drawn up in pursuance of Article seven or Article ten of the schedule to this Act shall be admissible in any proceeding, civil or criminal, as *primâ facie* evidence of the facts or matters therein stated.

(2.) If evidence contained in any such document was taken on oath in the presence of the person charged in such evidence, and such person had an opportunity of cross-examining the person giving such evidence and of making his reply to such evidence, the officer drawing up such document may certify the said facts, or any of them.

(3.) Any document or certificate in this section mentioned purporting to be signed by an officer authorised to act under the schedule to this Act for carrying into effect the Convention, shall be admissible in evidence without proof of such signature, and, if purporting to be signed by any other person, shall, if certified by any such officer to have been so signed, be deemed until the contrary is proved to have been signed by such other person.

(4.) If any person forges the signature of any such officer to any such document as above mentioned, or makes use of any such document knowing the signature thereto to be forged, such person shall be guilty of a misdemeanour and liable on summary conviction to imprisonment for a term not exceeding three months with or without hard labour, and on conviction on indictment to imprisonment with or without hard labour for a term not exceeding two years.

9. Where any offence against this Act has been committed by means of a vessel, or of any boat belonging to a vessel, the master of such vessel shall until some other person is shown to have been in charge of and navigating such vessel or boat, be deemed to have been in charge of and navigating the same, and be liable to be punished accordingly.

10. The provisions of this Act shall be in addition to and not in derogation of any other provisions existing at common law or under Act of Parliament or under the law of a British possession for the protection of submarine cables; and nothing in this Act shall prevent any person being liable under any Act of Parliament, law of a British possession, or otherwise to any indictment, proceeding, punishment, or penalty other than is provided for any offence by this Act, so that no person shall be punished twice for the same offence; and nothing in this Act, nor any proceedings with respect to any matter, shall exempt a person from any liability in any action or suit with reference to the same matter, so that no person shall be required to pay compensation twice in respect of the same injury.

11. This Act shall so far as such extension is consistent with the tenor of this Act extend to the whole of Her Majesty's dominions, and to all places within the jurisdiction of the Admiral of England, and to all places where Her Majesty has jurisdiction.

12. In this Act, unless the context otherwise requires,—

The expression "vessel" means every description of vessel used in navigation in whatever way it is propelled; and any reference to a vessel shall include a reference to a boat belonging to such vessel:

The expression "master" includes every person having command or charge of a vessel:

The expression "British possession" includes any part of Her Majesty's dominions exclusive of the United Kingdom:

The expression "person" includes a body of persons corporate or unincorporate.

13. This Act shall come into force on such day as may be fixed by a notice in that behalf published in the London Gazette, and if the Convention ceases to be binding on Her Majesty, shall cease to be of any effect.

DIAMOND COAL.—An almost incombustible coal, which stands between the graphite and the diamond, has recently been invented by a Swedish civil engineer, Mr. Westerlund, of Stockholm. The coal, we are informed, promises to be the best material for carbons used in arc lighting.

THE HOUSE OF LORDS AND THE PROTECTION OF SUBMARINE CABLES.

The longer the Convention for the Protection of Submarine Cables is under discussion the more evident it becomes that submarine cables and their owners would have been much better off without it. When those twenty-six meddling and ill-informed plenipotentiaries signed the Convention of Paris last March, there was evidently no thought in their minds that the very next cable operation of any magnitude would render their decisions of non-effect, or of so extremely vexatious a character as to be intolerable to the parties concerned. And as regards the parties themselves, being perfectly well satisfied with the English law as it stood, and having no suspicion that a body of alien gentlemen sitting in a foreign capital could virtually recast the laws of this country, they treated the Convention with the utter indifference which the Convention had shown towards them.

But when it is found that in compliance with the terms of the Convention the British Legislature is asked to alter existing laws, and when, too, the alterations demanded are such as will place English cable property—or rather its proprietors—in a more precarious position than they were in before, the Companies have bestirred themselves to protest as best they can against a proceeding which, whether intended to do so or not, puts them at a disadvantage as compared with those enterprising competitors who, since the Convention was formulated, have laid fresh cables with deliberate disregard of the positions and routes of previously laid cables. There would be no need for frosh legislation, and the Paris Convention might have been allowed to pass unnoticed, had any authority existed in this country capable of protecting existing rights against being wantonly invaded and wilfully endangered. The Duke of Richmond, as we predicted he would, has seen fit to accept a modification of Articles II. and IV., the effect of which will be to enlighten British juries as to the intention of the British legislators if not of the Paris plenipotentiaries. The captain of a repairing ship will not be liable to five years' imprisonment for breaking somebody else's cable, purposely put in his way, while repairing his own. But there still remains the question of future cable laying—the question, namely, whether such operations are to be regulated or not, and to this question we now wish to devote a few words.

In justice to the Convention, it must be owned that its intentions were good. By Article III., the contracting parties are pledged to insist upon proper measures of safety being taken as regards the track of any new cable, the concession for landing which is being sought. The natural assumption of the plenipotentiaries was that England, like every other country, had some authority over its shores; and the Marquis of Tweeddale's amendment, requiring the proposed concession to be treated as a provisional order, liable to be criticised and opposed on good reason being shown, proceeded on a like assumption. But, according to the Duke of Richmond, there is no such authority or right of prohibition in this country; or at all events, if there is, it ought never to be exerted. It passes our comprehension to understand how Article III. comes to be in the Convention at all if the British Government, whose subjects are the owners of nine-tenths of all the cables, is not prepared to carry it out—that is to say to create the right to grant concessions (or withhold them) if such a right does not exist at present. The legislative enactments recommended under the Convention are based on governmental control in the respective countries concerned; and indeed the Convention itself is a conspicuous example of conjoint interference and organised regulation on the part of national representatives. Only in England, apparently, does the parochial system prevail in defiance of Conventions and common sense.

For what else can the Duke of Richmond mean by his objections to the reasonable demand that all applications for concessions to land international cables on these shores should be made public, as is the case with purely internal concerns, before being confirmed? It would appear that all manner of public departments have rights of jurisdiction over the shore, and that it would even be a great hardship to any private individual "to whom the foreshore belongs, that he should not be able to grant a concession to a cable company to land on his property without coming to Parliament and having the application treated as a provisional order." We refuse to believe that the right to land a foreign cable can be conferred by any private gentleman who claims—a very questionable claim at best—to own the foreshore. But if this right exists, we venture to assert that, had the fact been disclosed at Paris, Article III. would never have been drawn up, and we gravely suspect that the rest of the Articles would have taken quite a different shape.

But this was not all. The noble Duke had the strongest objection to render concessions subject to the conditions of a

Digitized by Google

provisional order because, among other reasons, the proposal "is very much in favour of existing companies." We cannot credit the Duke of Richmond with this remarkable discovery. It must have been prompted by some understrapper at the Board of Trade who has surreptitiously assumed the mantle of the late President. Favour the existing companies! To be sure it does; whom else should it favour we would like to know? But favour or no favour, there are rights which ought to be respected, and which may not be set aside on the plea that to respect would be to favour them. It is urged that if such applications were made public the old companies might "endeavour to buy up" the new venture. Here we detect the mantle whose virtuous skirts are rent with indignation at thought of any competitive scheme being nipped in the bud. But on reflection the new President of the Board may see that if a competing conspiracy wants to be bought up it will not desire to conduct its preliminary operations in secresy; whilst if, on the other hand, it means to compete it will not be hindered doing so by conducting them above board. Anyway, the Paris Convention intended that the high contracting parties should insist upon certain conditions of safety to other cable property being fulfilled by parties applying for new concessions; and by the rejection of the Marquis of Tweeddale's amendment the present Act fails to carry out this wise and essential provision.

A CORRECTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should esteem it a favour if you would correct an error in your mention of my lamps at the Inventions in your last week's Supplement. The arc lighting Kapp dynamo drives *8* Statter lamps, each taking a current of *9·5* amperes.

Thanking you in anticipation.—Yours, &c.,

J. G. STATTER.

4, Lion-terrace, Chelmsford, August 4th, 1885.

PRIVATE INSTALLATIONS OF ELECTRIC LIGHTING.*

BY RALPH H. C. NEVILE.

Having for many years desired to use the electric light for domestic lighting, the author could not see his way to doing so while arc lights, and those anything but perfect, were all that were commercially practicable. When, however, incandescent lights were introduced he determined to make the experiment as soon as possible. Happening to have a 6 h.-p. portable engine some ten years old, which he had been using for pumping and for driving a saw, he determined to try this for the purpose, although warned that in all probability difficulties would arise in respect of the governing, as proved to be the case, in consequence of the governor being one of the old-fashioned kind with heavy balls revolving at a slow speed. In the course of last summer he arranged with Messrs. Edmundson, of Westminster, to carry out the wiring of the house, and in the autumn obtained from them a Siemens SD 9 compound shunt-wound dynamo, and completed the installation sufficiently to judge of the merits of electricity *versus* gas, which had been the previous illuminant.

The total number of lamps in the house is 125, divided over some fifty rooms and offices. The maximum number of lamps hitherto required at one time for purposes other than those of experiment has been fifty. All the main wires within the house have been laid to admit of the full number being used, and even of an increase to 150 or 200. The engine and dynamo are stationed in a shed about 180 yards distant from the point where the overhead cables enter the house; in this shed also is the saw table, so that by removing the belt from the dynamo and substituting one to the countershaft of the saw the latter can be driven by the engine when it is not required for lighting. The dynamo is driven direct from the fly-wheel of the engine by a 4in. linked leather belt, which suits the purpose very well, there being no uneven places caused by lacing or other joint to cause any unsteadiness in the running of the dynamo. Owing to the centres of the dynamo pulley and fly-wheel shaft being necessarily somewhat close together, the belt has to be kept rather tight when required to transmit the whole power of the engine. This, however, has never yet been required except for experimental purposes.

The current generated is led from the dynamo to a set of switches, by which it can be distributed into five separate circuits. The first of these is the circuit exciting the field-magnets of the dynamo itself. The second circuit furnishes lights for the engine shed and the carpenters' shop adjoining. The third goes to a schoolhouse near. The fourth goes by an overhead cable to the house, a branch being taken off to light the stables. The fifth circuit goes to a board, on which are fixed 100 lamps for experimental purposes; and this circuit is also intended to furnish current to secondary batteries or accumulators, which the author hopes to introduce before very long. The switches distributing these currents are two-way, so that the current can either be sent out direct or can be passed previously through one of Ayrton and Perry's spring ammeters, whereby the amount of current in use on any one or more of these circuits can at any time be ascertained without causing any interruption in the light. The ammeter in use, being constructed to register up to only 20 amperes, has been provided with two shunts of thick German silver wire, so that by using one or other of these the reading on the ammeter is reduced to one-half or one-third of the total amount passing; in this way the total current of 60 amperes can be registered.

The current for use in the house is led from the dynamo room to the roof in an insulated cable of fourteen No. 16 wires (0·065in. thick), and is thence taken overhead through a bare cable of the same size, suspended on poles, to the point at which it enters the house, where it is connected to a larger cable of nineteen No. 14 wires (0·085in.) This cable has been provided in order to admit of a larger number of lamps being used in the house at some future time, without disturbing the wiring, &c., inside the house. It leads well into the middle of the house, giving off on its way smaller branches to light sections of rooms, and then connects to a smaller cable, which again is reduced to a still smaller one before reaching the far end of the house. These cables all give off smaller branches to light the various rooms both up and downstairs. At their junctions with the mains the branches are fitted with fusible cut-outs, so that, in the event of any short circuit occurring of sufficient magnitude to cause any undue heating of the branch, the fusible plug would go, and would cut off that section. Most of the switches used have also fusible plugs in them, and are of the quick-breaking type, so that they cannot be left in such a position as to form an arc.

The lamps used are mostly 100-volt 20 candle-power lamps of the Edison and Swan make; but in some cases two 50-volt 10-candle lamps placed in series are used, instead of one 20-candle lamp. This is principally the case in passages, which are thus better lighted by the greater diffusion of the light; and moreover it is never required to light one of these lamps without the other. In the chapel there is a hanging chandelier with twenty lamps, in which the current is conveyed to the lamps by the suspending wires; and the chandelier is so arranged that, for the purpose of replacing lamps which have failed, it can be raised or lowered without disturbing any connections. In most other cases the lamps have either been left simply attached to the ends of the wires, or have been fixed to the old gas brackets. In the author's private workshop are a few lamps attached to flexible wires, which are very convenient for placing in various positions for working, and especially for turning.

The installation was first used in November last, and everything worked very satisfactorily, with the exception of the governor, which proved utterly unsuitable, the inertia being so great that its position would remain the same for a very considerable variation of speed, so much so that, although an

* Paper read before the Institution of Mechanical Engineers, at Lincoln, on the 4th inst.

Digitized by Google

adjustable resistance of considerable magnitude had been inserted in the circuit exciting the field magnets of the dynamo, it was found impossible, even with this, to control the electromotive force to the point required. Frequently, when resistance was inserted, thereby lessening the work done by the dynamo, the engine in consequence of the lightened load would increase its speed sufficiently to bring up the electromotive force to its old point. The consequence was that it was necessary to keep the steam pressure in the boiler almost absolutely constant, or rather to allow it so to vary in proportion to the load that it should keep the electromotive force constant. This was found exeedingly difficult in practice, and it was soon seen that it would be necessary to get some more efficient kind of governor. Having seen the working of Mr. Richardson's electrical regulator, and being much pleased with its principle of action and with its performance, the author decided to try it, and one was accordingly adapted to his engine. Although this old-fashioned type of engine does not lend itself very readily to the introduction of the necessary valve, the object was attained in a very efficient though possibly rather unsightly manner, by taking the steam from the top of the safety-valve fitting, and passing it through the throttle valve actuated by the governor, and thence downwards into the steam-chest.

The regulating part of this governor consists of a double solenoid magnet, placed vertically and wound with insulated copper wire, within which works a double core; and to the crosspiece at the bottom of the cores is linked the long arm of a lever, the short arm of which presses upon the spindle of a double-beat Cornish valve that controls the admission of the steam to the steam-chest. For incandescent lighting in parallel, the wire on bobbins is placed in shunt circuit between the main leads; and the size of wire used is adjusted according to the electromotive force which it is desired to maintain between the mains, so that when the electromotive force is at the right point the cores are suspended within the solenoids by their attraction. Inasmuch as the resistance of the solenoids is fixed, any increase in electromotive force causes an increased current to flow through them, whereby the cores are immediately attracted with an increased force, and are caused to move upwards, thereby acting through the lever to close the valve until the electromotive force has been brought down again to its normal amount. The required movement of the valve is exceedingly small; and this method appears to be the best suited for electric lighting. An automatic expansion-gear, on which the governor might be caused to act, has the disadvantage that, when but a few lights are burning, the steam is cut off at so early a period of the stroke that unless the fly-wheel is exceedingly heavy a fluctuation occurs in the light during each revolution of the fly-wheel, somewhat analogous, though of course in a much smaller degree, to the unpleasant bobbing generally seen in electric lights driven by a gas engine where there are no accumulators. In a large engine, where economy of coal has to be considered, probably the best way would be to have an expansion gear actuated by hand, which can be set approximately to the expansion required, leaving the throttle-valve to regulate the speed finally. But where perfect steadiness is desired, it is probably better not to cut off much before half stroke, especially if a single-cylinder engine is used. The use of accumulators as regulators would of course prevent a great deal of the fluctuation, and would permit of the steam being cut off much earlier without causing any apparent unsteadiness the light.

The electric governor was fixed on the engine and worked for the first time on 13th January last. The improvement was remarkable, the lights remaining steady without the sudden alternations of brightness and dulness which had occurred before. But it was still found that with any considerable variation of boiler pressure or of load the electromotive force in the mains varied more than was thought conducive to long life in the lamps. As, however, it was found that, by augmenting or diminishing the weight suspended from the core-bars, the electromotive force could be brought back to its normal amount, it occurred to the author to fix an upright cylinder in direct communication with the boiler, and to make its piston-rod press upwards on the core-bars; the diameter of the cylinder being experimentally determined by obseving the weight necessary to be added or removed for certain variations in boiler pressure. This arrangement caused a very great improvement, and when the load was approximately the same it maintained the electromotive force constant under very considerable variation of steam pressure. When, however, the load was varied very considerably, say from one lamp to a hundred, it was found that more variation took place in the electromotive force than was desirable.

The arrangement was accordingly modified by causing the piston-rod to act upon a lever, and by introducing a second cylinder supplied with steam from the steam-chest, the second piston-rod acting upon the same lever but upon the other side of the fulcrum. The end of the lever was furnished with a steel knife-edge, bearing against another knife-edge set at right angles to it upon the prolongation of the core-bars. The cylinders were also both of them made larger, and were placed so that they could either of them be moved nearer to or further from the fulcrum of the lever, whereby the resultant effect of their differential power could be easily adjusted.

(To be continued.)

THE TELEGRAPH ACTS AMENDMENT BILL IN PARLIAMENT.

In the House of Commons on the 30th ultimo upon the motion to go into Committee on this Bill,

Mr. Alderman LAWRENCE having expressed his strong disapproval of any plan which would abolish free addresses,

Mr. SHAW-LEFEVRE hoped that the House would allow the Bill to get into Committee.

The House then went into Committee accordingly, and Clause 1 was agreed to.

On Clause 2,

Lord J. MANNERS rose to move the amendment of which he had given notice. He said he regretted that the necessity under which the right hon. member for Reading lay in moving the second reading of the Bill on the very afternoon on which the House adjourned for the Easter holidays, made it impossible for him to raise the question involved in his amendment on that occasion. But he had no alternative now except to ask the House to decide the issue between himself and the right hon. gentleman at the present stage. The point immediately at issue was the abolition or the continuance of free addresses. In what had fallen from the right hon. member for the city of London he entirely agreed. He objected strongly to the abolition of free addresses, and he should ask the Committee to come to a decision on that point. Both the right hon. member for Reading and himself, in dealing with that question, were under the same financial restrictions. The right hon. gentleman had told the House very frankly that he might have proposed a scheme of a more liberal character but for the necessity that was imposed upon him by the Treasury of not exceeding the estimated loss of £180,000 by his proposal. Now the Treasury had, wisely as he thought, imposed the same restriction upon himself; and he had therefore so to arrange his scheme of free addresses as not to exceed the estimated loss of £180,000. The experienced officers of the department had assured him that the scheme which he now proposed met that Treasury requirement. Therefore, in regard to the financial aspect of his scheme, and that of the right hon. gentleman opposite, they stood upon a perfect equality, and what the Committee had to determine upon was the respective merits of the two schemes. He wished the Committee to decide that question not with reference to the effect of either scheme upon one class of the community or on another, but with reference to the interests of the general telegraphing public. He held also that they ought to have regard not only to those individuals or those classes who now used the telegraphs, but they should endeavour so to arrange the change about to be made as to induce classes and individuals who had not hitherto been in a position to avail themselves of the telegraphs to do so in future. He said that the scheme proposed by the right hon. gentleman opposite would not fulfil those conditions. He admitted that with respect to certain important classes they might see their way to derive advantage under the right hon. gentleman's scheme. Merchants, stockbrokers, and similar classes who had fixed and —what was very important—registered addresses might gain under the scheme of the right hon. gentleman. Another class of whom he wished to speak with every respect and consideration—the betting fraternity—might also gain under the right hon. gentleman's scheme. But he said that the State did not give 11 millions for the purpose of taking over the telegraphs from private companies in order that the influential class of merchants, rich traders, and still less the betting fraternity, should be favoured at the expense of all the other classes of Her Majesty's subjects. But further he held that the scheme of the right hon. gentleman depended entirely on what he must regard as an arbitrary assumption, namely, that the people who telegraphed could conveniently and safely cut down the words in their addresses from the average of 11 to the average of five. He was not disposed to think, because extremely clever and ingenious officers of his department assumed that that great reduction could safely be effected in the number of words used for addresses, that it could be safely or conveniently effected by the great body of the telegraphing

Digitized by Google

public. If when a person went to a telegraph office he always had one of those highly skilled and experienced officers of the department at his elbow to tell him how many words he might excise from addresses, that contention might be admitted. But that was not so. The great body of the telegraphing public would have to decide for themselves how many words it was expedient that they should use in addresses; and they must, in the last resort, be the best and only judges of what was and what was not a safe and satisfactory address, and whether it was one which would ensure that the delivery of the message would not only be certain but expeditious. The right hon. gentleman opposite, in one of his speeches recommending his scheme, mentioned the fact that in his office he had failed to discover any record of a decided opinion upon that point on the part of his lamented and distinguished predecessor. For himself, he was not surprised that the late Mr. Fawcett did not leave in the office any record of what he thought on that subject. But if he had left no such recorded opinion in the office, he had certainly expressed a decided opinion on the point in that House itself. Speaking on the 29th of March, 1883, Mr. Fawcett said: "There is no doubt much force in what the noble lord (Lord J. Manners) has stated, and that abolition of free addresses would bear most heavily on the poor. A well-known man's address is generally a short one, and in many cases would be simply the name of the town in which he lives; whereas a poor person's address would often have to name the court and the street in which he lived. It would be found that the poor person's address was often several words longer than the rich person's; and, therefore, to charge for the address at one halfpenny per word would undoubtedly press somewhat heavily upon the poor." So far as he knew —and he had several conversations with him after that debate—Mr. Fawcett never changed his opinion that the abolition of the free address, at any rate of the receiver's address, would be a great detriment to the poor class who might be anxious to use the telegraph. He would now quote the opinion of a gentleman engaged in business who had placed his view on that matter before the public. The noble lord then quoted various letters in support of his statement. He would state only one more class to which the abolition of free addresses would cause great inconvenience, and those were the officers, the non-commissioned officers, and soldiers of Her Majesty's service. There was no class which deserved greater assistance on the part of the House of Commons than the soldiers who served the Queen. Soldiers' messages were usually sent to relatives living probably in tenement houses or small streets or courts in the large towns of this country or in the metropolis, and the addresses were necessarily lengthy. In the same manner the messages sent to soldiers by their relatives required a large amount of description in order to identify them, and the claims of that class ought not to be overlooked. It had been found that the average length of soldiers' messages averaged sixteen words. It was very difficult to cut down addresses with any degree of safety, and if any hon. member doubted that let him try to do so in his own telegrams. The right hon. gentleman complained of the cost of this system of free addresses, which had been in operation for 16 years. But no complaint had been made by anyone outside the department, though no doubt the officers of the department thought that the addresses were unnecessarily long, and that they imposed unnecessary trouble and expense upon the department. But no complaint whatever as to addresses was made by the public outside. That being so, he thought the question was whether the department was created for the public or the public for the department. The right hon. gentleman had referred to the foreign system, basing his arguments on the allegation that a charge for addresses prevailed in nearly all foreign countries. He claimed that in giving free addresses we were ahead of and not behind foreign countries. Did any gentleman who had sent telegrams when abroad think that the method of charging for addresses was more convenient? His opinion was that it was a retrograde and a reactionary movement. How would it affect the people in many parts of Ireland, of Scotland, and of Wales, where the same surnames were largely repeated? Unless there was a full, clear, and distinct address you could not distinguish one Jones or Williams from another, and great uncertainty would arise in the delivery of telegrams. Reference had been made to a number of streets of the same name in this metropolis, and that was an important consideration. There were 54 Albert-villas, 61 Albert-terraces, 38 Avenue-roads, 60 Cambridge-terraces, 75 Charles-streets, 59 Church-streets, 52 Elizabeth-streets, 64 John-streets, and 70 Park-villas. If we abolish free addresses we should never get them back again. If the Committee would adopt the alternative scheme he suggested, there was nothing which would prevent its further application in the granting of more words for 6d. If the sanguine views of the hon. member for Glasgow were realised, and if the revenue were improved, nothing would be easier than to allow five or six words for 6d. with free addresses, the maintenance of which would add to the contentment and satisfaction of the great mass of the telegraphing community. If you once abolished free addresses, you might whistle for them afterwards. There was great elasticity in his scheme, because you could add words for every halfpenny, and at any rate it would work well until the anticipations of the hon. member for Glasgow were fully realised. The noble lord concluded by moving the following amendment:—"Clause 2, page 1, line 24, leave out sub-section (1), and insert—1, the charges for the transmission of written telegrams throughout the United Kingdom shall uniformly and without regard to distance be at a rate not exceeding 6d. for the first three words of each telegram, or for each telegram of less than three words, and not exceeding one halfpenny for each additional word; 2, the names and addresses of the senders and receivers of written telegrams shall not be counted as part of the words for which payment shall be required."

Mr. Shaw-Lefevre said that the course pursued by the noble lord with reference to the Bill had been entirely satisfactory to him. He had to thank the noble lord for the consideration shown to himself and to the Bill. Holding, as the noble lord did, so strong an opinion on the subject of free addresses and objecting so strongly to the abolition of them, it was not to be expected that he would adopt the Bill *in toto*. The noble lord, therefore, adopted a wise course in leaving to him the conduct of the Bill, and in proposing an alternative scheme as an amendment. The noble lord admitted that his financial proposition was sound and fair. In introducing the Bill, he stated that in the critical state of the finances of the telegraph service it was not possible in his opinion, and in that of the Treasury, to incur a greater loss than the estimated loss of £180,000. The noble lord had found the estimate accurate, and felt himself unable to propose a plan which would involve a greater loss. Therefore, the two plans were identical in this respect, and the House had to consider which was the more convenient. While objecting to the abolition of free addresses, the noble lord had abstained from saying much in favour of his own proposal, or quoting an authority in favour of it. Had any of those whom he had quoted had under their consideration the alternative scheme of the noble lord? Could he produce one authority in the department or outside it who would say that his alternative was satisfactory? He believed there was not one who would say that the proposal would be unsatisfactory and would give rise to dissatisfaction and to renewed agitation. His own proposal was to abolish free addresses, and to give twelve words for 6d., rising by 1d. for two words, but he was prepared to accept the suggestion of the hon. member for Glasgow, and substitute a halfpenny per word. Therefore, from 6d. upwards, the two schemes were the same. The only question was what was to be given for 6d., three words with address, or twelve without. Examination showed that of the twelve words five would be required for the address and seven would be left for the contents of the message, compared with the three of the noble lord. This estimate was the result of a long investigation, which showed that addresses could be reduced to five words or four, or even three. In many instances the sender's name could be omitted, and there was the provision that five figures were to count as a word. There was at present great telegraphic waste in addresses, and some of the examples were amusing. A milliner at Dover had used thirty-two words in describing her address. A noble lord who had gained some advantage in a Bill telegraphed the result of his success to a justice of the peace, and he used forty-six words in describing his own address and that of his friend. In the third case the late Postmaster-General telegraphed from the House of Commons to the head of the Telegraph Department informing him that this Bill would not come on; and he used eleven words for the two addresses. It was pointed out, however, that three words would have been sufficient, and if he had had to pay for the addresses he would probably have confined himself to that number. He had gone through a number of telegrams, and there was not one of them which did not contain superfluous words in the addresses. Therefore it was necessary to impose some limit in order to prevent the transmission of superfluous and unnecessary words, and he thought the only way of doing this was to give the senders of telegrams an interest in curtailing the addresses. If, in future, there were six unnecessary words in every telegram, and if they were multiplied by thirty millions—the number of telegrams which it was expected would be despatched annually when this Bill became law—they would amount to 23 per cent. of all the words sent over the wires. The very lowest estimate he had made of the cost was £250,000 a year. Now, was it not worth while to make some effort, even at a sacrifice of convenience to some classes of the community, to save so large a sum annually? The noble lord proposed in his alternative scheme to give free addresses and three words for 6d. Why did the noble lord limit himself to three words? It was on account of the great cost of the superfluous words sent in the addresses. If the noble lord could save these superfluous words and add them to the text of the message he would be able to give more words for 6d. Three words in the text were insufficient for almost any message. He had come to the conclusion that not one message in forty would be sent for 6d. under the noble lord's tariff. Inasmuch as there would be the same inducement under the noble lord's tariff as under his to cut down the words in the text as much as possible, he had come to the conclusion that under the noble lord's tariff the senders of telegrams would have to pay in every case for four additional words. The transmission of those additional words, if multiplied by thirty millions, would cost £260,000 a year. That £260,000 almost exactly met the cost of telegraphing superfluous words in the addresses. Forty per cent. of the telegrams would, he calculated, be sent for 6d. under his tariff, while, on the other hand, only one telegram in forty would be sent for 6d. under the tariffs proposed by the noble lord. This was not an assumption, but was founded on a careful investigation of a large number of telegrams. He had examined about 157 telegrams sent by working men, and had compressed them within reasonable limits, when it was found that 71 of those telegrams could be sent for 6d. under his tariff. It was also found that the average charge for all these telegrams would be 7½d. He had applied the same telegrams to the noble lord's tariff. The result was found to be that only four of them could be sent for 6d., and that the average charge on the whole of the 157 telegrams would be 1½d. more than under the tariff of this Bill. Which of the two tariffs would working men, therefore, be likely to prefer? The noble lord had mentioned various classes of people who objected to the tariff of the Bill, including Messrs. Sutton, of Reading, but he had reason to believe that if all their telegrams could be examined at the Post Office he should have a complete answer to all the statements which had been made. He had asked them for permission to to use their telegrams for the purpose, but they had not the fairness to allow the examination to be made. On all these points he thought the House would prefer the tariff proposed by the Bill to that of the noble lord. If only three words were conceded there was danger that the senders of messages would use part of the address as a code. He had shown that by the noble lord's tariff only three words were conceded; secondly, that every sender would be required to pay for four extra words as compared with the tariff in the Bill; thirdly, the average charge of each message

Digitized by Google

would be from 1½d. to 2d. more than under the Bill; and, fourthly, no less than £250,000 would be expended in useless addresses. On the other hand, under his plan addresses would be paid for, and the department would be saved the expense of telegraphing 23 per cent. of useless words in the address.

Mr. GRAY preferred the plan of the late to that of the present Postmaster-General, but he saw no reason why they should not have the number of words given by the late Postmaster-General together with the free addresses of the noble lord. He was inclined to think that if the department were more carefully managed a message of 12 words and free addresses might be given for 6d. When the telegraphs were taken over by the State, Press messages were transmitted at the rate of 4d. or 4½d. a hundred words. If the telegraph companies found it remunerative to send Press messages at that rate there must be a great want of economy in the department if, as was stated, something like £150,000 or £200,000 a year was lost by the department in respect of Press messages. He felt sure that a more economical management in this respect would enable the Government to allow the present shilling message to be sent for sixpence.

THE CHANCELLOR of the EXCHEQUER said the Government could not agree to give a larger number of words and free addresses. The choice lay between the scheme of the late Postmaster-General and that of his noble friend, and the Government were prepared to carry out whichever of those alternative proposals the Committee preferred.

The Committee divided, when the numbers were—

For the amendment	62
Against	108
Majority	—46

Mr. SHAW-LEFEVRE said that in pursuance of the arrangement which had been entered into he begged to move that progress be reported.

Lord J. MANNERS having intimated that he did not propose to move any further amendments,

Mr. SHAW-LEFEVRE withdrew his motion for reporting progress.

The Bill then passed through Committee, and was ordered to be reported to the House without amendments amid some cheering.

On the 31st ultimo, Mr. Alderman LAWRENCE put a series of questions, of which he had given private notice, to the late Postmaster-General, who has charge of the Telegraph Acts Amendment Bill. He desired to know what course the right hon. gentleman intended to take with respect to the charge for numerals in the address of a telegram, and for the initials of metropolitan districts.

Mr. SHAW-LEFEVRE said that up to five figures would count as one word. He intended to move to recommit the Bill in order to substitute "a halfpenny a word instead of one penny for two words" in Clause 2. Practically the change would make no difference in point of finance. The initials of metropolitan districts would count as one word, not as two.

Mr. Alderman LAWRENCE asked whether an address such as "Oxford-street" would count as one word, and similarly the name of an island like the "Isle of Wight," "Isle of Man," and so on.

Mr. SHAW-LEFEVRE: I am afraid I shall have to say "no" to both the e questions.

Mr. Alderman LAWRENCE said that when the Bill was recommitted he would move that the amendments which he had alluded to should be inserted.

On the 2nd inst., on the third reading of the Bill,

Mr. SHAW-LEFEVRE moved to recommit the Bill, with the object of inserting an amendment in Clause 2.

Mr. Alderman LAWRENCE also moved that it be recommitted in respect of two other new clauses. His object was to secure that initials in the metropolitan district should not be counted as words, and that the names of streets, gardens, &c., be counted as one word.

Mr. SHAW-LEFEVRE said he could not accept the amendments.

The amendments were negatived, and the House resolved itself into Committee on the Bill on the original motion.

Mr. SHAW-LEFEVRE moved in Clause 2 the omission of the words "1d. for each additional two words or parts of words," in order to insert "½d. for each additional word."

The motion was agreed to.

The report of amendments was then brought up and agreed to, and the Bill was read a third time.

On the 3rd inst,

Lord J. MANNERS said it was hoped that the scheme for sixpenny telegrams would come into operation on October 1.

In the House of Lords, on the 4th inst., Lord MOUNT-TEMPLE, in moving the second reading of this Bill, said that it would confer a very considerable boon upon those persons who were now obliged to pay for 20 words when their messages contained less than ten words. It was calculated that if the Bill passed there would be a large increase in the number of messages sent, and there was no doubt that the measure would be a very great advantage to the public at large.

The Earl of MILLTOWN wished to know whether the Government assented to the Bill, and whether the first section meant that the name and address of the sender must be upon the message.

The Earl of IDDESLEIGH said that the Bill was introduced into the Commons by the late Postmaster-General. When it came on for discussion the present Postmaster-General proposed that it should be carried with an amendment of which he had given notice. His noble friend was defeated upon that, and thereupon left his predecessor to take charge of the Bill. So far as the Government were concerned they looked upon the Bill as one for which the late Government were responsible.

Lord MOUNT-TEMPLE said he was requested by the late Postmaster-General to take charge of the Bill. He understood that the sum of 6d. was to be paid for any number of words not exceeding twelve, and the sender might put them either in the address or in the message.

The Earl of MILLTOWN said that in Committee he would move an amendment in order to make the Bill more clear on the point raised by his question.

The Bill was then read a second time.

On the 5th instant the Bill passed through Committee and was reported without amendment to the House.

THE PIONEER CABLE.

A complimentary dinner was given on Wednesday night at the Star and Garter Hotel, Richmond, by Mr. Cyrus W. Field, to commemorate the twenty-seventh anniversary of the completion of the first Atlantic cable. A special train, conveying upwards of 200 guests, left Waterloo Station shortly after five o'clock, returning at the conclusion of the dinner. The chair was taken by Mr. Cyrus Field. Among those present were Sir Lyon Playfair, M.P.; Mr. Shaw-Lefevre, M.P.; Lord Houghton, Mr. Phelps, the United States Minister; Sir A. Otway, M.P.; the Lord Mayor, M.P.; Sir G. Campbell, M.P.; Professor Thorold Rogers, M.P.; Sir William Thomson, Sir S. Waterlow, M.P.; Sir W. Lawson, M.P.; Senator Hawley, of Connecticut; Canon Farrar, Sir J. Anderson, Sir D. Gooch, M.P.; Sir G. Elliott, M.P.; Sir Charles Bright, the Chief Justice of the United States, and others.

The CHAIRMAN, in proposing the toast of "The Queen," said American citizens always drunk this toast with as much enthusiasm as if they were British subjects. They could never forget that Her Majesty, in all her relations with the United States, had ever been actuated by the noble sentiments to which she gave expression in the message which she sent through the cable to President Buchanan in 1858. "The Queen," she said, "is convinced that the President will join with her in fervently hoping that the electric cable, which now connects Great Britain with the United States, will prove an additional link between the nations, whose friendship is founded on their common interest and reciprocal esteem." He had the honour to give "The Queen, God bless her."

After the toasts of "The President of the United States" and the "Illustrious Memory of General Grant" had been drunk,

The CHAIRMAN, in proposing the toast of the evening, "Success to the Atlantic Cables; May they Perpetuate the Peace, Friendship, and Prosperity of Two Great Kindred Nations," said that when the first telegraph land line in the United States was successfully completed many years ago the very first message which passed over the electric wire was sent by a lady of his acquaintance. She telegraphed these four pregnant words:—"What has God wrought?" And in briefly reviewing the history of the Atlantic cable he did not think he could use language more appropriate—"What has God wrought?" There were many eminent persons present who, having shared the labours and successes of that great undertaking, naturally regarded its history as "a twice-told tale;" but he felt sure that, even in this case, he should not be guilty "of vexing the dull ear of drowsy men." Personally he had much reason to feel grateful to Almighty God when he recalled the meeting at which the first important step was taken in the direction of establishing telegraphic communication between the two continents. That meeting was held in his own dining room in New York on March 10, 1854; and he was now the sole survivor of the little company which assembled on that occasion. More than three years elapsed before an attempt to lay a cable across the Atlantic was made; for it was not till the 5th of August, 1857—28 years ago—that the first expedition sailed from Valencia Island. Those who were present would never forget the lofty tone of eloquence in which the late Lord Carlisle, then Lord-Lieutenant of Ireland, spoke on the eve of the departure of the "Niagara" and the "Agamemnon" on their mission of peace. "Moral links," he said, "there have been—links of race, links of commerce, links of friendship, links of glory; but this, our new link, instead of superseding and supplanting the old ones, is to give them a life and intensity which they never had before;" and in the same sanguine spirit, he pointed out that while hitherto "the inhabitants of the two worlds have associated with each other in the chilling atmosphere of distance, they can now be hand to hand, grasp to grasp, pulse to pulse." These high expectations, however, were for a time destined to be blighted; for the cable was broken on board the "Niagara" after 335 miles had been sunk in the depths of the Atlantic. But, as their friends knew, they did not yield to despair; and their spirits revived when, on August 5, 1858, 27 years ago, the next cable was successfully laid. Unfortunately, it only had a brief existence of 27 days, for on the ensuing 1st of September it ceased to work. Great was their discouragement, and severe also were their struggles to raise money for what seemed to many people to be an insane venture. The attempt was not renewed till the year 1865, when the cable, after more than 1,200 miles had been paid out, was again lost. It was not till July 27, 1865, 19 years since, that the cable was successfully and permanently laid; and from that day to the present—thanks to the multiplication of cables and to the wonderful skill displayed in making and laying them—there had been no further interruption of telegraphic communication between England and America. When the first Atlantic cable was laid the largest submarine line in the world was that which connected England with the Continent of Europe. Contrast with this the fact that, at the present time, the oceans of this planet were spanned by no fewer than a hundred thousand miles of submarine cable. To the promoters of the Atlantic telegraph belonged the credit of having given the original impetus to this great work; and to them—as inventors, as electricians, as manufacturers, as financiers, as journalists, as statesmen—was due, in no small degree, the great expansion of submarine telegraphy which had taken place during the last quarter of a century. They had covered both earth and sea with a subtle and instantaneous means of

Digitized by Google

intercommunication which was destined, in its far-reaching consequences, to bind together all the branches of the great English-speaking family, and to play an important part in advancing the general well-being and progress of mankind.

Senator HAWLEY, Sir G. ELLIOTT, M.P., and Sir J. ANDERSON having spoken,

The CHAIRMAN proposed the toast of "The men of science and enterprise to whom submarine telegraphy is so largely indebted," coupling with the toast the names of Sir. W. Thomson and Sir Charles Bright.

The health of "The Chairman," proposed by the LORD MAYOR, brought the proceedings to a close.

LEGAL.

Liardet and another v. The Hammond Electric Light and Power Supply Company (Limited).

This was an action brought by the plaintiffs, John Evelyn Liardet and Thomas Donnithorne, to recover the sum of £45,000, damages for the alleged breach by the defendant company of certain covenants in an agreement bearing date the 17th of June, 1882, and to enforce specific performance of the other covenants. The agreement was for the sale by the plaintiffs to the defendants of three patents—a patent for hydraulic motors, a patent for the arrangement of electric lighting apparatus in railway trains, and a patent for an apparatus for the storage of electricity. The price to be paid by the Hammond Company was £30,000, half in cash and half in shares, a deposit of £6,000 in cash being paid into the bank in the names of two nominees of each of the parties. The completion of the above contract was subject, however, to the following conditions, viz., that the vendors should prove before the 1st of the following December that the accumulators were practically half the cost for equal power and half the weight of the Faure accumulator, and that they were equal for commercial and practical purposes to the Sellon-Volckmar; failing which the deposit was to be immediately repaid the defendant company. The defendants contended that the plaintiffs had failed to give the required proofs, and claimed a return of the deposit money.

Mr. Barber, Q.C., and Mr. Macrory were counsel for the plaintiffs; the Attorney-General, Mr. J. F. Moulton, Q.C., and Mr. Ashton for the defendants.

Mr. Donnithorne, one of the plaintiffs, examined by Mr. Macrory, stated that he was one of the patentees of the Liardet battery. The battery manufactured for the Hammond Company was in accordance with the specification. Witness explained the process of manufacture. It was not at all like the Faure battery, because in that ordinary sheet lead was used, and in their battery foreign substances were introduced in the lead. In the Liardet battery the electricity was obtained at once, while in the Faure it was not produced until after several months' action had taken place upon the lead. His battery was half the weight of the Faure.

Cross-examined: He was a solicitor still in practice. Swore that the batteries submitted to the Hammond Company were constructed in accordance with the specification and the manner described by him that morning, with the exception that porous cells were used instead of the two porous plates. Could not say whether his description accorded with that in Dr. Hopkinson's report. Had seen the Sellon-Volckmar battery in use at the Crystal Palace Exhibition in 1882. The Alhambra Court was lighted there by means of them. Had not tested them, as he had no means of doing so.

This concluded the plaintiffs' case.

Mr. MOULTON submitted that there was no case made out by the plaintiffs, and was about to give reasons, when

His LORDSHIP intimated that he need not trouble. He had heard the evidence of a solicitor, one of the patentees, who had suggested that the things, viz., the Sellon-Volckmar accumulators, with which the proofs as stipulated were to be given before the 1st of December, could not be obtained. Well, if so, so much the worse for the people who had to furnish them. Further than that, the description given by the only witness called before him of the battery made for the defendants seemed totally different to that in the specification. He therefore dismissed the action with costs, and ordered the return of the deposit to the defendants.

COMPANIES' MEETINGS & REPORTS.

The Anglo-American Telegraph Company (Limited).

The ordinary general half-yearly meeting of the proprietors of the Anglo-American Telegraph Company (Limited) was held at the City Terminus Hotel, Cannon-street, on Friday last, the Right Hon. Viscount Monck presiding.

The SECRETARY (Mr. T. H. Wells) read the notice convening the meeting, and the minutes of the last half-yearly meeting, which were approved by the present meeting and signed as correct by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN: It now becomes my duty to move the adoption of the report, and in doing so I shall not adopt the plan I have usually pursued of comparing the figures of this half year with those of either the preceding or corresponding half year, and for this simple reason that the conditions under which we have been working this half year are so completely different from those which prevailed in former half years that the comparison would be useless. Gentlemen, we have been operating during the past half year under the influence of depressed trade, increased competition, and diminished tariff. We have also in addition to these disadvantages been specially unlucky in regard to our cables. I mentioned to you at the last half-quarterly meeting that several of the cables belonging to our combination were out of order and not working. I regret to say that that state of things has not been completely got rid of yet. We have still cables of the combination incapable of carrying messages across the Atlantic, one of the Jay-Gould and one of the Pouyer-Quertier Companies'. Every effort is being made to repair these cables, and I trust that before long our whole system will be in operation. It will be evident to you that this state of things places us at a very great disadvantage in more ways than one. In the first instance it increases our expenses by compelling us to do more than our proper share of the whole traffic without any proportional increase in our incomes. In the next place it ties our hands very much with reference to the competition of those who are opposed to us, because it would be madness for any man or any set of men to embark in a hostile competition, or war of rates, even if such a policy were deemed advisable when the weapons of warfare were not in proper order. In addition to this consideration, which affects us in another way, our opponents have not had much experience of the working of ocean telegraphy, and of course they are very much guided in their views in respect to the future and their relations with us by the receipts they obtain. Now, you are all aware, because I have often noticed it from this place, that we have observed in our experience that there is a rule which regulates the distribution of traffic among competing cables, and which acts almost with the certainty of a natural law, giving to each cable competing its allocated part of the entire traffic. From this it naturally and necessarily follows that the smaller the number of cables there are in operation at any one period, the larger the receipts of each will be, and therefore the commercial cable as it is called—the Mackay-Bennett cable—is at this moment receiving a larger share of the traffic than it would do if all our cables were in operation. Well, all I can say is this, that we are doing our best (when I say we, I mean our allies as well as we) to place our plant in proper condition, and I trust that before long we shall be in a position either by a hostile competition, if that should be considered desirable, or by the force of circumstances, to bring our opponents to a sense of reason and to induce them to take steps which may enable us all to gain a living. I am not despondent on the subject. I believe such an arrangement can be come to and is quite feasible. It is difficult to speculate what will be the conduct of men who, as far as our judgment goes, have already shown so much recklessness in spending large sums of money on telegraph cables when there was really no need of them. But I don't believe that they are so different from the rest of mankind as to forego a profit on their capital in the interest of pure philanthropy and cheap telegraphy. That being so I trust that before long we shall come to some arrangement which will enable us to give you a more satisfactory dividend than, I am sorry to say, we are capable of giving on the present occasion. I now come to our old friend, or enemy, whichever you may call it, the renewal fund, and in opening my observations on that portion of the case perhaps you will allow me in all good feeling and good humour to say a few words in deprecation of the heated and angry tone which characterised the discussion on this subject on the last occasion of our meeting in this room. Now this is a mere matter of business, and we can surely afford to discuss it without getting excited, or using language which I am certain those who used it were sorry for afterwards. This question has been discussed as if your Board had some unworthy personal motive in the policy which they had adopted. Now, I think if you reflect for one moment you will see that nothing but a strong sense of duty would have induced the Board to take up the position they did take up. You may differ from them in opinion, but I am sure you will all allow that if they could have conscientiously done so it would have been much more agreeable to the Directors, to use a slang phrase, to make things pleasant all round, and meet their constituents with smiling faces. We could not, however, do so as men of business, as men of conscience, and as efficient managers of your affairs. In the discussion that has taken place it seems to me as if the contributions which we make to the renewal fund were regarded as having been adopted by some rule of thumb—a mere chance shot at whatever would do to replace the cables. I assure you that is not the case. This sum was arrived at—and I may mention in a parenthesis that this sum was approved of by the shareholders—["No, no," and hear, hear]. I beg the gentlemen's pardon. I have always been Chairman of the Company, and I remember perfectly well what occurred at former meetings—it was approved of at former meetings of the shareholders over and over again. It was arrived at not by any mere rule of thumb or guess work, but by elaborate calculations based on the best information which we could obtain and on the opinion of those most competent to advise us. I beg leave to say for myself—and I believe I speak the feeling of my brother Directors—that no change has taken place in my opinion either as to the legal liability of the Directors, which I have often stated from this place, or as to the general principles on which our renewal fund should be based. There are two elements which we must of course consider in endeavouring to ascertain the annual amount to be set aside towards the renewal fund. One is the duration of a cable in a state of efficiency, and the other is the cost of replacing it. On these two elements of course depend—it is a mere actuarial calculation—the amount that is necessary to set aside for the renewal fund. Now, with regard to the first of these elements, the duration and efficiency of a cable, of course every year that a cable lasts gives you stronger faith in its continuance. But it is an element that is not capable of being very accurately measured in figures. The other element, the cost of replacing it, is one very capable of being measured in figures. I am happy to tell you that on a careful reconsideration of the whole case your Board have discovered a mode in which a large economy can be effected in replacing your cables, and this has enabled them so far to meet your wishes without

Digitized by Google

sacrificing their own convictions in this half year, and in future half years, to reduce the large contribution towards the renewal fund to £50,000 per half year. That is taking off £50,000 a year from the contribution which has hitherto been made to the renewal fund. We propose that that state of things—assuming that there is no disturbing cause at work—should continue for three years, and we then hope we shall be able to make a further reduction from the contribution to the renewal fund. I hope I may count on the confidence of the shareholders in reference to this matter. The difference between the management of a private firm and a joint-stock company is this, that a private firm need not give to the public any information as to the management which it may think unadvisable for the interests of the firm to mention. A joint-stock company, on the other hand, if it has not the confidence of its shareholders, and the Directors are obliged to declare to them all the motives of their actions, cannot do so without taking the public into its confidence also, and thereby very possibly compromising the interests of the Company. I make this observation because I do not think it would be advisable to state here what it is or in what respect we mean to make that economy which I told you enables us to reduce the contribution to the renewal fund. As I said before, I trust that any discussion that takes place on this subject will be conducted with order and regularity, and, let me add, in conformity with the Articles of Association of the Company. The Articles of Association have been sneered at, and we are told that they are hurled at the shareholders' heads. But we cannot manage this Company, or any business, without having rules for our management. These rules are embodied in the Articles of Association, but there is a prescribed clause by which these Articles of Association can be altered if they are opposed generally. But as your Chairman, who must see that order is maintained while these rules form part of the Articles of Association, I should be acting illegally and should subject myself to legal penalties if I did not see that that was the case. I trust this being the law of the land you will not, if things are pointed out as not being in conformity with the Articles of Association, sneer about the Articles being hurled at your heads. I should be guilty of a dereliction of duty if I did not see that those Articles of Association were enforced. I will not detain you longer, but will now move, "That the report of the Directors and the accompanying statement of accounts to the 30th June, 1885, submitted to this meeting be and the same are hereby received and adopted."

The Most Hon. the Marquis of TWEEDDALE seconded the motion.

Mr. THOS. SMITH questioned whether the Directors were men of business, as the Chairman had said, in view of the beggarly dividend which they were paying to the ordinary shareholders, while they were not paying much more to the preferred shareholders. He could not call them men of business when they divided £35,000 among the shareholders, and put £62,000 odd on one side which they could not touch. He intended to submit the following motion:—"That no further additions to the so-called renewal fund should be made from the 1st of the present month, with the exception of the accruing interest." He considered that a very simple resolution which every shareholder could understand. To some extent since the last meeting the Directors had admitted the fairness of this proposition; but when he remembered that at the end of this half year the so-called renewal fund would represent an amount of over £800,000, with merely the addition of the interest to it, he thought, considering the distress and suffering of the smaller shareholders, that it stood at a sufficient amount for the requirements. He had had a great many letters from shareholders in all parts of the country, complaining of the action of the Board in setting aside to the renewal fund twice as much as they were going to distribute among the shareholders. He had bought his preference stock at £90, and it was now £47 or £48, representing a very serious loss to his representatives if anything happened to him and his executors had to sell his holding in the market. Since 1880 the Directors had taken from the shareholders £1,400,000, of which £800,000 now remained at the credit of the renewal fund, £600,000 having been devoted to laying a new cable, which was given into the hands of the Telegraph Construction Company without any competition from others. He supposed that some day that the £800,000 now in the renewal fund would be used, without heeding the shareholders, for laying two new cables. Well, they were never asked before for their sanction, and he did not suppose they would be asked in future. But he maintained that they ought to be consulted in the matter. He thought they would agree with him that an end ought now to be put to the flagrant injustice and robbery of the shareholders by continual additions to the renewal fund, for which he contended there was no necessity. If they required two new cables at once, and they were to put up the work to public competition, they would get them for less than £800,000. He was told so by authoritative persons. They did not want to lay new cables from shore to shore, but only the deep sea portion, as the shore ends were always good. If, however, a few more thousands beyond the £800,000 were required, it could be very easily raised with the splendid credit enjoyed by the Company. The Chairman was also the Chairman of the Brazilian Submarine Company, and when they laid a new cable he did not take all the money out of the renewal fund, but forestalled the future by issuing redeemable bonds, and in this Company they ought to be treated in the same way. In the seventh paragraph of the report, the Directors had said that the £150,000, annual contribution to the renewal fund, had been adopted with the full consent of the shareholders, but this he denied. When he first brought this question of the renewal fund before the shareholders he was laughed at, but now that they were being pinched, they seemed to think that he had not been far wrong.

Mr. SEELEY seconded the motion, and having spoken of the small dividend which was going to be paid, argued that their affairs had for a long time been going from bad to worse, and that the Company was really a nursery ground for other companies. They repaired the cables of other companies, found ships for them, and transmitted their messages,

The MANAGING DIRECTOR (Mr. Weaver): At a price.

Mr. SEELEY: Do we make any profit out of it?

Mr. WEAVER: Certainly.

Mr. SEELEY said he would prefer the Company to dissolve all their existing arrangements with other companies and stand on their own bottom. They had four good cables, and a reserve fund of an amount equal to two more, and if they were working alone he was convinced that they would earn more than a dividend of one per cent. This state of things could be altered by adopting the suggestion which had been made of not adding further to the renewal fund.

The CHAIRMAN: It is right that I should tell you that this resolution proposes substantially to alter the Articles of Association. The Articles provide that before declaring a dividend the Directors shall set apart to the renewal fund whatever they in their discretion should consider desirable, and this resolution expressly forbids them doing anything of the sort. It takes away the discretion. It may be right or wrong that the Board should have that discretion; but as long as that provision remains in the Articles of Association I cannot allow such a resolution as this to be put to the shareholders.

Mr. SMITH: Then why call a meeting of the shareholders at all?

The CHAIRMAN: I do not wish in any degree to appear to desire to muzzle the shareholders. I must follow the Articles of Association. If the shareholder desires to pass this as a recommendation to the Directors there is no objection to it, and I will put it to the meeting. It is legal to put it as a recommendation to the Directors.

Mr. SMITH assented to this alteration.

Mr. STOCKDALE supported the motion of Mr. Smith, as he was one of the shareholders in the Company who were not in accord with the Board as to the question of the sum that it was desirable to put to renewal fund. He, in conjunction with a few other large and influential shareholders, determined to ascertain the views of the general body of the shareholders on the subject. They therefore went to the trouble and expense of sending out a circular and a blank form of proxy, desiring those who agreed with them that it was time that no further appropriation should be made to the renewal fund to send in their proxies in favour of himself and friends. They received a very considerable number of proxies which on Wednesday last they, in accordance with, as they thought, the regulations on the subject, took to the officers of the Company at 11 o'clock in the morning, which was more than forty-eight hours before the time appointed for the present meeting. But they were told by the Secretary that he could not receive the proxies because they had not been delivered at midnight on the previous evening. He wished to know if the Board meant to take advantage of such a mean subterfuge and not to accept the proxies. If so, he maintained that only one deduction could be drawn from such conduct, which was that they were afraid to go to a poll on the matter. The Chairman at a meeting a year ago had stated that the Brest, as being the oldest cable, would probably be the first to break down, and that the sum required for its renewal would be £800,000 or £900,000, and that therefore the £150,000 a-year set aside to the renewal fund would go on. He did not hesitate to say that the Chairman's estimate for the repairs of the Brest cable was some hundreds of thousands out, and that three cables could be put down instead of one for the figure mentioned, for the probability was that the shore ends of the cables were better than ever, and in that case they would only have the deep sea portions to lay. If the Directors did not willingly act on the advice of the shareholders and cease adding anything more to the already large and inflated reserve fund they would not relax in their efforts to make them. There were five Directors on the Board who between them held only £8,350 of the stock, which was worth at the present time about £2,400, and those five Directors formed a majority of the Board, and according to their interpretation of the Articles of Association those five men had full power at their own will to do what they liked with the £800,000 at the credit of the renewal fund. There was no wonder that their shares stood so low in the market, and that people had no confidence in buying them. He thought a clause ought to be added to the Articles of Association to the effect that the qualification of a Director should be at least £10,000 stock, which would give them some interest in the concern.

Mr. JACKSON, referring to the seventh paragraph of the Directors' report, stated that the Board had not been severely criticised and strenuously opposed for forming a renewal fund, but on account of the exaggerated and excessive amounts taken from the impoverished shareholders when that fund had reached an amount that the Board, he ventured to say, never expected to see. They had, in fact, he maintained, two new cables now in their renewal fund, and it was to be remembered that of their four cables three of them had virtually, and two of them absolutely, been replaced out of their dividends. Contributions to the renewal fund ought, therefore, to cease.

Mr. GRIFFITH said that the shareholders had been told that the renewal fund had been accumulated on the principle of a sinking fund. He maintained that that was a most erroneous principle for them to go upon. The Chairman had spoken of the sense of duty, but he (the speaker) thought that the sense of duty that had guided the Directors had rather carried away their judgment. On a previous occasion he found from the reports that they had a cable 1,100 miles long, purchased and laid down for £475,000. But surely in the last few years the price of cables had diminished owing to science and competition, and they ought, therefore, to obtain cables at a lower rate. Therefore, what resulted from the figures before them was this—that in a short time they would have enough to lay down two new cables, which, however, he contended, were certainly not wanted, especially in view of the working arrangements which they had with the other Atlantic companies. He had a high opinion of the Chairman and of his sense of duty, but he did not think that all the Directors were unanimous with him, for at a meeting eighteen months ago Lord Tweeddale, who presided, admitted that these large additions to the renewal fund ought to cease. There was no necessity for accumulating

Digitized by Google

the renewal fund to such a large amount, and the loss of dividend which that proceeding entailed was severely felt by the shareholders, who, moreover, saw a great depreciation in the market price of their stock. He hoped the Directors would not be hurried by their sense of duty into a policy of war to the knife with their opponents.

Mr. BURTON said he regarded the amendment as a vote of censure on the Board, for it implied either that the Board were not men of business or not so capable of judging what was for the best interests of the Company, or else that they were guided by self-interest. For his part he believed that the Board, from their long experience, their well known character, and the opportunities they had of viewing the question from all points, were better able to judge what was best for the interests of the Company than Mr. Smith and his friends. One argument in favour of those who preceded him was that by not giving more dividend the stocks of the Company were depressed in the market. But that was a matter of opinion. If they paid £50,000 away in dividend, so far as he was concerned he would not be prepared to give so much per share if he went into the market to buy, as he would if they put by that £50,000 to meet future emergencies. He regarded the renewal fund in the light of an insurance, and for the best interests of those shareholders who were permanent. It had been said that they had laid two cables out of dividends. But supposing those cables had not been laid, what price would their shares have been at in the market?

Mr. PRUST said that his views had very much changed since the last meeting, and seeing now that the preferred shareholders were cavilling on account of their dividends, he was in favour of the £800,000 being increased till it got to a million, when he hoped the Directors would be satisfied and keep it intact. At the last meeting he joined in the attack that was made on Mr. Cyrus Field, but he had since inquired into the charges that were then made, and, as an English gentleman, it was his duty to say that those charges were perfectly unfounded. They were to the effect that Mr. Field was concerned in competitive schemes against the interests of this Company; but from what he had learned since the last meeting the very opposite had been the case, and Mr. Field had always laboured for the shareholders, and not against them.

Mr. SMITH, in reply to one remark of Mr. Prust, stated that he held £45,000 worth of the deferred stock, and, therefore, in what he had said he had not been guided by personal motives, which Mr. Prust seemed to think.

Mr. JOHN NEWTON also desired to apologise for the part which he took at the last meeting in connection with the charges made against Mr. Field. Referring to the latter clause of the seventh paragraph of the report he stated that he had made no suggestion that the interest of the renewal fund should be divided. What he had suggested was that it should be shown clearly in the accounts what they placed to the renewal fund—£175,000 or £125,000, whatever the case might be—in the year. He thought that the deferred and the preferred shareholders should be brought together, and suggested that if one of the cables broke it should not be renewed. They ought to find some way by which the existing generation of shareholders should get a return for their money.

Mr. TROTTER expressed approval of the steps taken by the Directors in reducing the contribution to the renewal fund, but he wished they could have gone further and decided to increase that fund by only £50,000 a year instead of £100,000. The Chairman had made some remarks about the Articles of Association, but he could not help saying that, not being present at the last meeting, and having read the account of the proceedings, it had seemed to him from what took place that the shareholders in general meeting could do nothing. He therefore obtained a copy of the Articles of Association and read them, and then asked himself for what object were these meetings held, for there was literally nothing which the shareholders could do, framed as the Articles of Association were at present. The Directors could pass a resolution if they pleased that no dividend should be paid to the shareholders for the next ten years, and that the whole of the earnings should be applied to the renewal fund. He thought it would be wise for the Board to make such an alteration as would give the shareholders the power of at least determining questions which were of importance to their interests. The Board thought that the affairs of the Company had been wisely managed. He wished that he could agree with that view, but he could not, nor apparently could the public. The stock of the Company was £7,000,000, the market value of which was about £2,000,000 [A Voice: "£1,600,000]." He thought it was more than that. If they took from that sum of £2,000,000 the £800,000 to the credit of the renewal fund, it would be seen that the four cables of the Company, in the estimate of the public, were worth only about £1,250,000, and they knew that the four cables could not be laid for less than double that. In 1866 he bought 10 shares in the Company at £14. 10s., and in 1867 he bought more of the £10 shares for £18, and since then he had always continued to be a shareholder. He wished, with his £100 stock at £30, that he could believe the management of the Company had been entirely wise, and such as to command the confidence of the public. He did not believe in dividing the whole of the earnings among the present shareholders, or in putting an exaggerated amount by for future shareholders. There was some medium, and he trusted the Directors would see the wisdom of finding it.

Mr. VEARES objected to the continual increase of the renewal fund.

Mr. CHESTER thought that, in view of the statement which had been made that five of the Directors held together only £8,000 stock, and constituted a majority of the Board, they ought, as men of business, to pass the following resolution, or, as the Chairman pleased, recommendation to the Board:—"That no contract for the laying of any new cable be entered into by the Board of Directors without first obtaining the consent of the shareholders in public meeting." Having referred to the condition of the cables belonging to this Company and to the arrangements which had been entered into with other companies, there was, he contended, no reason why his proposal should not be accepted.

Mr. CYRUS FIELD, referring to the attack which was made on him at the last meeting, said he would read the concluding portion of a letter which Mr. William Abbott wrote, addressed to Mr. Burt, the solicitor of the Company, a letter which reflected credit on Mr. Abbott. The part he would read was as follows:—"Under these circumstances it affords me pleasure to withdraw the statements which I made at the last meeting of the Anglo-American Telegraph Company, and to express my sincere regret that Mr. Field should have experienced pain or annoyance from what occurred through the action which I took, as I considered, in the interest of the stockholders of that Company." Then there has been a frank retraction from every shareholder who made any remarks against me. I do value very greatly the opinion of my English friends (among whom are many of the best friends I have in the world), and desire to keep what I have gained in over thirty years—their confidence and their respect. I do not feel as despondent as some of you appear to be about the Anglo-American. The Anglo-American has four cables, and pools its receipts with four belonging to other companies. Three of its cables are landed in Newfoundland, and one at St. Pierre, near the coast of that island, and on the 6th of February (the day of your last meeting of shareholders) they were the only ones that were working. The other four were all broken. Two have since been repaired, but two still remain useless. The Mackay-Bennett cables were both broken soon after they were laid. They were repaired, but one was again broken this week. Thus of the ten Atlantic cables, everyone has been broken within the past year except those of the Anglo-American Company landed in Newfoundland. Could anything show more conclusively that a cable laid direct from Ireland to Newfoundland, across the great telegraphic plateau, is much more likely to be kept in working order than a longer line traversing other parts of the ocean? Where would your Company be now if it had no connection with Newfoundland, and had been obliged to seek a landing on some more distant point of the American coast? Yet you could not have touched Newfoundland without the consent of the Newfoundland Company, which had an exclusive right for fifty years to land cables on that island. Sir James Anderson, who has had great experience in the landing of cables in different parts of the world, can tell you what he considers these exclusive rights are worth to the Anglo-American Company. I beg to return my sincere and grateful thanks to Lord Monck, Mr. Weaver, and the 1,068 shareholders who supported me, against a minority of 3, on February 6th, for the confidence they expressed in me—the first two by their speeches, and the rest by their votes. Their esteem I value so highly that I should deeply regret if any of them had attached the slightest credence to the voice of misrepresentation and calumny which was so unexpectedly raised against me in my absence. Probably a good deal of the excitement which prevailed at the last meeting was due to the smallness of the profits divisible among the shareholders. I would remind those who are dissatisfied with the position of the Company that the Directors have not made that position, but are the victims of circumstances beyond their control. They should remember that the successful laying of our two cables in 1866 unfortunately produced an exaggerated idea as to the profits which the undertaking might be made to yield. This has led to a too keen competition, which in its turn has naturally borne fruit in fluctuating tariffs and diminished dividends; but the fault of this untoward state of things assuredly does not lie at the door of the Directors, who, I firmly believe, have done all in their power to administer the affairs of the Company with efficiency and success.

Mr. WILLIAM ABBOTT said that the reason why he had withdrawn what he had said at the last meeting about Mr. Field was that Mr. Burt, the solicitor of the Company, had given him proof beyond all doubt that Mr. Field had nothing to do with the Wabash Railway or with the competition of the American Union Company, by which the pooled receipts of the Anglo-American Company had been reduced by about 22 per cent. He, however, wished Mr. Field to understand that the shareholding public in England were six months ago, as they were now, in a condition of great excitement as to the state of American investments, and it had been generally stated (he knew now wrongly stated) that Mr. Field had had something to do with the two concerns which he (Mr. Abbott) had just mentioned. He urged on Mr. Field to try and impress on the railway magnates of America the duty of acting honestly towards those who had entrusted them with their capital. As one gentleman who had spoken had so well pointed out the public had no idea of the inherent strength of this Company, and of the fact that something like £600,000 or £800,000 had already been spent out of revenue, not in "watering" the Company, but in strengthening. He thought that all who were coming into the concern as shareholders should know what amount had been subscribed by or paid out of the pockets of the present shareholders in strengthening the Company. He had been amazed at the freshness of Mr. Smith in thinking that he could do anything with the Board, so fully intrenched as they were behind the Articles of Association which they had so ostentatiously on the table at that meeting. Mr. Smith, however, might rest assured that the feeling among the shareholders to manage their own affairs was steadily growing.

The CHAIRMAN: I will now try and answer the different criticisms which have been made. In the first instance let me say that there are two general propositions stated to which I consent with the greatest pleasure. One is that the Board feel no ill disposition towards the shareholders because they have criticised our proceedings. It has been asked, what is the use of these general meetings? The use of such a meeting, as it appeared to him, was to give the Directors an opportunity of ascertaining the general views of the shareholders, and enabling them so to qualify their views as to meet as far as possible the wishes of the shareholders. That has always been my desire and my practice during the many years I have been Chairman of this Company. The other proposition is one that Mr. Abbott has just made, which is, that it is becoming more the fashion of shareholders to look sharply after their own interests. I am delighted to hear it. Nothing in the world gives me greater pleasure than to see the

Digitized by Google

shareholders come forward and express their views on the policy of the Board, and of the government adopted by the Board. On the other hand, I must protest against the idea that Directors are not to direct. If you do not concede that your Directors are managing your affairs on proper principles, or if you have not confidence in their integrity or honesty, turn them out. But I do not think it is right when Directors come before you, as we do, with a full candid declaration of policy and the reasons of the policy which they adopt, to say that the Articles of Association protect the Directors in the course they are taking, and that you are muzzled and can do nothing. That is not the fact. You have the power of turning out the Board and of altering the Articles of Association if you consider them against your interests. We are now discussing this burning question of the renewal fund. It has been over and over again before you. It has been thrashed out till there is not a grain of wheat left in it. At the last meeting we discussed this question for three hours, and I have not heard to-day a single observation which was not made and answered at that meeting. There was a full report of that meeting printed and distributed among the shareholders. In our half-yearly report we hark back on the subject. We call the attention of the shareholders to it, tell them on what grounds we were acting, and the lines we intend to pursue in the future, and we asked them for their proxies in support of that policy, and here they are (pointing to proxies). We have had a larger number of proxies sent to us on this occasion than we have ever had before. Under these circumstances, the question having been fully discussed, I hope, gentlemen, you will not consider it disrespectful if I do not take up the time of the meeting in answering in detail the observations which have been made. I think you have the whole case fully before you, and we are quite prepared to stand or fall by your judgment. May I ask Mr. Smith to let me put the resolution for the adoption of the report first?

Mr. SMITH: You pledge yourselves that the Directors will take this recommendation into consideration.

The CHAIRMAN: A recommendation from the shareholders will always meet with the respectful attention of the Board. He then put the motion for the adoption of the report and accounts, and declared it carried with one dissentient. Continuing, he read Mr. Smith's motion, and said: With regard to that, as I have said before, any recommendation coming from the shareholders, will be considered by the Board of the Company. But at the same time it must be evident to any one who has read our report that unless we entirely change our minds we cannot give effect to this recommendation. Therefore I should not like Mr. Smith to go away with the notion that we accept this recommendation as what we are going to adopt. I shall vote against it.

Mr. PRUST: Will you give us distinctly to understand that you will consider one million enough for the renewal fund?

The CHAIRMAN: What we intend is fully stated in the report. Mr. Burt calls my attention to the fact that what is stated in the report is not that we should stop when we get a million, but that at present we have £788,331, and that we mean for three years—this year and the two following years—to add £100,000 to that amount. After that period we hope that a still further reduction will be made in the amount added to the renewal fund. That is the statement in the report. He then put Mr. Smith's motion, and said it was carried, 29 having voted in favour of it and 26 against it. A poll was then demanded on behalf of the Directors.

Mr. SMITH said it was useless to have told him to put his motion in the form of a recommendation, and then for the Directors to vote against it. They did not intend to adopt it, and the whole thing was a farce.

The CHAIRMAN: It is impossible that we could allow 30 shareholders to control 20,000. I have received a requisition signed by five shareholders for a poll, and it will be taken immediately after the conclusion of the business, and closed at three o'clock. It is now proposed by Mr. Chester, as a recommendation to the Directors, "That no contract for the laying of any new cable can be entered into by the Board of Directors without first obtaining the consent of the shareholders in public meeting." Having put the motion in the usual way he declared it carried, 29 having voted for it and 18 against it. He intimated that a poll could be taken on this motion as well as on that of Mr. Smith.

Mr. SMITH said that the Directors could take the poll by themselves, as the shareholders would not oppose them, it being a mere farce to do so with the proxies of the Globe Company.

On the motion of Mr. EDWARDS, seconded by Mr. NEWTON, a vote of thanks was passed to the Chairman and Directors, and the CHAIRMAN having briefly returned thanks the proceedings terminated.

The adjourned meeting was held on the following day (Saturday), Sir James Anderson in the chair. He stated the results of the polls to be as follows:—

Votes representing £6,753 stock had been given for the recommendations, whilst votes representing stock to the value of £2,598,511 had been given against them. The recommendations were therefore rejected by a majority in favour of the Board of 32,920 votes, representing stock to the value of £2,591,758.

Submarine Telegraph Company.

The half-yearly meeting of the proprietors of this Company was held at the Company's offices, 2, Throgmorton-avenue, London-wall, on Tuesday last, under the presidency of Sir Julian Goldsmid, Bart.

The SECRETARY (Mr. S. M. Clare) read the notice convening the meeting and the minutes of the previous meeting, after which the Company's seal was affixed to the register of shareholders. The report and accounts were taken as read.

The CHAIRMAN then said: You will observe by the report that the gross receipts amounted to over £66,000, which enables us to add the usual 15 per cent. to the reserve fund, and to pay a dividend at the rate of 15 per cent. per annum, which leaves a balance of £889. That shows a considerable increase over the corresponding period of last year. Of course you can easily understand that the troubles in the East and the change of Government, and various other circumstances, have led to a considerable increase of telegraphing between this country and the Continent, and the result is shown in the figures which we put before you to-day. I cannot myself think—I never like to mislead you—that this is a permanent improvement of traffic, or sufficient to give us a permanent increase of income, because, as far as my experience goes, you have these fits and starts in telegraphy just as much as you find them in every other kind of business, and I do not see that general improvement in business which would lead me to believe that we should have an improvement in our affairs. I think the one thing goes with the other, and although we are told that the promising time has come, it has not yet come it seems to me; but when it does we shall hope to realise some advantage from it. I do not think the time has come for us for another reason also (because I look on the statement which I now hold in my hand with some alarm—a statement which always interests me, and, I think, has interested the shareholders considerably), and that is the number of words per message, and the average length of messages. In 1884, by the end of June, we sent 1,377,419 messages. Those messages contained 16,583,147 words, and their average length was 12·04. During the same period of 1885 the total number of messages transmitted was 1,462,430, showing an increase of 85,000 messages. The words in 1885 were 17,134,855 as against 16,583,147, showing a large increase—nearly 500,000—and the average length of each message was 11·72 words. You will therefore see that the average length of messages is continuing to decrease. I have been asking the Secretary to-day, and I find that during the month of July this year has shown a still further decrease, so that we have not got to the limit of the decrease yet, which of course considerably affects our profits. There is one circumstance which accounts for a considerable amount of the increased profit, and that is the condition of our cables. You will remember that I have stated to you on more than one occasion that for a long time it was my duty constantly to press the Government to make some arrangement with regard to the condition of the Dutch cables, and after a great deal of work and considerable delay—in fact, after many months had expired, we at last induced the Government to take the matter in hand, and they replaced one rotten cable altogether by an entirely new one, and during the past winter they have put in thirty miles in the other one; so that I may say they are now both in excellent order. I had the pleasure of talking with the Dutch Minister here this morning, and he said that there have been no complaints since this work has been done, so that shows that to the mercantile classes the change is very satisfactory. To us it is still more satisfactory, because the amount expended on cables during the half year under review was only £629, whereas before the sum spent on cable repairs was £2,684. Therefore we have spent £2,000 worth less of cable in the half year mainly owing to the condition of the Dutch cables. That accounts for the large diminution of outlay. There is one thing in which we have an increase of cost, and although it is money out of the pockets of the shareholders it is not a subject of unmixed regret. We established some years ago a scale of increase of wages, and from time to time, owing to their length of service, a considerable number of persons have risen to a higher scale. I do not think that is a matter for regret. I believe it enables you to obtain a good staff, and to get your work properly and efficiently done. That is practically the condition of our affairs. We bear in mind constantly to be economical as far as possible, but there are some things which are entirely beyond our control. He concluded by formally moving the adoption of the report and accounts.

The Hon. ASHLEY PONSONBY seconded the motion, which was carried unanimously.

The CHAIRMAN next proposed the declaration of a dividend at the rate of 15 per cent. per annum, less income tax, for the half year ending June 30th last.

The Right Hon. ROBERT BOURKE, M.P., seconded the motion, which was agreed to.

The retiring Directors, the Right Hon. Robert Bourke, M.P., and the Hon. E. Chandos Leigh, Q.C., were unanimously re-elected to their seats at the Board. The auditors were subsequently re-appointed, and on the motion of Sir THOMAS DAKIN a hearty vote of thanks was passed to the Chairman and Directors, and the proceedings terminated.

The Edison and Swan United Electric Light Company (Limited).

The second annual general meeting of this Company was held on Friday, the 31st ult., at the Holborn Viaduct Hotel, Holborn Viaduct, Mr. James Staats Forbes in the chair.

Major S. FLOOD PAGE (the Secretary) read the notice convening the meeting, and the report of the Directors was taken as read.

The CHAIRMAN said he thought the report bore out the prediction which the Directors made at the last meeting. After carefully looking into the concern the Board came to the conclusion that a profit might be made out of it, instead of a very heavy loss. That had been carried out in their first year's working. There was nothing really so eloquent as figures after all. The accounts were for the year ending 30th June, 1885, and there was one thing they might note. Their business was now so much better organised, that they were enabled to call the shareholders together on the last day of July instead of in November, as was the case last year. This year they had got it pretty close up, because their operations being brought down to the 30th June they were able to tell the shareholders on the 30th July

Digitized by Google

what the outcrop was. The outcrop had simply turned a loss of £28,000 odd into a profit of £12,000 odd, and he supposed that so far they might consider it as satisfactory. The balance of profit as shown by the profit and loss account was £12,353, and, subject to going through the figures a little later, he had better go on with the rest of the report, just emphasising it as a measure of the altered position of the Company, that in one year they had transformed, and transformed by legitimate means, a loss of £28,000 into a profit of £12,000, and therefore the difference was, as they would see, about £40,000 in favour of the present moment. He might at once go to the fifth paragraph of the report, which stated that they had determined that the factories at Newcastle must be given up. They were risky buildings involving not only a dangerous risk, and, as a consequence, the payment of an exceptionally high premium, but further they might involve them in even a more serious matter, and that would be the destruction of their reserve stocks. They had taken to some extent precautions to guard against such a calamity, and they had found for that and other reasons the best thing in the interests of the Company would be to transfer the factory to proper premises in the neighbourhood of London. They were fortunate enough to find premises already built in every way suitable, and at a very moderate price, and, acting upon what they knew to be the interests of the Company, they had purchased those premises, and were now occupied in fitting them up for the permanent manufacture of their lamps, so to speak, under their own eyes. Newcastle was a very long way off, and "out of sight out of mind." They thought it better to have a matter so important to their future as the efficient manufacture of their lamps under their own control, and for that purpose it was necessary to transfer the factories to or near London. Paragraph No. 6 they must take *cum grano*. They had some complaints in the early part of the year as to the character of the lamp, because lamps, like everything, did not attain perfection at once. The lamp had been subjected to a great many experiments with the view of improving it, making it more efficient, giving it longer life, greater power of resistance, and so forth, well some of those experiments, though initiated in good faith, were not altogether satisfactory, and for a short time they no doubt raised a good deal of odium for turning out a lamp which was not quite so good as it might have been. Happily, now, they had cured that evil, and they knew, as a matter of experience that the present lamps which were being manufactured and sold were a great improvement upon the preceding ones, and were, in fact, giving entire satisfaction to the consumer. At the last meeting he had occasion to dwell upon two distinct parts of their business, one was lamp making and selling, and the other was installing. Most of their grief had come about from their having rushed a little too rapidly and without sufficient knowledge (he was not talking about themselves individually, but he meant their predecessors of the two companies) into what they called installation work at rental. He thought almost without exception those installations, though initiated in entire good faith, had been attended with large loss. Anyone who undertook to light at a rental must have a very imperfect knowledge of his own interest. They determined at the last meeting—and he laid great stress upon this—that they would have no more of it, that they would not work at all on installations except for ready money, and at the risk of the gentlemen for whose benefit the installation was laid down, and eliminating all the bad things and getting rid of rentals as rapidly as they could was the policy on which they had gone. They would not now install and light people at a rental; they would only install when people were satisfied to run the risk of installation by paying for it as the work proceeded. That of course had rather diminished the volume of their business, but he had no doubt they would agree that it was better to make a large profit on a small business than to make a heavy loss upon a big one. That was exactly what they had had impressed upon them by their experience, and it was what they were hanging on to very hard and fast. Paragraph 8 followed it up by showing that as rapidly as they could they were getting out of these bad contracts. The contract with the Glasgow Post Office and at Messrs. Gartside's works had terminated through effluxion of time, and had not been renewed, and as other opportunities arose of doing the same they would avail themselves of them. The ninth paragraph of the report referred to portions of their business which he was afraid involved the Directors at all events in a vast deal of trouble and responsibility, and that was in looking after the remarkable class of people called "infringers." Of course, as he said before at the meeting last year, those gentlemen played a waiting game; they hung back until some invention of great value was taken by the public, and then they came, and under one pretext and another, they tried to intervene between the man who had generated it and who should receive the profits. There were a good many of these persons, but the most persevering were Messrs. Woodhouse and Rawson, who were under injunction, and had been for a very considerable time. They were keeping an account of the lamps Messrs. Woodhouse and Rawson manufactured, and an action against the firm had been pending for a considerable time. He hoped it would be tried in November. He was afraid they could hardly escape, like other great inventions, the test of legal validity, but as far as they were advised they had every reason to believe they would succeed. If those infringers thought it worth their while to go to the test of action, the shareholders must rely upon the Directors doing their best in the matter. They were well advised, and had pretty nearly the same brains and technical skill behind them as the telephone company had had when they had to fight their telephone patents, which they had done, under the presiding genius of their Chairman, with uniform success. The tenth paragraph of the report dealt with provisional orders. That was a very old story. Everybody at first was a little mad about electric lighting; they certainly were who were induced to give such enormous sums in money and shares for the privilege of working out these patents; but they were no madder than the rest of the public, and certainly not as mad as those who were called the local authorities, vestries, and others who thought it such an immense thing that they attached the great privilege of supplying light to them at a probable heavy loss to the contractor. The public authorities having in mind what they regarded as the parallel atrocities of the gas companies and the water companies, who, like themselves, having to initiate the supply of an article of daily necessity, after they had taken all the risk of doing it on express contract, were thought to be the most grinding people in the world because they wanted the contract fulfilled, attached such enormous conditions in the way of penalties, and took such exceedingly good care of themselves in the event of its turning out successful, that they managed to enlist on their side the Board of Trade, for whom he had the greatest respect, and who, he was bound to say, acted in entire good faith, on evidence, and listened to everybody. It was very popular, the theory of laying hold of the results of other men's brains and enterprise when it was possible to do it by evading contract. It was rather sad, but it was very common. Well, happily this company and others had had the scales fall from their eyes in respect to the Electric Lighting Act, and the gentlemen of the vestries and others were very like the people who killed the goose that laid the golden eggs, because their conditions and obstructions had been so entirely effectual that there was really no electric lighting in London—what they called central station lighting—nor did he think there was likely to be on any large scale, because he could not imagine any body of men now being so entirely denuded of common sense as to go into any electric lighting on the terms of the Electric Lighting Act, and, therefore, it was a dead letter. He had himself attended one or two deputations to the Board of Trade. The late right hon. President of the Board of Trade (whatever his political qualities, which he was not going to discuss) was certainly one of the best men of business he had ever met there. He had done business with the Board of Trade for forty years with all sorts and conditions of men as president, and he had never met a more courteous or able man, a man who could so readily grasp the ins and outs of questions submitted to him as the right hon. gentleman from Birmingham. He thought Mr. Chamberlain had been persuaded that this Electric Lighting Act wanted a great deal of amendment and modification. Until it was so modified he (the Chairman) ventured to predict that there would be no electric lighting done under it. This company certainly would not do it. They had better stick to their lamp, and to those installations which they could accept if they pleased, and which, having installed, they were done with, and they were not liable, as the Electric Lighting Act proposed, to have them left on their hands if they did not pay, and to have them taken from them if they did. In Paragraph 11 there was a sort of declaration of policy that they were not going to cut the throats of other companies or firms; that was to say they were not entering into unprofitable rivalry with other companies. They proposed to go on steadily. They thought they had a very good business, and that the year past was only an indication of what was to come. Of course, one could not shut one's eyes to the possibilities of what electric lighting might become. He was told that private lighting was extending enormously, and no doubt every day it would develop, and he thought if they were wise they would go on steadily waiting, availing themselves of all opportunities and extending their business on the theory of making a fair profit out of it. There was an appeal to assist the Directors in endeavouring to obtain installations and orders for lamps. He did not know that such appeals to shareholders were of much good, but he hoped they might be in their case. He thought they were deserving of consideration. He was told that fire insurance companies and other kindred institutions had got a good deal of business through their shareholders, and therefore they took the liberty of telling those present and those who might read the report of these proceedings that they might do them some good, first of all by themselves lighting up and then by urging on their friends the enormous advantage which they would experience when they had adopted the use of the electric light. That was the end of the substantial part of the report; but perhaps he had better take them through the balance-sheet. The accounts were very simple; it did not want much knowledge of figures to master them. If they looked at the debtor side of the balance-sheet they would see that the share capital remained as before. There had been no change there; it was practically the same, £353,478. Then there were "B" shares to be issued, those representing Mr. Edison's contingent interest in the value of this concern after the ordinary capital had divided a cumulative dividend of 7 per cent. per annum. Well, at the present moment that did not appear to be what they might call very proximate; but he thought that even Mr. Edison might keep up his spirits, although he had to clear away a great deal before he arrived at the contingent to which he was entitled for his inventions. With regard to the creditors, they had diminished them from £19,937 to £11,769. The last and most satisfactory element in this balance-sheet was the profit and loss balance of account for current year, £12,353, against not only *nil* last year, but as he had said before, a balance of loss of £28,000. Then, on the other side of the account, they would find the first post, £300,988. 7s. 7d., remained the same. Further expenses thereon since, £10,821; that was the amount of their capital they had taken the liberty of spending in different ways during the current year, extending their business, works, and so forth. Then they had released a quantity of old plant, embraced in the first post "Cost of patents, preliminary outlay, loss on working, &c." which involved certain elements which might or might not turn out to be dead loss—not wholly so. They had realised useless or other plant, which was not necessary for their purposes, £6,753; therefore the post stood net at £305,057. The freehold property had increased somewhat. They had made some additional purchases, partly on account of the permanent factory which he described early in the meeting. The installations in progress had diminished somewhat, from £6,100 to £2,000. That showed that they had not as much money locked up in installations as they had this time last

Digitized by Google

year. Plant and stock £28,850 ; that had rather increased. They had rather a larger amount of lamps in hand, lamps and other materials, as they would see by reference to the profit and loss. They began on the 1st of July, 1884, with £13,900, and had £19,384 on the 30th June, 1885. The furniture at London and Newcastle was £1,054. The debts, which were £32,142 in the last balance-sheet, were now £19,000. They believed them to be sound and good. Cash at the bankers and in hand was £12,896. Carrying them down to the profit and loss, which really, after all, was the material part, there was, "By sales of lamps, fittings, &c., and charges for work done," £80,925. 17s. 9d. ; last year it was £98,285. 11s. 9d., but, as he had told them, their business was to give up two classes of business—doing installation work at a loss, and to retire as soon as possible from the working of other installations upon which not only was there the first loss on what they might call the sunk capital, but the loss in working from day to day. It was to the elimination of those two bad parts of the old business they owed the compression in the volume of work from £98,000 to £80,000. The balance of interest and discount account and transfer fees was £242, and the stock on June 30 was £19,384. They were obliged to keep on hand a very large stock of lamps in anticipation of orders, and it had been thought desirable to increase rather than to diminish the stock in view of the slight disarrangement which would take place in removing the factories. They were manufacturing in anticipation of orders, so as to save during the transition period. Most of the stock consisted of lamps, but there were other things, such as dynamos, and others which he need not mention. The result was a total of £100,552, against £140,502 last year, including £28,000 of loss. On the other side of the account the stocks on hand were £13,943. He did not know that he had much to say about wages, &c.—£56,000 as compared with £75,000. Then the salaries, Directors' fees, and so forth, were £15,078, less £750 waived by Directors. The new Board of Directors thought it advisable to put themselves in the same boat with the rest of the Proprietors—at all events, for a time. Then there was salary to Mr. Swan, that was under the original contract, and the depreciation of plant was £1,928, against £2,302. It was a lower figure of course, because a good deal of the value of the plant had been written off in the last year's account. The balance, being profit, was £12,353. 15s. 9d. He should be very happy to give any further enlightenment on these figures if any proprietors wished for it. He thought the figures justified what he had said at starting that they really had carried out their pledges to the proprietors, that they were not deceived in considering that this business had really a substantial foundation, and that as soon as early errors were corrected and they put themselves upon the ground of conducting business on the theory of making profit it would be a good property. The Directors recommended them to carry the profit forward, as they wanted to make this a sound property in the future. In conclusion, the Chairman moved that the report and accounts be received and adopted.

Mr. LEYLAND, in seconding the motion, said the losses they had previously suffered from arose really from an inheritance of bad business that they could not get out of. There were contracts which they were bound to carry out.

Mr. ADDISON asked if the amalgamation of the two companies had been carried out.

The CHAIRMAN replied that the amalgamation had been carried out, but the foreign business of the Swan Company, as originally intended, would be carried on separately.

A SHAREHOLDER would like to know if any of the takers of the installations had continued the lighting and purchased the plant, or whether the Company had removed the plant. He thought that would throw some light on the advantage to be derived from the use of the electric light in the eyes of the hirer.

The CHAIRMAN replied that as far as the Glasgow Post Office was concerned they were continuing it under some arrangement with some other firm—he did not know who. At Messrs. Gartside's works they had given it up, and the Company had removed the plant. At Holborn Restaurant, which was one of the most important installations, it was in a transition state, but that would no doubt end in Mr. Gordon buying their plant, and carrying it on on his own account. The contract with Gatti's was not up yet.

A SHAREHOLDER asked if the lighting of Victoria Station had been satisfactory, and if it was now carried on by the Chatham and Dover Railway Company.

The CHAIRMAN replied that the Victoria installation had not yet been transferred to the Chatham Company. He meant to say that it had not yet attained that pitch of perfection which was promised by the gentleman who was good enough to install it for them, and although the Chatham station had been lit for some time, the installation had not yet been taken over by the Chatham Company.

A SHAREHOLDER asked what were the probabilities of the Chatham Company taking it over.

The CHAIRMAN replied that if the installation fulfilled the conditions of the contract it was exceedingly likely they would take it over—that was to say, they would pay a consideration if they got the light ; but he did not think they intended to take over the installation itself, which was an installation erected not only for the Chatham Station, but for the whole of the surrounding neighbourhood. There was no rule without an exception, and that did appear to be a place where the experiment of a central station might be developed, because there was abundance of capacity there. There was the Brighton Station, the Underground Railway, the Grosvenor Hotel, and a number of works, all of which could be got at without interfering with the public streets.

The report was then adopted, and the retiring Directors and Auditors having been re-elected, a vote of thanks to the Chairman and Directors terminated the proceedings.

Anglo-American Brush Electric Light Corporation.

The following is the report of the Directors :—

Nearly six months having elapsed since the last general meeting, the Directors feel it will be a satisfaction to the proprietors to learn that business continues steadily to improve, and that there is substantial evidence that the high quality of the electrical apparatus manufactured by the Corporation is now fully recognised and appreciated. The business effected during the past half year compares favonrably with the result of the operations during the corresponding period of last year, and the present position of finance would enable the payment of an interim dividend. The experience in past years shows, however, that there is some degree of uncertainty as to the maintenance of the same average volume of business during the autumn months, and the Directors have decided, after careful consideration, that the interests of the shareholders will be best served by carrying forward the profits realised on the working of the last half year, rather than by the payment of an interim dividend to take up a position which might lead to disappointment when the accounts of the whole year come finally under review and adjustment. It is much to be regretted that the Electric Lighting Act of 1882, which has so greatly impeded the progress of electric lighting, is still unamended. The recent change of Government has interrupted the negotiations, which had been initiated with much care and consideration, with the view of obtaining an early amendment of the Act, and it is not probable that anything can be done until after the General Election. The matter, however, is receiving the constant attention of your Board and of the committee of experts and representatives of the leading companies formed to watch over electric lighting interests, and to confer from time to time with the Board of Trade. It is now generally admitted that considerable modifications in the Act are required both in the interests of the public who desire the light, but are unable to obtain it under the existing repressive restrictions, and of those whose business it is to make such supply a commercial possibility. Sufficient proof has now been afforded of the practicability and advantages of the electric light, and the outlook may be considered as most encouraging so soon as the more equitable conditions, which must be eventually conceded by Parliament, have been established.

NOTES.

A NEW TELEPHONE EXCHANGE.—A new telephone exchange is to be opened at Reading, Berks.

THE EARTHQUAKES.—A shock of an earthquake has been felt at Booleroo, in South Australia.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending July 31 amounted to £3,325.

UNDERGROUND WIRES IN CHICAGO.—The work of placing the electric light, telephone, and telegraph wires underground in Chicago is proceeding rapidly.

THE NEW PAVILION MUSIC HALL.—We understand that the Edison-Swan Company are to have the electric lighting of the new Pavilion Music Hall in Tichborne-street.

THE EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of July amounted to £48,081, and £50,072 in the corresponding period of 1884.

ELECTRICIANS IN LIQUIDATION.—We note that Paget Higgs (Limited), some time carrying on business as electricians at 58B, Rose-street-lane South, Edinburgh, are in liquidation.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of July, 1885, were £1,260, against £1,501 in the corresponding period of last year.

THE ELECTRIC LIGHT IN MINES.—We are informed that the Ashington Coal Company are about to have the electric light adapted to the requirements of their extensive colliery near Newbiggin, Northumberland.

THE GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this company are as follow:—Receipts for July, £25,200; 1st January to 31st July, £168,040; corresponding months, 1884, £155,880; 1883, £145,640.

THE EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of July amounted to £46,099, and to £40,870 for the corresponding period of 1884; increase, £5,229.

50,000 CANDLE-POWER.—One of the largest single electric lights ever constructed was placed on exhibition at Seneca Falls, N.Y., recently. It was of 50,000 candle-power, was made in Ilion, and is intended to illuminate the whole village.

THE ELECTRIC LIGHT IN LIEGE.—M. Jaspar has made an offer to the Municipal Council of Liège to install the electric light in the Theatre Royal in that town. The tender, which includes an engine of 40 horse-power, amounts to about £800.

WELL DESERVED.—We are glad to note that M. Trouvé has obtained a silver medal at the International Inventions Exhibition for scientific research. Probably no living inventor has contributed more variously to electrical science than this eminent French electrician.

A NEW CONTEMPORARY.—A new French scientific has been brought out under the title of *La Science Universelle*, M. H. Graffigny being the editor. The issue forwarded to us is a very interesting one, and our new contemporary should command a fair share of success.

A NEW MEDICAL GALVANOMETER.—Gaiffe's new medical galvanometer contains but one needle and has no directing magnet. Correct proportion between the current strengths and deflections is obtained by means of a special form given to the frame upon which the wire is wound.

UNDERGROUND WIRES IN NEW YORK CITY.—The commissioners on putting electric wires underground in New York City have elected Charles E. Loew president, and Theodore Moss secretary, and have requested the companies to submit maps, plans, and methods within sixty days.

NARROW ESCAPE.—During a thunderstorm lately at Benares, the electric fluid passed right through a room in one of the barracks in which several men were present, but without doing any harm, and fell in the roadway, ripping up the earth for about thirty yards, and making a hole of about four feet in depth.

THE ADMIRALTY AND THE ELECTRIC LIGHT.—The necessary arrangements are now being made at Chatham Dockyard for lighting the workshops and factories with the electric light, the results of the trials carried out for some past in those of the workshops already lighted by electricity having been found to be satisfactory.

THE EDISON SYSTEM ON BOARD SHIP.—According to a recent list of the Edison Company we notice that no less than 46 vessels have been fitted with this system, with a total of 7,805 lights. The largest number of lights on board any one vessel is 920, this being the number installed in the "Pilgrim," belonging to the Fall River Line.

THE CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of July was 3,058, estimated to produce £2,500, against 3,596 messages, producing £3,219, in the corresponding month of last year. The traffic receipts for the month of April, estimated at £3,700, realised £3,886.

SIXPENNY TELEGRAMS AND REGISTERED ADDRESSES.—In the House of Commons on the 7th inst., Mr. King-Harman asked the Postmaster-General whether under the Telegraph Acts Amendment Bill any alteration would be made in the existing system of registration for addresses for telegraphic purposes. Lord John Manners was understood to say that no alteration would be made.

THE SOUDAN TELEGRAPHS.—Our contemporary, the *Military Telegraph Bulletin*, is informed that the line from Cairo to Halfa is in a very rotten condition., all the wooden poles being ant-eaten to the very summit. It seems a wicked waste, says the *Bulletin*, to abandon all the Siemens iron poles between Halfa and Debbeh, but the army is short of transport as it is, and iron poles won't float.

THE ANTWERP EXHIBITION.—On the 30th ultimo, the Central Gallery and the Machine Hall were for the first time electrically lighted. In the Electrical Section *diplômes d'honneur* have been awarded in the following order:—1. Telegraphs of the Belgian State; 2. Gaston Planté; 3. Mourlon and Van Rysselberghe; 4. Société Générale des Téléphones de Paris; 5. Schubart, of Ghent; 6. Compagnie Générale d'Electricité, of Brussels; 7. J. Jaspar, of Liège.

TECHNICAL EDUCATION.—The Saddlers' Company have established four studentships, each of the annual value of £30, and tenable for two years, at the Finsbury Technical College of the City and Guilds of London Institute. The studentships will be competed for at the entrance examination to be held at the College on Oct. 1, and are open to pupils above 14 years of age who are attending, or who have attended, any public elementary school in the United Kingdom.

THE AMERICAN TELEGRAPH COMPANIES.—The Baltimore and Ohio Telegraph Company replies vigorously to Mr. Jay Gould's stories about its being bankrupt. The Bankers and

Digitized by Google

Merchants' Company have reorganised, in a promising manner, as the United Lines Company of Land and Ocean. The rivalry of the Western Union Company appears to increase. It is surmised that the competition between the Cable Companies is one reason of Mr. Jay Gould's anxiety to control the chief competitor.

THE NATIONAL ARTILLERY ASSOCIATION AT SHOEBURYNESS.—The telephone is again this year in operation between the scoring parties at the ranges, the batteries, and the statistical office in camp. The postal and telegraphic arrangements are on the same scale as before. A special tent is pitched in the camp, to which a wire is laid from the local post office, and a staff from the telegraph office has been sent down to work it with punching instruments and Wheatstone transmitters, so that no delay is experienced in getting off even the longest messages.

THE TELEGRAPHS IN BRITISH NORTH AMERICA.—In the annual estimates submitted to the Dominion Parliament the following provisions are made for the extension of the telegraphs of the country :—"Telegraphic communication between Amherst Island, Bay of Quinte, and the mainland at Bath, 1,500dols.; reconstruction of line between Battleford and Edmonton, *vid* Fort Pitt, additional amount required to complete, 20,000 dols.; land line on north shore of St. Lawrence between River Pentecost and Mingan, to complete, 500 dols.; Grosse Isle quarantine telegraph, 2,150 dols.

THE TELEPHONE IN FRANCE.—Public Telephone Exchanges are now in actual operation at the following places in the north of France :—

CABLE COMMUNICATION IN THE WEST INDIES.—The chairman of the West India and Panama Telegraph Company has forwarded a letter praying the Court of Policy of Demerara to reconsider its decision in ordering a certain amount to be deducted from the subsidy of the company on the ground that direct cable communication had been interrupted for a considerable time. The Court understood the company simply petitioned the Court for a reconsideration of the matter, and that there was no question raised as to the power and right of the Court to deduct the sum. The matter was therefore ordered to stand over for further consideration.

THE UNITED TELEPHONE COMPANY.—The United Telephone Company have issued a circular giving notice that they are now prepared to afford certain important facilities for the transaction of business to their customers. The payment of a special £12 rate will enable subscribers to talk from their own houses to the principal shops, clubs, theatres, &c. An arrangement has been made with the General Post Office whereby subscribers will be able to despatch from, and receive at, their own offices telegrams direct to and from any part of the world. The directors contemplate establishing a complete network of public telephone rooms in London and the suburbs.

THE RECKENZAUN ELECTRIC TRAMWAY IN BERLIN.—The preparations for this line, which leads from the centre of the town into the Ausstellungspark, are in active progress, and it is expected that the line will be opened for traffic by the end of this month. The first experimental car has been built by Messrs. Herebrand, of Cologne, and is being fitted with motors and gear made by the Electrical Power Storage Company, under Mr. Reckenzaun's directions. The accumulators are made by Epstein in Berlin, and in regular service they will be charged from the electric light circuit already existing in the palace of the exhibition. Herr F. Zacharias is the engineer to the company.

AN ELECTRICAL YACHT.—There is now being constructed at Mr. Skelton's yard, Millwall, a small yacht, which will be propelled by electrical power. The boat is 36ft. in length by 7ft. in breadth. It is constructed of galvanised steel, lined inside with wood and lead. The accumulators are placed below the floor of the boat, so that with the exception of a small compartment aft for the dynamos, the whole of the space is available for passengers. Two masts and a full suit of sails are also fitted for use when required. In the course of a few days it is intended to take the yacht on a trial trip from Dover to Calais, when it is fully anticipated that a good speed will be obtained.

THE ELECTRIC LIGHTING OF TRAINS.—On the occasion of their visit to Lincoln the members of the Institution of Mechanical Engineers witnessed, on the 7th inst., the trial of an electric lighting experiment by Mr. Oakley on the Great Northern Railway. A train was run by that gentleman from Lincoln to Grantham, which had on board an arrangement whereby the carriages could be lighted by electricity, with switches and storing accumulators, by which the light could be regulated when the train stopped. The members then proceeded to Gainsborough, and visited Messrs. Marshall and Co.'s Works, where nearly 2,000 men are employed in the manufacture of agricultural and other machinery. These works are now partially lighted by arc lamps of 3,000 candle-power.

TELEGRAPHIC COMMUNICATION WITH AFGHANISTAN.—It has been pointed out—and the suggestion is well worthy of attention—that the Ameer should be moved to consent to the immediate extension of the telegraph to Candahar and Herat. The difficulty of making a line would not be great. A strong ruler like the Ameer could guarantee its safety, and the Indian Telegraph Department could easily train a staff of Mahomedan clerks, whose presence would neither alarm nor irritate the Afghans. Such a line, besides being of the greatest use politically and strategically, would probably soon command a large commercial traffic, for during the British occupation of Candahar the merchants of that place were not slow to learn and avail themselves of the use of the wire. Moreover, when the line was once made to Herat it would be easy to connect it with the Persian system from Meshed and Russian Sarakhs, thus giving a new route between India and England.

ELECTRIC LIGHTING OF BUCKINGHAM PALACE.—It is not often that the perusal of the columns of the gas lighting journals are productive of much that is either interesting or reliable in so far as electricity is concerned. Last week, however, in a weak moment, and with a misguided belief in the possible truthfulness of a contemporary, a paragraph was allowed to creep into our columns relative to the alleged electric lighting of Buckingham Palace on the occasion of a State ball. That paragraph was absolutely incorrect. Buckingham Palace, as many of our readers will be aware, possesses a fixed installation, under the able superintendence of Mr. W. H. Massey, of Twyford, Berks. This comprises one 500-light Siemens dynamo, two 400-light Crompton machines, and one 350-light Victoria, running over 1,000 incandescent lamps of various kinds. The dynamos are driven by Willan's engines, fitted with the electrical governors of the same maker.

Digitized by Google

THE ELECTRIC LIGHT IN NEWSPAPER OFFICES.—The publishers of the *Courier*, of Evansville, Ind., have written as follows to the New York *Electrical World*:—"We have a 30-light United States plant in our office, which we put in about the 1st February. For the benefit of newspaper publishers we wish to give a statement of what the cost has been to us, and how much can be saved by using the incandescent lamps in place of gas. We had a good engine and boiler, and hence had no expense in putting in plant, except cost of dynamo, wires, wiring, and lamps. Our coal bill has been increased 10dols. per month. Cost of lamps (600 hour guarantee) 15dols. per month, attendance 15dols. per month, making total cost of 30 lights (we have 36 in, but do not use them all at any one time), 40dols. per month. Gas at 2dols. per 1,000 would cost from 80dols. to 100dols. per month. Coal oil, including breakage of lamps and chimneys and attendance, had been costing us over 35dols. per month. So publishers who have the power will find the incandescent lamp the best and cheapest."

THE INCANDESCENT LAMP A BELGIAN INVENTION!—Our excellent contemporary, the *Journal de Bruxelles*, which is nothing if not patriotic, puts forward on behalf of M. Léon Somzée a claim to priority in the invention of the so-called "Edison" incandescent lamp. The patent of M. Somzée, says our contemporary, which is identical with that of Edison, was taken out on the 5th of November (auspicious date), 1879, at which time the invention was completed, whilst the Edison initial patent was not granted until the 21st of November in the same year. A second patent, having reference to the form and resistance of the carbon, dated from the 30th of December. It was, then, in the fertile brain of M. Somzée that the incandescent lamp had its origin. Messrs. Swan and Edison are deserving of thanks perhaps for bringing the thing to a practical and successful issue, but that's nothing—nothing at all. The only fact that we are to be lost in admiration of is, that "C'est à un Belge qui revient la gloire de l'invention de la lampe à incandescence." Strange to say M. Léon Somzée is the representative of the gas industry in Brussels!

SERIOUS ACCIDENT.—A Newry telegram reports a serious accident on Friday evening on the Bessbrook and Newry Electric Tramway. During the week experiments had been conducted with a view to testing the electric machinery, and on Friday evening Mr. Davis, J.P., estate agent for Mr. Richardson, M.P.; Mr. Edmund Davis, his brother; Mr. Harrison, the manager of the line; and James Williamson, the engineer, started in a passenger car from the Bessbrook Junction for a trial trip to Newry. About half-way between Bessbrook and Newry there is a very sharp decline, and when the car had reached this point the electric power was cut off and word given to put on the brake; but from some unexplained cause the apparatus did not work, and the car dashed down at a terrible rate. On reaching Craigmore it was seen that two empty goods trucks were standing on the line about half a mile ahead, and the occupants of the car recognising that if they remained where they were they would meet with certain death, jumped out and were hurled on to the line with terrific force. Mr. William Davies was thrown on his face and rendered unconscious, Mr. Edmund Davies sustained severe injuries, and the driver was thrown on his head and cut severely. The car rushed on and, striking the trucks, threw one on the other and both off the line.

THE WHITWORTH SCHOLARSHIPS.—The following candidates have been successful in the competition for the Whitworth Scholarships, 1885:—Scholarship of £200: T. Clarkson, engineer, Manchester. Of £150: H. O. Bennie, engineer, Glasgow; R. H. Unsworth, engineer, Pendleton, near Manchester; H. M. Martin, engineer, Gateshead; W. T. Calderwood, mechanical draughtsman, Glasgow; J. Richards, blacksmith, Cardiff; E. R. Dolby, engineer, Leeds; J. Rorison, engine fitter, Paisley; A. J. Moulton, engineer apprentice, Preston. Of £100: W. M'Neill, mechanic, Birmingham; G. W. Moreton, fitter, Crewe; S. E. Mallinson, assistant analyst, London; H. C. Jenkins, engineer and millwright, London; R. Smith, engineer, Glasgow; T. W. Nash, engineer, London; H. F. W. Burstall, engineer apprentice, London; J. Stopher, mechanical engineer, Nottingham; S. H. Wells, marine engineer apprentice, London; G. Milnes, fitter, Charlton, Kent; H. Begbey, engineer, Old Charlton, Kent; J. Goodman, engineer, Brighton; M. H. Crummie, mechanical engineer, Hull; O. Marsh, fitter and turner, Crewe; T. Galbraith, pattern maker, Manchester; J. H. Bowles, engine fitter, Stratford. The College of Science and Arts, Glasgow, has again secured the best position in Scotland in regard to the competition for the Whitworth Scholarships, H. O. Bennie being second, and William T. Calderwood fifth, both trained there for four years, while James Rorison, eighth, and Robert Smith, fourteenth, were also students of this College for one and two sessions respectively, and last year of Anderson's College.

THE ELECTRIC LIGHTING ACT.—In the address delivered recently by the Earl of Pembroke before the Liberty and Property Defence League, and published in the current number of the *National Review*, the following reference is made to Mr. Chamberlain's attempt to legislate for electric lighting on Socialistic principles:—"In the last generation men who risked their money in enterprises which, if successful, would benefit the public, were looked upon as public benefactors, and encouraged. Now they are looked upon as public enemies—as Shylocks who use their legal rights to plunder the public, and against whom, therefore, any spoliation that is legal is fair. The benefits they confer, the risks they run, the failure of other capitalists, less skilful or less fortunate, are all forgotten; nothing is remembered but their bitterly grudged profits. Water companies, railway companies, lighting companies, are looked upon as burdens rather than benefits. To take one instance out of many. I read in *The Times* a few months ago that those interested in electric lighting went as a deputation to the President of the Board of Trade and pointed out to him that the progress of electric lighting had been stopped by a provision of Parliament to the effect that the public should have the right to take over the property of any public electric lighting company at the end of twenty-one years, at a certain price. The childish simplicity of the idea is more worthy of the dark ages than of the nineteenth century. The companies were to take all the risk of failure, and in the event of success were to be deprived of the profits. As a natural consequence public electric lighting is at a standstill. Could anything be more foolishly shortsighted? Could there be a more absurd instance of the policy of killing the goose that lays the golden eggs?"

A NEW ELECTRIC RAILWAY SIGNAL.—In a new system of automatic railway signals, a train moving over a line protects itself both in front and in the rear automatically, and sends a signal to two posts beyond the one at which it is situated. From that point a signal is sent back to the first point beyond the train, and the signal is set at that point. If the train ahead has not left the block, the signal will not be sent back, and when the train arrives at the post it will find the signal at danger. If the block is clear, however, the signal will be sent back and will set the

Digitized by Google

disc at safety. In point of fact, the second post in advance notifies the first post in advance that it is safe for the train to proceed. In the same way, while signalling forward, the train also signals to the rear, and thus sets the signals for the train following. The mechanism includes a small motor for turning the signal disc, and the latter is fitted with an electric lamp which enables the trainmen to see it at night. This lamp at each post is in a normally open local lighting circuit, and is so connected that a current will be diverted through it, giving a light at the approach of a train. The switch by which the connections are controlled is operated by the movement of the signal mechanism. As soon as the train passes, however, the signal disc turns again, operates the switch, and extinguishes the light. Thus the waste of electric energy is prevented and the lighting circuit being entirely local, any accident to it will not affect the operation of the main circuit. The signals are all automatic, no clockwork being used. The motor, actuated by a current from a local battery, turns the signal disc in the proper direction. While entirely automatic in its operation, the mechanism can be operated by hand, and thus in case of necessity a railroad *employé* provided with a key could set the instrument and transmit signals accordingly. Mr. W. T. Waters, of Atalanta, Ga., is the inventor of this ingenious apparatus.

Reducing Salary by Telephone.—A Paris tenor singer of repute and an electrical friend, says the *Electrical World*, visited the recent electrical exhibition at the Observatory, and inspected the telephone. The tenor wished to talk with his manager. The friend busied himself about the apparatus, "to establish the connection," as he said, and then retired, not wishing to hear the conversation. But as a matter of fact he entered a private cabinet with which he had connected the wires. "Can I have a word with you, Monsieur le Directeur?" inquired the tenor. "Certainly," answered a distant voice. "It gives me such pleasure that I am able to converse with you at this distance. What's the news?" The voice replied, "That you are fast losing your voice and have lately been singing dreadfully out of tune. You are no longer a tenor, but a veritable hurdy-gurdy!" "I must have misunderstood you," observed the singer in the greatest alarm. But the extraordinary statement was repeated, with the addition: "You will plainly see that I cannot go on paying you the same salary. If you are willing to stay on for half——" The tenor, flushed and excited, ran out of his cell and down the steps, and called for a cab to take him to the address of his manager. He did not stop to say good-by to his friend who stood watching him and laughing aloud. A few minutes later the tenor stood before the manager. "I am willing to stay for two-thirds of my former salary, but let me tell you one thing—my voice isn't a hurdy-gurdy. You understand?" "To be sure," said the manager, who thought this member of his company had gone out of his mind. "You know how greatly I prize your voice, and especially now that you are reducing your claims. I am greatly obliged for your spontaneous offer." "Spontaneous offer?" exclaimed the bewildered artist; "when you wanted to cut down my salary by half . . . through the telephone! That confounded invention. . . ." The manager saw that a trick had been played on the unsuspecting tenor, and is said to have declined acceptance of the proffered reduction.

Heavy Thunderstorms.—The West Berks district was visited by several terrific thunderstorms on Friday. The first occurred at about two o'clock in the morning, when the flashes of lighting were frequent and vivid, and the peals of thunder particularly loud. A second storm commenced shortly before midday; but the most serious storm broke over the district in the afternoon.—A heavy thunderstorm prevailed in the neighbourhood of Aylesbury on Thursday and Friday, accompanied by torrents of rain. In Hartwell Park, nineteen sheep belonging to Mr. Lee, which had taken refuge under a tree, were struck by lightning. Sixteen were killed on the spot, and the other three were so injured that they had to be slaughtered. A fireball fell on Hartwell Vicarage lawn during a flash of exceptional vividness and a terrific thunderclap. In other parts of the district injury has been done, Some farm premises at Tring were struck. —At Melton Mowbray two houses were struck by lightning. One, occupied by Mr. Robinson, a solicitor, in which three rooms were partially wrecked, and the other the shop of Mr. Smith, a jeweller.—One of the most terrific hailstorms ever experienced in Warwickshire visited the Bedworth district on the same date. Thunderstorms, accompanied by vivid flashes of lightning and torrents of rain, also prevailed in this district at intervals during the day.—At Leamington a Mrs. Rouse was struck by the lightning, and rendered blind.—North Lincolnshire also suffered severely; and at Sheffield, whilst the storm was at its height, a main sewer in one of the hilly parts of the town burst with a loud report, tearing up the roadway for a number of yards and flooding houses and shops on both sides of the road. The water in the street was several feet deep. Damage amounting to £1,000 was done. A sewer in another part of the town also burst.—A heavy thunderstorm also raged over Birmingham. Two houses in the occupation of persons named Daly and Downing in New Summer-street were struck with lightning, the chimneys being knocked through the roofs and other damage caused. Two or three persons narrowly escaped death.

New Books.—"Once a Month," a magazine for Australia (Griffin, Farran, and Co., London), is a readable monthly on orthodox lines. The specimen copy forwarded to us is well written, well printed, and fairly well illustrated. It compares very favourably with other publications of its kind.—"Alphabetical Time Tables" between London and all parts of the United Kingdom and Ireland (Wyman and Sons, London). This is a penny guide; evidently an imitation of the well-known "A B C," but very inferior to it in point of general handiness. We hold that nothing is cheap unless it does all that is required of it, and this the penny alphabetical table does not do. The section devoted to "London Environs" is palpably incomplete, and although in a later edition we may reasonably look for an improvement in this direction we hesitate to recommend the subject of our review to those who are in search of an exhaustive guide to the railway system of the United Kingdom.—"Magnetic and Electrical Laws," by E. Hurren Harding (London and Glasgow: William Collins, Sons, and Cox). This is a sixpenny *brochure*, intended chiefly for the use of students preparing for examinations under the South Kensington Science and Art Department. It is very properly not put forward as a substitute for existing text books, but as a collection and condensation of useful truths, or of notes which may serve for the foundation of lessons, it will be appreciated by many. Besides the general laws of magnetism, the relation of electricity to magnetism, induction, laws of strength of charge and discharge, Ohm's law and its variations, Joule's laws, &c., the little work contains some excellent notes upon chemical action, thermo-electricity, the effects of heat, mutual action of currents, and some miscellaneous information upon various subjects connected with electrical science.—*Received:* "Electrolysis," a practical treatise on nickelling, coppering, gilding, silvering, the refining of metals, and treatment of ores, by means of electricity. By Hippolyte Fontaine. Translated from the French by J. A. Berly, C.E. (London: E. and F. N. Spon.)

LIGHTING OF THE AUSTRALIAN HOUSES OF PARLIAMENT BY ELECTRICITY.—The Australian Electric Lighting Company, says a contemporary, were engaged during the recess in introducing the electric light into both the Assembly and Council chambers and their approaches. The work, which was carried out under the personal direction of the company's manager (Mr. Josephs), was practically finished early in June; and, according to the latest advices received, it was to be publicly tested for the first time on the reassembling of the House on the 16th of that month. The present scheme is not intended for all parts of the building, as in the reporters' rooms, domestic quarters, &c., the use of gas will be continued. In accordance with the wishes of the Parliamentary Buildings Commission the company submitted two tenders. The first provided for five groups, which comprised the number of arc lights required for the exterior of the building; and the contract price, including the extension of the installation to all parts of the building, was about £7,000. The second tender contracted for fittings for only four groups of the building; but it was stipulated that the motive power to be supplied under the contract should be sufficient for five groups. The price named in this contract was about £5,600; and the tender was accepted on the understanding that the company should, if required, extend the installations to the fifth group at the price stated in the first contract. There are two 20 horse-power engines which drive two dynamo machines, each capable of supplying 275 lamps, or a total of 550 lights for the two. This, it is thought, will sufficiently light the whole of the building. But as a necessary precaution, a third dynamo has been provided in the event of any mishap occurring to the two already mentioned; thus dispelling any fear of sudden stoppage in the supply of the light. The company have endeavoured to provide against any sudden emergency that might arise, the gas fittings being still retained in both chambers and in the library; but unless both engines should break down it is presumed there will not be occasion to resort to the use of gas for lighting purposes.

THE EFFECT OF ELECTRICITY ON DUST, SMOKE, AND METALLIC VAPOURS.—A correspondent of the *Journal of Gas Lighting*, writes as follows:—"Descriptions have been given of the effects of high-tension electricity upon dust, smoke, and vapours of various kinds, when confined within glass vessels or other closed chambers. The discovery is due to experiments made by Professor Lodge, of Liverpool, who read a paper on the subject before the members of the British Association at Montreal in 1884. As an illustration, the following remarkable and interesting phenomena are to be noted:—If a glass receiver be filled with smoke of the densest (blackest) kind, and quietly left to itself, some hours will elapse before it will settle. If a current of electricity be passed into the jar, the smoke will begin to whirl about the brass-point conductor, and in a few seconds gather in flakes on the sides and bottom of the vessel. So also with a metallic vapour—say the fumes from lead smelting furnaces. This treated in the same way will quickly form itself into white flakes, not unlike snow-flakes. Electricity! What do we know about it? I began to work at it in 1817; and I am now a learner more anxious for further information than ever before. By the discoveries just now breaking in upon us, may it not be expected that this science—already so high up among the sciences—has many more secrets yet to reveal? Grand and beautiful as some of the exhibitions of electric lighting are, with more yet to be done in this way, may we not believe that here and now we are only looking in over the threshold of a widely-opening doorway, beyond which are stored practical applications of this all-pervading element reaching beyond our thoughts or imaginings? Now comes the question to which all the preceding has been conducting; and it is this: Are there not some gas experts who would turn their hands and thoughts in this direction, and observe the effects of high tension electricity upon coal gas? This should be done in (say) four of the successive stages of its production—(1) Crude gas direct from the hydraulic; (2) after passing through scrubbers, washers, and condensers; (3) at the outlets of the purifiers; and (4) as delivered into the street mains. The experiments would not be difficult or expensive; only special care must be taken that no air be mixed with the gas in the receiver, so as to guard against explosion."

THE ELECTRIC LIGHT IN ART GALLERIES.—A report has been presented to the City Council of Manchester by the Art Gallery Committee with reference to the adoption of the electric light for the Art Gallery. The sub-committee, to whom the subject was referred in November last, we are informed, state that before deciding upon any system they visited the Liverpool Corporation Free Library and Reading Rooms, where the electric light has been in use in several of the rooms for the past five years, with such satisfactory results in regard to the improved temperature of the rooms, better lighting, and other advantages, that they are now extending the system to all the other public rooms in the buildings. The committee recommend that the tender of the Edison Electric Light Company, amounting to the sum of £1,715, be accepted, subject to the approval of the council, and to such terms as to the completion of the works as the committee may decide on. This tender includes the following, viz:—Two 16 h.-p. Otto gas engines, with all the latest improvements and necessary fittings; two compound self-regulating Elwell-Parker dynamos, each capable of delivering a current sufficient for 250 lamps; provision also is made for 385 lamps, with all the necessary wiring up, including foundations for engines and dynamos; the work to be carried out in conformity with their specification and the general memoranda prepared by the city surveyor, dated February 11, 1885, and maintained by them for a period of six months after completion. In considering the question of cost, the sub-committee are of opinion that the increased annual expenditure will not exceed £259. 10s., made up as follows:—4 per cent. on £1,715 for first cost, £68. 10s.; depreciation of engines and dynamos—say £1,300, at 7 per cent.—£91; renewal of lamps, £80; attendance (extra), say £20—total, £259. 10s. The present expenditure for gas lighting amounts to about £100 per annum, and the same amount of gas would still be required for feeding the gas engines. The figures given in this report as to the annual cost show that it would be more expensive to light the building by the electric light than by gas, but when the following considerations are taken into account the sub-committee are strongly impressed with the desirability of adopting this system:—1. Improved lighting of the building. 2. Improved temperature of the rooms, as less heat would be generated, and therefore less necessity for the admission of such a plentiful supply of cold air, which has a tendency to carry with it dust and soot. 3. Additional attractions to visitors, increasing the receipts at the annual exhibitions. 4. The rooms on the ground floor could be better utilised and made more attractive for the permanent exhibition. 5. Additional inducements to artists to send in better pictures. 6. Great saving of damage to pictures, more especially to the permanent collection. 7. Annual saving in the cost of cleaning and painting the rooms. The Art Gallery Committee approve of the sub-committee's report.

ON THE DESIGN AND CONSTRUCTION OF DYNAMOS.

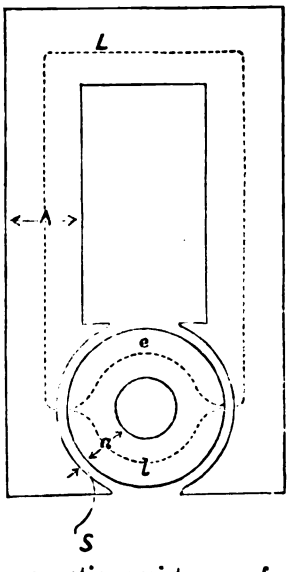
BY GISBERT KAPP.

(Continued from page 191.)

We have seen that the magnetic resistance of the air space is of the character, length divided by area, and it is reasonable to expect that the two other resistances, namely, that of the field magnets and that of the armature, can be similarly expressed. We are not able to prove this on mathematical grounds in the same simple and rigorous manner as was possible when we determined the resistance of the air space between the poles of a perfect magnet, and, indeed, the question of saturation greatly complicates the case; but experiment shows that for low degrees of magnetisation this view of the nature of the resistance of iron is sufficiently accurate for practical purposes, the more so as the resistance of the air space is always considerably greater than that of the iron in field magnets and armature together. Before proceeding with the determination of these resistances it will be necessary to make an assumption as regards the question of saturation. The formula $J = \frac{4\pi P 10^{-1}}{2\delta}$ contains no so-called saturation term, and as it is rigorously correct if δ be very small in comparison to the extent of the polar surfaces—a condition which is fulfilled in most modern dynamos—we shall be justified in assuming that it is impossible to saturate the air space with lines; in other words, that the number of lines passing across the air space in a perfect magnet is always strictly proportional to the exciting power. On the other hand, we know that in our dynamos there is a limit beyond which no amount of exciting power, however large, can produce a sensible increase in the number of lines, and that saturation comes in somewhere in the magnetic circuit. Since it cannot be in the air space it must take place in the iron. This has long been recognised by all who have experimented with electro-magnets, and a number of formulæ have been proposed by which the relation between exciting power and magnetic moment of an electro-magnet can be more or less accurately expressed. These formulæ are all intended for straight bar magnets, spheres, or ellipsoids, and consequently quite useless for the complicated and irregular shapes of dynamo magnets. The only formula which meets the case in some sort of way, though very imperfectly, is that devised by Fröhlich, in which he introduces a so-called saturation term. According to this formula, the strength of field is given by the expression

$$\frac{GP\kappa}{1+\sigma P},$$

κ being the coefficient of magnetic permeability—that is, the power of the core to multiply the magnetic effect of a simple solenoid taken *per se*—whilst σ is the coefficient of saturation, and G a coefficient depending on the shape, size, and arrangement of the field magnets and pole pieces. The latter is now, as before, the stumbling block to a practical application of this formula. It is of no use to know κ and σ if we must also know the coefficient G, which can only be found by experiment after the dynamo is built. What is wanted in practice is a formula by which we can determine, with a fair degree of approximation, the performance of a dynamo before it is actually made. But Fröhlich's formula has also this defect, that it does not take into account the difference which evidently exists with regard to saturation in those parts of the magnetic circuit which lie in iron and those which lie in air. If Fröhlich's formula were correct the characteristic curve of a separately excited dynamo—we take this as an example so as to avoid the complication of critical resistance—would be a continuous curve from the origin to infinity, presenting its concave side to the axis of abscissæ. In reality, however, this is not so. The curve consists in nearly all cases of two portions, one almost a straight line starting from the origin, and the other a curve proper. In some cases it even has an inflexion near the origin presenting its convex side to the axis of abscissæ. A formula to be of practical value must at least in some measure fit these experimental facts, but Fröhlich's formula does not fulfil this condition. In attempting to establish a more serviceable formula it will simplify matters if we neglect saturation at first altogether; in other words, if for the present we only deal with very low degrees of magnetisation. All the magnetic resistances can then be simply expressed as quotients of length and area. Let in the annexed sketch L be the length of that part of the magnetic circuit which lies within the field magnet, and which is indicated by the dotted line; let A be the thickness of the core, the same all round, and B its width. Then if the core be of rectangular



cross-section the magnetic resistance of the field magnet taken from one polar surface to the other will be proportional to $\frac{L}{AB}$. Similarly, if we call a the radial depth and b the length of the armature core, this length being exclusive of any insulation by which the mass of metal may be subdivided into a number of thin discs, the area of iron available for the passage of lines of force will be $2ab$, and their mean length within the armature will be given by the dotted line l. The magnetic resistance of the armature core is therefore proportional to $\frac{l}{2ab}$. The magnetic resistance of the two air spaces has already been found to be proportional to 2δ divided by the surface of the air space. Let λ be the arc embraced by either pole piece; then λb is that surface, and $\frac{2\delta}{\lambda b}$ multiplied with a certain coefficient gives the magnetic resistance of both air spaces. The question is how to find these coefficients for armature, field-magnets, and air. It must be remarked that these coefficients simply depend on the quality of the iron, but have nothing to do with the geometrical form of the machine. In this respect they are not open to the same objection as the coefficient G, which must be determined experimentally for every new form of magnet. Once these coefficients are determined for a certain quality of iron they can be used for all machines made of this iron, no matter what their size, special form, or arrangement may be. The author has found from numerous experiments made with machines of different forms, but all having magnets and armatures of soft wrought iron carefully annealed, that the coefficients are:—2 for the field magnets and the armature, and 1,440 for air. Our formula therefore stands thus,

$$Z = \frac{P}{\frac{2L}{AB} + \frac{2l}{2ab} + \frac{1{,}440 \cdot 2\delta}{\lambda b}}$$

where Z is the total number of lines entering the armature core between two neutral points, and due to the exciting power P on one complete horseshoe of the field magnets, and where the other symbols have the meaning, as explained above. If the field magnets be of cast iron the formula must be modified to

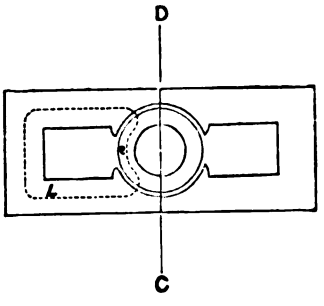
$$Z = \frac{0{\cdot}8\ P}{\frac{3L}{AB} + \frac{2l}{2ab} + \frac{1440.2\delta}{\lambda C}}$$

Digitized by Google

Denoting, as before, by Nt the number of wires counted all round the outside of the armature and by n the number of revolutions per minute, we find the internal electromotive force in volts by the formula

$$Ea = 10^{-6} Z N t n.$$

The expression for Z has been deduced under the supposition that the field magnets consist of only one horseshoe. If there be a double horseshoe magnet as shown in the annexed sketch, the whole machine can be considered as symmetrical to the line C D, and each horseshoe has to supply only half the amature with lines. Calling, again, P the exciting power on one horseshoe and λ half the length of arc in inches



embraced by each pole piece, we have for wrought-iron magnets

$$\frac{Z}{2} = \frac{P}{\frac{2L}{AB} + \frac{2l}{ab} + \frac{1440.2\delta}{\lambda C}}.$$

In this formula, as in the preceding one, all dimensions are to be taken in inches and the exciting power in ampere turns. The lengths L and l should be measured from points about the middle of the polar surfaces so as to represent the average length of lines.

If we divide the number of lines by the area of the core which carries them, we obtain the density, and this must not exceed a certain limit. Otherwise we approach saturation and the above formula for Z cease to be applicable in their present shape. In this case a correction becomes necessary by the introduction of a saturation term which will be given later on. The limit for the density of lines is not very rigidly fixed, as one can easily see from any characteristic curve, which shows that the transition from the straight to the bent part of the curve is very gradual. Neither is it necessary that we should know the limit with any great degree of accuracy, for the working condition of a dynamo is for commercial reasons always considerably beyond it. From actual experiments the author is inclined to consider ten lines per square inch as the density of lines in either armature or magnet cores, up to which no effect due to saturation can be detected. Beyond this density saturation begins and makes itself felt by an apparent increase of magnetic resistance. This increase is seldom less than 25%, but may reach 100% and even higher in machines which contain so little iron that the density of lines becomes abnormally great. Formulæ for determining the apparent increase of magnetic resistance will be given later on; for the present we shall content ourselves to find its amount by a practical example. For this purpose we choose the Edison-Hopkinson dynamo, which has lately been described in *The Engineer*. From the figures there given we find that the armature core is 9·7in. diameter, 18in. long, whilst the magnet core has an area of 171 square inches, and the two exciting coils are each 24in. long. Total number of external wires on armature, 80; speed, 800 revolutions per minute, and external electromotive force 110 volts. Since the loss of electromotive force due to resistance of armature is only about 3 volts, we have

$$Ea = 113 = 10^{-6} Z \,.\, 80 \,.\, 800,$$

and therefore $Z = 1760$.

The air space is about ·55in. wide, and the arc spanned by either pole piece is 12in. We do not know what is the proportion between iron and insulation in the armature, but we may take it that out of the 18in. total length about 1·5in. is occupied by insulation, making $b = 16·5$.

From a sketch of the machine we take $L = 85$, $\lambda = 12$, $l = 12$, and $a = 3·25$. The magnetic resistance is now computed as follows:—

Field magnet	$R_F = \frac{2L}{AB} =$	1·000
Armature	$R_A = \frac{2l}{2ab} =$	·225
Air	$R_a = \frac{1,440 \cdot 2\delta}{\lambda b}$	7·450
	Total	8·675

If there were no such thing as saturation, the exciting power required for this machine would therefore be $8·575 \times Z = 15,200$ ampere turns. In reality we find, however, that the exciting power required, or at least provided, for this machine is 21,300 ampere turns. It is as though the magnetic resistance had been increased by about 40 per cent. In this machine the density of lines is in the armature 16·4 and in the magnet cores 10·3 per square inch. It will hardly be necessary to point out that when speaking of lines we do not mean unit lines in absolute measure, but those representing the arbitrary measure we have adopted in the preceding equations. The relation between our lines and lines in absolute measure is 1 to 6,000; that is to say every one of our lines represents the magnetic effect of 6,000 unit lines, or, in other words, one line of our system will act on unit pole with a force of 6,000 dynes. To prove this we have only to go back to the conception of intensity of field given in a previous article (page 512, Vol, XIV.). Let J be the average intensity of field in the air space taken over half the circumference; let, further, d be the diameter of armature, and let the other symbols stand as before, with the only difference that now centimeters and not inches are meant, then we have

$$Ea\,10^8 = J\,b\,\frac{Nt}{2} \,.\, \pi\, d\, \frac{n}{60}.$$

We write $\frac{Nt}{2}$ because both halves of the armature are coupled parallel, and $\frac{Nt}{2}$ is actually the number of wires within the field of one pole. $\pi d \frac{n}{60}$ is the speed of these wires in centimetres per second. Writing now the equation in the form

$$Ea\,10^8 = J\,b\,\frac{\pi}{2}\,d \,.\, N\,t \,.\, \frac{n}{60}$$

we see that $J\,b\,\frac{\pi}{2}d$ simply represents the total number of lines passing across the semi-circular air space. Call this number ξ, we have $60\ Ea\,10^8 = \xi\, N\, tn$, whilst in our system we have $Ea\,10^6 = Z\,N\,t\,n$. It follows, therefore, that $\xi = 6000\ Z$.

Having now definitely settled the relation between our lines and absolute measure, we will turn to the application of the above formulæ to some practical cases. It will be evident that in all self-excited dynamos the exciting power must depend on the electromotive force—in fact, is proportional to it. On the other hand, the electromotive force exists only by reason of the field magnets being excited, and therefore depends on the exciting power. Unless a given exciting power can produce an electromotive force slightly higher than is absolutely necessary for maintaining that original exciting power, the machine ceases to act. Here we have the principle of the critical speed in dynamos, a term probably first made use of by Marcel Deprez. If the speed is too low, or is gradually diminished until the critical point is reached, the electromotive force is gradually reduced and finally sinks so low that it cannot produce that minimum of exciting power to which it corresponds, and the machine ceases to be magnetic. An example will make this matter clear. Say we have a series wound dynamo supplying a current, c, to a circuit of r ohms. Its own electrical resistance is r_0 ohms, and there shall be T turns of exciting wire on its field magnet, which we assume to be a single horseshoe. The magnetic resistance of the

Digitized by Google

dynamo we denote by R. The following equations must now obtain :—

$$Z = \frac{P}{R} \qquad c = \frac{Ea}{r_0 + r}$$

$$P = c\,T \qquad Ea = 10^{-6} Z\,N t\,n.$$

On the critical point exciting power and electromotive force just balance each other without any margin on either side. In this case we have

$$P = \frac{T\,10^{-6}\,Z\,N t\,n}{r_0 + r}$$

and dividing by Z, we find

$$R = 10^{-6}\frac{T\,N t\,n}{r_0 + r}$$

In order that the dynamo may work without the danger of losing its current entirely, its magnetic resistance should be smaller than this value

$$R < 10^{-6}\frac{T\,N t\,n}{r_0 + r}$$

If R be larger the dynamo will not self excite.

(To be continued.)

PRIVATE INSTALLATIONS OF ELECTRIC LIGHTING.*

BY RALPH H. C. NEVILE.

(Concluded from page 236.)

The arrangement mentioned answered very well, and the lights could be varied from 1 to 100 and the boiler pressure from 30lb. to 60lb., with very slight variation of electromotive force in the mains, provided of course there was sufficient steam to do the work required. It is also quite easy to cause the electromotive force to rise as the load on the engine increases—or in other words as more current passes through the main—by simply giving greater leverage to the piston connected with the steam chest. In fact with this arrangement the electromotive force can be maintained practically constant, or can be made to vary in any desired manner with variations of steam pressure or of load.

The main leads to the house having a resistance of about 0·2 ohm, there is a loss of about 12 volts of electromotive force when 60 amperes of current are passing along them between the terminals of the dynamo and the house, whereas when only one or two amperes are passing the loss is practically *nil*. Hence, if the electromotive force were maintained constant in the dynamo room, it would fall at the house as more lights are turned on. In the case of an engine controlled by an isochronous governor this difficulty is supposed to be met by the compound winding of the dynamo machine. There are, however, several disadvantages in that plan. One is that each dynamo ought to be specially wound for the electromotive force desired to be maintained, and for the external resistance between the lighting centre and the dynamo; and if either the electromotive force of lamps used or the external resistance is varied, the adjustment of the machine is destroyed. This also in a great measure prevents the use of reserve machines for a large installation where several circuits are used, because the reserve machines cannot suit all the circuits equally. Another disadvantage in a compound machine is that, if it be used in conjunction with secondary batteries and the engine be permitted to slow down before the connection between the dynamo and the batteries is broken, the current from these last will flow back through the dynamo, and will reverse the polarity of the magnets if it be a compound machine; and when next started the batteries and dynamo will be wrongly connected, and considerable harm may ensue both to batteries and to dynamo.

The plain shunt-wound machine is free from these objections; but the disadvantage has hitherto been that, as more lights were put on, the electromotive force fell just when it should rise. With an electrical governor this can be obviated, as indicated above, by a suitable arrangement of the piston actuated by the steam from the steam-chest. But a still better plan is probably that adopted by the author, of taking certain points as lighting centres, and keeping the electromotive force between them constant. For this purpose small wires are connected with the mains at the required points, and the current to actuate the governor is taken off there, instead of direct from the terminals of the dynamo. One of the points is just outside the house, where the wires enter; and the other point is in a room. The electromotive force between one cable at the first point, and the other cable at the second point, is maintained constant by the governor.

This arrangement could easily be applied to a large installation for a town, each engine and dynamo having its particular district. The cables would be led direct to the district, and governor wires would be led back from the district to the engine governor. The arrangement of splitting up the required power into several small engines, instead of employing only one or two very large engines, permits of this plan; and also requires very much less reserve of power to provide against a break-down. For example, if the lighting of a town be estimated to require 2,000 indicated horse-power, and this be divided between two engines of 1,000 indicated horse-power each, it will be necessary to have either one or two similar large engines in reserve, according as it is intended to provide against a single or double break-down. If, however, the same power be divided amongst forty engines of 50 indicated horse-power each, it will only be necessary to have a reserve of one or two of these smaller engines for providing against similar contingencies. A simple arrangement of switches would then at once permit of a reserve engine with its regulator being switched on to any particular circuit on which it might be required, owing either to a temporary break-down or to a special extra demand for current.

Another advantage of an electrical governor over any arrangement of isochronous governor, however perfect, is that the electrical regulator takes its regulation from the mains, and not from the engine; consequently if there be any loss, either by slip of belt, or by extra heat in the field-magnet circuit or the armature, causing increased resistance, this will be compensated by the electrical governor at once driving the engine so much faster as to make up for it. On one occasion when experimenting with the governor this was specially noticeable; for when the load got rather heavy, the belt at the time being rather too slack, the engine suddenly increased its speed considerably, but the voltmeter remained at the same point, and the dynamo was found to be running at just about its ordinary speed, the extra speed of the engine being evidently caused by slip of belt.

When the lever arrangement was completed several experiments were made by Mr. Richardson and the author, the results of which were as follow. When the load on the engine was allowed to remain constant, with only one lamp alight, it was found that while the steam pressure was allowed to vary between 31lbs. and 55lbs. the electromotive force remained constant at 90 volts. Afterwards, with the same extent of variation in steam pressure, and with the load also varying from 1 lamp to 91 lamps, the electromotive force varied only 2 volts, namely from 91 volts to 93 volts. The following are the particulars of this second set of trials :—

Steam Pressure. lbs.	No. of Lamps.	Electromotive Force. volts.	Steam Pressure. lbs.	No. of Lamps.	Electromotive Force. volts.
55	1	92	45	61	92
55	11	91	35	50	92
55	21	91	32	41	93
55	31	91	32	31	93
55	41	92	32	80	92
55	51	93	30	71	92
55	61	92½	35	91	92
55	71	92	40	91	93
55	81	92	45	91	93
55	91	92	50	91	92½
50	91	92	50	91	92

The arrangement of the governor has since been modified in order to obtain a neater looking arrangement and also better results. Here there is also the advantage that, if an ordinary centrifugal governor be added to the engine—which

* Paper read before the Institution of Mechanical Engineers, at Lincoln, on the 4th inst.

Digitized by Google

may be done as a measure of safety, in view of a wire breaking or of the main driving belt coming off; and which must be done if the engine be required to do other work, such as sawing or pumping, at times when the dynamo is not running —the throttle-valve will still be compensated by the lever, which would not be the case if the compensating arrangement were attached only to the solenoid.

As regards the variation in upward pressure on the valve spindle, caused by different pressures in the steam chest and boiler, in one diagram which was taken the maximum difference shown is 6lbs., and in a second it is only 3lbs.; and as the solenoid used has a pull of about 25lbs. with an electromotive force at its terminals of 100 volts, while a variation of 1 volt causes a variation of about 4lbs. in the pull, the maximum difference in the electromotive force ought not to exceed 2 volts in the first diagram, or 1 volt in the second. When the cores of the solenoid are in the most favourable position, the difference of pull caused by a small movement of them is very slight; and the movement required to open or close the valve is very small.

When it is desired to vary the electromotive force in the mains, a set of adjustable resistance coils is inserted in the governor circuit; by increasing these resistances, a higher electromotive force is required to drive the normal current through the solenoid, and thus to close the valve. In this way the speed of the engine and the electromotive force in the main wires may be varied to almost any required extent, and from a point however distant from the engine. The author has one set of these coils fixed in the circuit in the dynamo room, and another at a certain point in the house, and by moving either of these the resistance may be increased or diminished, producing a corresponding variation in the electromotive force. This is found a great convenience when exceedingly exact electromotive forces are required for experimental work, which sometimes cannot be carried on in the immediate neighbourhood of the dynamo machine. It may also be arranged practically to dispense with the necessity of any telegraph or signal to the engine room, because a switch and set of coils placed in any convenient position afford the means of varying the light as desired, without any reference to the engine driver, whose work then consists simply in seeing that steam and water are maintained in the boiler, and the bearings kept oiled.

In the case also of an engine doing any other work, where it is desired to vary its speed from a distance, the same governing arrangement may be applied by causing the engine to drive a small dynamo just sufficient to furnish electricity for the electrical regulator. The electromotive force in the mains would then furnish at any desired point an indication of the speed of the engine at any moment; and a switch and set of resistance coils would afford the means of altering the speed to any other desired rate. As the amount of current required for driving the regulator is only small, the coils and switch may be made very small and compact, so that in a theatre, for example, they might be placed in the prompter's box, and the whole system would then be under his immediate control.

The introduction of this governor has in the author's opinion contributed very largely to the duration of the lamps used. From the first start until the end of last year the time of running was 370 hours, and during that time with the old governor five lamps gave out, although they were all new when the installation was started; the average current during that time was 16 amperes. Up to 13th January last, when the new governor was first introduced, the time of running was 477 hours, and thirteen lamps had given out; probably also many of the others had been damaged. Nevertheless, during the 487 hours' running in February, March, and April, although the average current used had increased owing to the extension of the installation, only ten lamps gave out; and during the 84 hours' running in June only two lamps gave out. Hence it appears that a good governor will soon save its own cost by an increased life for the lamps.

Thus far reference has been made solely to incandescent lighting in parallel; but for arc lighting in series the advantages of a governor of this description are very conspicuous. Probably the best system of driving arc lights in series is by the use of a series-wound dynamo, especially if a compound engine be used for the purpose, because then the steam-chest pressure remains approximately constant, and the speed varies approximately in accordance with the number of lamps in use. Here an isochronous governor is obviously altogether useless. An electrical governor, however, meets the case perfectly. Here the whole of the current to the lamps is led round the solenoids, which are of course made with fewer coils of a thicker wire. When any lamps are short-circuited, a momentary increase of current takes places, which instantly raises the cores in the solenoids, and shuts off the steam, reducing the engine to the required speed for the number of lamps left on. The following are particulars of some experiments made in 1883 by Prof. Thompson, of University College, Bristol, with a machine of this description:—

Lamps alight.	Amperes of current.
0	10·6 — 11·2
5	10·0 — 10·5
11	10·0 — 10·3
16	9·9 — 10·2
17	10·1 — 10·2

Before the introduction of this regulator very considerable trouble was experienced in keeping the speed at the proper point, and many of the fine-wire coils of the Brush lamps were destroyed by an excess of current going through the circuit. Now, however, the current has been effectually controlled, and any number of lamps can be switched in or out without any attention being paid to the engine. An arrangement has also been introduced by which, should the main lead become accidentally severed, the engine is at once stopped. A small electro-magnet is introduced, round which the current is led with a few turns of wire. The magnet supports a weight of several pounds, which is attached to a lever so pivoted that, when on the cessation of the current the weight falls, the lever presses with great force on the the top of the valve-spindle, and shuts off the steam altogether.

A CORRECTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Allow me to point out an error in your notice of Mr. Richardson's governor on page 227 with reference to compound engines. It is not claimed for this governor that with it a compound engine will develop 5 horse-power with the same economy as 50 horse-power *at the same number of revolutions per minute*, but that when using a series machine for arc lighting it will reduce the number of revolutions per minute very nearly in proportion to the horse-power developed, and *thereby* produce an equally economical result whether developing 5 or 50 horse-power. For example, in the case of the installation at Messrs. Robey's works referred to at the end of my paper on "Private Electric Lighting," the machine used is a Brush machine. To keep up the proper current the engine driving this machine makes 150 revolutions per minute when all seventeen lamps are alight, but when they are reduced the speed of the engine falls in almost the same ratio, until when they are all short circuited the engine makes only fourteen revolutions, just causing enough E.M.F. to drive the current through the field magnet coils and the electrical regulator. It must be evident that this arrangement causes very much greater economy than continuing to drive the engine at full speed, with perhaps only one-tenth of its full load on, and diminishing the power of the dynamo by any such device as shifting the position of the brushes or shunting a portion of the current past the field magnet coils. Moreover, the electrical regulator performs this office, instantaneously reducing the speed as soon as the moving parts can lose their momentum after any lamp or lamps are short circuited, and automatically, thereby requiring no attention or signal to the engine driver when it is intended to extinguish any lamp or group of lamps.

—Yours, &c., R. H. C. NEVILE.

Wellingore Hall, Grantham, August 11, 1885.

P.S.—The economy is evident even when using an ordinary high pressure engine, but is most noticeable with a compound engine, to which Mr. Richardson's paper was especially referring.

THE INTERNATIONAL TELEGRAPH CONFERENCE.

We have had recently to animadvert on the danger to cable property resulting from the undue political influence of a particular State; we have now to protest against interference which may prove even more dangerous, due to the combination of a number of States, hardly any of whom possess cables of their own, and none to be compared with the possessions of private companies. The officious interference of France, and the servility with which her leading has been followed in the matter of "protecting" submarine cables were bad enough; but the manner in which the international confederacy, now sitting at Berlin, proposes to deal with their revenues is something even worse. Just as at Paris, the great cable proprietors have no voice in the decisions to be arrived at, or if they have a voice at Berlin they have no vote. This, however, is perhaps not to be regretted, for the representatives of the fourteen submarine companies who are unofficially present at the Conference might be easily outvoted; and for the purposes of an effectual protest a non-voting position is stronger than one that has been beaten on a fair division.

With the Conference's proposals relating to a uniform international inland tariff we need not concern ourselves very much. The fundamental charge (*grundtaxe*) of fifty centimes, and twenty centimes per word, are far too low for States of great territorial magnitude, and we are not surprised that Russia, for one, objects to this proposition. The transit tax—that is the claim which one State through which a message passes will have upon the forwarding and receiving States—is extremely small, though an attempt is here made to graduate it according to the size of the transmitting intermediary. Great Britain, though counted among the larger countries, will claim only four centimes—less than a halfpenny—per word for messages travelling, say, between the continents of Europe and America, and passing over her land lines; a claim which will not assist her in recovering the probable loss on sixpenny telegrams locally. But the respective countries concerned may be safely left to fight their own battles with the weapons they are privileged to use. The Cable Companies have their independent position to defend, and this with no instrument except that which free speech in a just cause affords them. They have not had much for which to thank these Telegraph Conferences in times past; but hitherto they have submitted with a good grace. On the present occasion, if the propositions which fell through at the last gathering, and which are revived in the present, should be carried, cable owners will have to reconsider their position with regard to the Union, for there will be then, it seems to us, no choice between disloyalty on the one hand or ruin on the other.

Dr. von Stephan's proposition has only to be stated to make this clear to most of our readers. He recognises that the uniform international rates above described will require to be increased where a message traverses a submarine cable; but the extent to which he thinks it right to modify the uniformity is at most by the magnificent sum of ten centimes per word; for distances under 300 nautical miles by only five centimes per word. Now, a vast number of messages travelling over submarine cables are transit messages—that is to say, messages not originating at the offices of the companies; consequently, for all this traffic the cable companies would be paid often at only a halfpenny per word, never more than at a penny. Even if such rates were possible of acceptance for this portion of the business, it is obvious that the higher rates on messages originating with the companies could not long be maintained; and it is equally obvious that the addition of fivepence *grundtaxe* would not enable them to do the business and live. Of the present European Submarine Cable rates the lowest is sixpence per word, ranging from this to one shilling and eightpence per word. The cables most affected are not in a flourishing condition even with these rates; and if Germany is to have her way in this matter they may as well close their offices at once. All the other companies would be more or less injuriously affected, some to the tune of fifty or sixty thousand pounds per annum. Not one of them would at this moment voluntarily reduce its rates in any material degree, nor to a uniform rate of any kind; and certainly not to one as low as the present lowest rate, which is a vast deal higher than that which Dr. von Stephan proposes to confer upon them.

Of course there is the usual talk about the increase of traffic consequent upon reduced charges. This may be or may not be true of inland telegraph traffic; but there is no probability of ever creating a popular tariff for submarine cabling, and assuredly no present possibility of forcing it. Popular tariffs are for local traffic, or for countries closely adjoining. The principles which hold good for them cannot be applied to countries wide apart, especially if separated by the watery barrier which submarine cables bridge over but do not annihilate. We are warned by the inspired Berlin correspondents of the London newspapers against a short-sighted and insular policy. Dr. Stephan is held up to us as a sort of German Rowland Hill, and in one quarter we are invited to believe that the main object of his proposal is to "add a new bond to international relations in the interest of peace." That may be a consequence, but it can hardly be the object; or, at all events, if such it be, it is pursued with flagrant disregard for the welfare

Digitized by Google

or peace of the community to whom more than to any other we owe the bonds of modern international relationship. Legislating for themselves the States represented at Berlin have a right to sacrifice their pecuniary interests for the sake of peace or anything else they may fancy; but they cannot expect private capitalists to do more than sympathise with these lofty motives. If more is demanded in the interests of European amity, then the European States ought to purchase their right to legislate, and stand by the loss. It is impossible to suppose that the Conference will be able to convince itself of the financial advantages of a five or ten centimes word rate for cablegrams; and this being so there is not the smallest justification for asking cable proprietors to perform the happy despatch in order that the reputation of Dr. Stephan or the interests of the European commonwealth may flourish and be glad. In the course of their career the Cable Companies of Great Britain have afforded many and conspicuous proofs of their patriotism, public spirit, and unselfishness. But as they do not enjoy the advantages of governmental administrations, who can fall back upon general taxation to make good their deficits, their generosity is necessarily limited by their unaided resources; and these at present are not over ample.

ON THE USE OF DANIELL'S CELL AS A STANDARD OF ELECTROMOTIVE FORCE.*

BY J. A. FLEMING, M.A., D.SC. (LOND.).

(*Concluded from page 233.*)

A large U-tube, about ¾-inch diameter and 8 inches long in the limb, has four side tubes (Fig. 2). The two top ones,

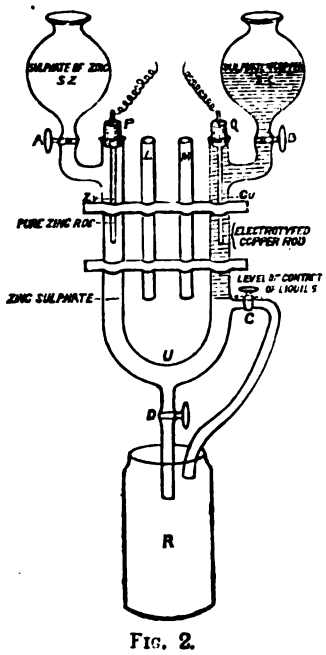

FIG. 2.

A and B, lead to two reservoirs, Z and C, and the bottom ones, C and D, are drainage tubes. These side tubes are closed by glass taps. The whole is mounted on a vertical board, with a pair of test-tubes between the limbs. Suppose, now, a Daniell's cell is to be formed with solutions of zinc sulphate and copper sulphate, and that the zinc sulphate solution is the denser. The left-hand reservoir S Z is filled with the zinc solution, and the right-hand reservoir S C with the copper solution. The electrodes are zinc and copper rods, Zn and Cu, passed through vulcanised rubber corks, P and Q, fitting air-tight into the ends of the U-tube.

The operation of filling is as follows:—Open the tap A and fill the whole U-tube with the denser zinc sulphate solution; then insert the zinc rod and fit it tightly by the rubber cork P. Now, on opening the tap C the level of the liquid will begin to fall in the right-hand limb but be retained in the closed one. As the level commences to sink in the right-hand limb, by opening the tap B copper sulphate solution can be allowed to flow in gently to replace it; and this operation can be so conducted that the level of demarcation of the two liquids remains quite sharp, and gradually sinks to the level of the tap C. When this is the case, all taps are closed and the copper rod inserted in the right-hand limb.

Now it is impossible to stop diffusion from gradually mixing the liquids at the surface of contact; but whenever the surface of contact ceases to be sharply defined, the mixed liquid at the level of the tap C can be drawn off, and fresh solutions supplied from the reservoirs above.

In this way it is possible to maintain the solution pure and unmixed round the two electrodes with very little trouble; and the electrodes, when not in use, can be kept in the idle cells or test tubes L and M, each in its own solution. In making experiments concerning temperature, the whole U-tube can be immersed in a vessel of water or ice up to nearly the top of the reservoirs, and the temperature in the solutions taken by means of a thermometer passing through the rubber cork. Each of the electrodes can be removed for examination or change without in the least disturbing the surface of contact of the solutions. If experiments are being made in which the sulphate of copper solution is the denser, the position of the solutions is interchanged. The bottle R serves to collect the waste solutions.

The electrodes are made of rods of the purest zinc and copper, about 4 inches long and ¼-inch diameter. The zinc found most suitable is made from zinc twice distilled and cast into rods; the copper prepared by electro-depositing on a very fine copper wire, until a cylinder of the required thickness is obtained.

With these appliances to hand, all the facts recorded by previous experimenters have been carefully repeated and confirmed, and the influence of each variable upon the electromotive force examined. The results are collected as follows:—For the sake of brevity, a Daniell's cell in which zinc, sulphate of zinc, sulphate of copper, and copper are the elements will be called a normal Daniell; and the statements here below refer to the variations in the difference of potential between the poles of the normal Daniell, when sending either no current or only an infinitesimal one, caused by variations in the physical state of the four elements. In each set of experiments the greatest care was taken to keep all the elements constant, except the one which was purposely being varied in order to detect the influence of it on the whole electromotive force.

1. *The Effect of Variation in the Copper Surface and Condition.*

In these experiments the copper- and zinc-sulphate solutions were sometimes of the same specific gravity, sometimes different; and in some cases the zinc electrode was a rod of the purest cast zinc amalgamated with pure mercury, sometimes a rod of commercial zinc wire cleaned but not amalgamated. Some scores of observations were made with identical zinc plate and solutions, but various kinds of copper plates*; and all observations have confirmed the conclusions of Dr. Alder Wright that the most uniform results are obtained from copper plates freshly electrotyped over with a new clean pinkish surface of virgin copper, when the plate is taken

* From the *Phil. Mag.* for August (communicated by the Physical Society. Read June 27, 1885).

* All the following values are given in real volts, taking Lord Rayleigh's value for the mean B.A. unit of resistance as equal to ·9867 earth-quadrant per second.

The determinations have been made against a Clark cell, kindly compared by Lord Rayleigh with his No. 1 cell, whose value is given in his paper in the *Phil. Trans*, part ii. (1884) as 1·435 true volt at 150° C. My standard, called hereafter F_{20}, is greater than this by 3 parts in 4,940, or is 1·436 volt at 15° C.; and experiments have shown that its variation-coefficient is nearly that found by Lord Rayleigh, viz., ·082 per cent. per degree diminution of E.M.F.

Accordingly, the value of this standard Clark cell F_{20} has been taken as equal to

$$1{\cdot}436(1 - {\cdot}00082\,t^{\circ}) \text{ volt at } t^{\circ}\text{ C.},$$

and all values given in the text are in terms of this.

Digitized by Google

straight out of the electrotyping bath and put into the cell without any delay or touching except a slight rinse with distilled water. The result of comparing a freshly electrotyped rod with a rod scraped and glass-papered, was to show that the scraped copper rod gave a higher electromotive force by about four parts in 629, or six parts in 1,000. When both rods were freshly electrotyped in the same bath, and inserted in the same cell, there was absolutely no difference between them. Cells were compared with solutions of equal density 1·2 at 15° C. and amalgamated pure cast zinc, but different copper rods, as follows:—

	E.M.F.
Electrotyped copper rod	1·105 volt.
Scraped copper rod	1·111 „

The exact amount of difference varied slightly in other experiments; but with equally clean surfaces, the electrotyped fresh surface has a lower electromotive force than the scraped. The effect of amalgamating the copper rod is, like electrotyping, to lower its value below that of the clean scraped, but it is not so uniform. The following are values obtained from equal copper rods in the same cell, one having an electro-plated surface and the other being slightly amalgamated with pure mercury:—

Freshly Electro-deposited Copper Rod	Freshly Amalgamated Copper Rod.
1·103	1·104
1·106	1·104
1·105	1·104
1·106	1·105

The mean of the values of the electro-deposited copper exceeds by about 1 in 1,000 the mean of the amalgamated copper; but if the amalgamation is done thickly it causes more serious deviations, and though more convenient is not quite so reliable as electroplating the rod with fresh copper, but is preferable to employing simply a scraped or glass-papered surface of rolled copper. A large series of determinations were next made on the effect of oxidation of the copper surface. If a copper rod, newly electroplated, is left in the copper-sulphate solution, it gradually gets oxidised and covered with brown patches of oxide, and if amalgamated, the mercury sinks in and the surface gets brown and patchy. When this is the case the electromotive force rises, and by uncertain amounts, depending on the degree of oxidation. It is very remarkable how small a trace of brownish oxidation on the surface raises the electromotive force several parts in 1,000 amounting in some cases to nearly one per cent. The following is one set out of many experiments on this point:—

Two solutions of zinc and copper sulphate were prepared of the pure crystals. The specific gravity of the zinc sulphate was 1·4, and that of the copper sulphate was 1·1. A rod of pure unamalgamated zinc and one of electrotyped copper was also taken. Keeping all other conditions constant, the rod of copper was first cleanly and carefully electrotyped over with a new fresh surface of copper, and exhibited no trace of oxidation; and the E.M.F. of this cell was then taken against a carefully tested standard Clark cell of known value; and the rod was then suffered to oxidise on the surface by successive exposure to the air, the E.M.F. of the cell being taken at each stage.

	E.M.F. of Cell.
Copper, perfectly pure, unoxidised	1·072 volt.
„ slightly oxidised, brown spots	1·076 „
„ more oxidised	1·082 „
„ covered with dark brown oxide film	1·089 „
„ cleaned, replated with fresh pinkish electro surface	1·072 „

Many other experiments of this sort showed the same thing. A Raoult cell was formed by taking two beakers, one containing zinc sulphate of specific gravity 1·2, and the other copper sulphate of the same specific gravity, and using amalgamated cast zinc and electro-deposited copper rods. The beakers were connected, when required, by a piece of clean cotton-wick dipped in water, and connecting both solutions by dipping into each. The copper pole was first freshly electroplated, and the following values obtained for the E.M.F. of the cell as it gradually oxidized:—

	E.M.F. of cell.
Freshly electro-deposited surface of copper	1·105 volt.
Slightly oxidised, faint brown tinge	1·106 „
More oxidised	1·107 „
Still more oxidised	1·109 „
Re-electroplated surface	1·105 „

Hence these and many similar experiments all teach that oxidisation, even the slightest trace, of the copper raises the E.M.F.; and that, in order to get the real value proper to the combination, the copper must be electrotyped over with a thin pure film of copper, and exhibit no trace of brown spots of oxide, and be used at once.

2. *The Effect of Variation in the Zinc Surface and Condition.*

Numerous experiments have been made to investigate whether there is any certain difference between zinc amalgamated or unamalgamated or cast or rolled. There is very little, if any, certain difference between perfectly pure cast zinc unamalgamated and the same amalgamated with pure mercury. There are greater differences if the zinc is not pure, and variations are introduced if impure mercury is used for amalgamation, all of them uncertain in amount.

The effect of oxidation of the zinc is to lower the electromotive force. If the bright surface of the zinc becomes tarnished, it always shows a slightly lower E.M.F. The smallest deposit of copper upon the zinc, due to diffusion of the copper salt into the zinc, is indicated by a marked depression, amounting to 2 or 3 per cent. On the whole, the only consistent values are obtained from chemically pure zinc with a bright fresh untarnished surface, whether amalgamated or not; and the best results are given with pure zinc amalgamated with pure mercury. In Dr. Alder Wright's memoir the above conclusions are enforced by tabulated results of most extensive experiments.

On the question of amalgamation of the zinc we may quote a note on the subject by M. G. Lippmann in the *Journal de Physique*. There is an opinion expressed by some authors that amalgamated zinc has a higher E.M.F. than unamalgamated, even if pure. If a plate of each of the two substances be immersed in sulphate-of-zinc solution, a couple is formed in which amalgamated zinc forms the negative pole, inasmuch as it is the more readily acted upon by oxygen. Such, at least, is the result obtained if ordinary commercial zinc is used and ordinary sulphate-of-zinc solution. In a recent work, M. W. Robb shows that if care be taken to use electro-deposited zinc, and also zinc sulphate solutions deprived of free acid, the element zinc, zinc sulphate, and amalgamated zinc will not manifest any appreciable E.M.F. The superiority of amalgamated zinc over ordinary zinc is easily explained; but when pure zinc is used, deprived of any oxide on the surface by slight rinsing in dilute sulphuric acid before placing it in the sulphate of zinc, there is little or no certain difference, to the extent of one part in 1,000 in the case of the normal Daniell, between the pure zinc amalgamated or unamalgamated.

3. *The Influence of Density of the Solutions on the Electromotive Force.*

The chief reason for the differences in the values assigned by various observers to the E.M.F. of the normal Daniell is due to the great influence that the specific gravity of the two exciting solutions exerts on the resultant E.M.F. of the combination; and the general law of the effect is this. If a Daniell cell be formed of amalgamated pure zinc, freshly electrotyped copper, and solutions of pure zinc sulphate and copper sulphate of equal specific gravity, then, taking this cell as a standard of reference, increasing the density of the zinc sulphate lowers the electromotive force, and increasing the density of the copper sulphate raises the electromotive force, within, at any rate, the limits of density from 1·01 as an inferior, up to saturation as a superior limit. Zinc sulphate saturated at 15° C. has a density of a little above 1·4, and copper sulphate similarly saturated 1·2; and Dr. Alder Wright shows by experiments that the increment and decrement of E.M.F. for identical increment or decrement of density of

Digitized by Google

both solutions are so nearly equal that for equally dense solutions, within limits, the E.M.F. is independent of the absolute density of both. This fact has been confirmed by many other observers. Amongst other careful experiments may be noticed those of Carhart*, whose experiments were specially directed towards ascertaining the influence which variation in the density of the zinc sulphate exerts on the resultant E.M.F.

In using a Daniell cell as a laboratory standard it is necessary, therefore, to prepare and standardise the solutions of zinc and copper sulphates with the same care as if they were to be used for volumetric analysis. It is a good plan to prepare two large stock bottles of solutions, and having carefully determined the density to adjust them to known specific gravity by the aid of the specific gravity bottle or hydrometer. For general use two standard solutions of each salt are specially useful. First, a solution of sulphate of copper very nearly saturated at 15° C. and having a specific gravity of 1·200, and a solution of sulphate of zinc of equal density. Secondly, a solution of sulphate of copper of density 1·100 at 15°, and a solution of sulphate of zinc of 1·4. These last values are chosen because they were employed by Sir W. Thomson in his standard gravity cell; and they can be used in either his form of gravity cell, or in the U-tube form above, or in Raoult's form of separate vessels and siphon.†

A very large number of comparisons have been made of the E.M.F. of cells set up with these solutions and the E.M.F. of Clark's cells, whose value has been compared directly with cells standardised in absolute measure.

If a Daniell cell is carefully made up, either in the Raoult form or U-tube form, of solutions of pure zinc and copper sulphate not sensibly interdiffused at the level of contact, and with pure amalgamated cast zinc and freshly electrotyped copper plate, which is evenly plated with a new uniform pinkish deposit of electro-copper free from all brown spots of oxide, the E.M.F. of this cell, taken at once, is very close to 1·102 true volt, and the ratio of the E.M.F. of this cell to a corrected Clark cell at 15° C. is very nearly ·768 to unity;‡ the Clark cell being taken as 1·435 at 15° C.

If, instead of taking the equidense solutions, we take zinc sulphate of specific gravity 1·400 and copper sulphate of 1·100 at 15° C., and the same plates, the E.M.F. of the cell lies close to 1·072 volt, and the ratio of the E.M.F. to that of the corrected Clark is ·747.

If, however, instead of taking the electromotive force at once after the freshly electroplated copper pole is introduced into the cell, the cell is allowed to stand an hour or so, both the above values will be increased by about ·003 volt, provided always that no interdiffusion of solutions has taken place, and that the zinc retains a perfectly bright untarnished surface.

4. *Influence of Temperature on the Electromotive Force of the Normal Daniell Cell.*

The researches of experimenters who have studied the Clark cell have established the fact that its E.M.F. diminishes with rise of temperature. The exact value of the coefficient of variation seems to depend on the mode in which the cell is made up; and very careful examination has been made of the Daniell cell as above described, to see if its real E.M.F. is affected by temperature. Some writers have asserted that it is; but it is obvious that the variation of internal resistance must be eliminated entirely by the use of a null method of observation of the E.M.F. The condenser method is not a sufficiently accurate one to apply, and the potentiometer method is the most trustworthy.

Two U-tube cells were prepared with 1·4 sp. gr. zinc sulphate and 1·1 sp. gr. copper sulphate; and these cells were respectively immersed, the one in a water bath at 20° C, and the other in melting ice at 0°. A pair of zinc and copper poles was likewise prepared; and when the solutions in the U-tubes had acquired the temperature of the baths, the E.M.F. of each cell was taken with the pair of zinc and copper plates, first in one and then in the other, with the following results:—

Plates in the warm cell at 20° C. E.M.F. of cell.	Plates in the cold cell at 0° C. E.M.F. of cell.
1·081	1·082
1·079	1·082
1·079	1·082
1·078	1·083

The experiments showed a very small but decided fall of E.M.F. as the cell is warmed, and at the rate of about three parts in 1,000 for 20° C. This is only about $\frac{1}{50}$ of the variation of a Clark cell for the same range; and, practically, we may say that the E.M.F. of a Daniell cell is independent of temperature for such range as occurs in the natural temperature of the air in our climate.* This quality of the normal Daniell is very important, and goes very far towards helping it to sustain its position as a standard cell against its rival the Clark cell.

The various coefficients of temperature-change which have been found for Clark cells indicate that it is unsafe to rely upon any cell taken at random, whose history is unknown, having a coefficient of variation accurately the same as that of the cells whose coefficients have been actually determined.

It would be a great advantage if instrument makers would construct these cells in the form suggested by Lord Rayleigh—enclosed in a test-tube and having gutta percha covered leading-in wires passing through a rubber stopper. The coefficients of variation would then be easily obtained for any cell, just as those of standard resistance-coils are ascertained and marked on each cell with the range of temperature over which it is applicable.

As a check on the foregoing experiments on the Daniell, the coefficient of variation of the standard Clark cell used was obtained. Two cells were taken, exactly equal at 18° C., and one of them was immersed for 48 hours in melting ice. The difference on the potentiometer wire was then obtained between this cold cell and its fellow kept in water at 18° C. The potentiometer-readings were as follow:—

	i.	ii.	iii.
B, cell at 0° C.....	961 ...	971 ...	974·4
A, cell at 18° C.	947 ...	957 ...	960
	14	14	14·4

From the experiment 1 the reading for the warm cell would have been $947 + \frac{14}{6} = 949\frac{1}{3}$ at 15°. And hence the coefficient of variation is $\frac{14}{18}$ in $949\frac{1}{3}$, or ·0819 per cent. in the neighbourhood of 15° C. Lord Rayleigh gives ·082 as the value for his cells. It is obvious that Clark's cells cannot be used for standardising galvanometers without a careful determination of their coefficients of variation.

The normal Daniell cell has a certain advantage in that when null methods for determining electromotive force are employed, its value is independent of temperature throughout a considerable range.

By the employment of the above two instruments—a potentiometer as described and a standard normal Daniell carefully constructed with all the precautions named—it is very easy to make very accurate measurements of strengths of currents of large magnitude. If a resistance is formed of such character

* A paper read before the American Association for the Advancement of Science, Sept. 5, 1884. *See Telegraphic Journal and Electrical Review*, Vol. XV., p. 250.

† If 28·25 parts by weight of pure crytallised sulphate of copper ($CuSO_4$, $5OH_2$) are dissolved in 71·75 parts by weight of distilled water, the resulting solution will have very nearly a specific gravity of 1·200 at 18° C.; and if 16·5 parts of the crystals are dissolved in 83·5 parts of water, the solution will have a density of 1·100 at 15° C.

For the zinc-sulphate solutions take 55·5 parts by weight of crystallised zinc sulphate ($ZnSO_4$, $7OH_2$) and dissolve in 44·5 parts of distilled water. The resulting solution will have at 20°·5 C. a specific gravity of 1·400.

If 32 parts by weight of the crystals are dissolved in 68 of water at the same temperature, the solution will have a density of 1·200. These are useful densities.

‡ Lord Rayleigh assigns a value very close to ·770 for this ratio, and Dr. Alder Wright ·765. The figure in the text is derived from about 50 experiments of my own.

* The same result has been obtained by Mr. Preece in his experiments on the effects of temperature on the electromotive force and resistance of batteries, see *Electrician*, March 3, 1883, Vol. X., page 367. He gives a table, showing the E.M.F. at various temperatures, obtained by the condenser method, and shows that there is no perceptible change in E.M.F. of a normal Daniell between 0° and 17°, and a slight fall subsequently of about nine parts in 1,000 between 17° and 28°, but a rise, however, after reaching 63°.

Digitized by Google

that the current to be measured can be passed through it without much affecting its temperature and the potential measured at the extremities of this resistance by means of a comparison on the potentiometer between it and that of the Daniell, this gives at once the current.

In order to construct a resistance whose value at the instant of passing the current can be accurately measured, the following device is adopted:—On a board are mounted a series of copper blocks, *a*, *a*, *b*, *b*, like the connection pieces on a resistance-box (Fig. 3). These can be connected by plugs *p*, *p*. At opposite sides and ends are main terminals as M′; and the blocks *a*, *b* are connected by brass or German silver wires wound in a spiral; similar coils of equal resistance

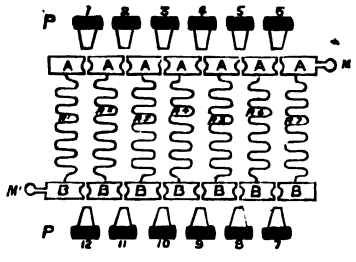

FIG. 3.

connect each pair of opposite blocks. The number of coils must be an odd number.

If the plugs 1, 11, 3, 9, 5, 7 are put in, it is obvious all the coils $R_1, R_2 \ldots R_7$ are a series, and their resistance can be measured; call it *r*. If, then, the other pegs are inserted, the coils are now in multiple arc or parallel, and if there are *n* coils the resistance is $\frac{r}{n^2}$. By this arrangement the resistance in parallel can be inferred from the resistance in series; and although each coil has a very small resistance, yet by using a large number, not only is a very easily measureable resistance obtained when the coils are in series, but a resistance of large current-carrying capacity when they are put in parallel.

The mode of using it is as follows:—The pegs are all put in, and the current to be measured is sent through the coils in parallel. By means of the potentiometer and standard cell the difference of potential is found between the terminals M and M′ when the current is passing. The alternate pegs are then removed, the current stopped, and the resistance taken of the coils in series, and the time noted which has elapsed between the measurement of potential and of the resistance. A few observations are taken of the resistance at intervals of time, by which to construct a curve of cooling; and by projecting back the curve, it is easy to ascertain very nearly the resistance at the time when the potential was measured. If small currents only are employed, it is not necessary to change the resistance; the current can be sent through it in series, and its resistance also measured in series. The writer has had constructed a large resistance of this kind at the Victoria Electric Lighting Station, for the measurement of dynamo currents up to 500 amperes. In this case the resistance consists of 36 wires of brass, No. 14 B.W.G., arranged in parallel and of equal resistance. One of the wires can be disconnected and arranged instantly on a bridge to measure its resistance; and in this way, after measuring the potential at the ends of the 36 wires in parallel, with the current passing through them, one wire is disconnected, and its resistance taken immediately, from which observations it is possible to approximate very accurately to the resistance of the whole wires in parallel. In order to afford data for constructing such resistances, experiments were made of passing various currents through coiled spirals of naked wires of different sizes and materials.

A large number of wires were prepared of copper, brass, iron, German silver, each 25ft. long, and of six sizes respectively, Nos. 10, 12, 14, 16, 18, 20, B.W.G., the diameters being given below. These wires were coiled into spirals round wooden rods about 1in. diameter, and the turns of the wire well separated, so that each coil or spiral was about 18in. long. Measured steady currents were sent through these for some hours, and so adjusted that after the temperature had become steady the wires were all at a temperature just about bearable by the hand, that is near 60° C. The currents respectively carried were as follows:—

Size of wire	No. 10 B.W.G. ·134in. diam.	12 ·109	14 ·083	16 ·065	18 ·049	20 ·035
Currents carried in amperes.						
German Silver	18·75	13·5	8·25	6	4·12	3
Brass	30	18·75	15	9·75	7·5	5·25
Iron	18	11·25	10·5	8·25	5·25	3·75
Copper.....	49·5	38	26·25	20·25	15	9

These currents passed through the above-described naked spirals bring the respective wires to about a temperature of 60° C., when equilibrium is established; and for the purposes of measuring currents not more than one-third of the above currents should be used with wires of the size appended. Thus for 300 amperes, about 50 No. 10 B.W.G. wires will carry it without much sensible elevation of temperature; and by arranging 50 wires so that their resistance can be quickly measured in series, a resistance can be made suitable for measuring the potential at the ends of a known resistance.

By the use of this method it is easy to standardise any current or potential galvanometer at any part of the scale, and obtain the absolute or corrected value of the deflections; and these methods have been employed with success for some time in standardising the working galvanometers used in the lamp factory of the Edison and Swan United Electric Light Company.

In conclusion may be given other results, collected from various authors, respecting the electromotive force of the Daniell cell.

Wiedemann (*Galvanismus*, vol. i. cap. iv., *Bestimmung der Electromotorischen Kraft*, p. 341) gives a description of Raoult's cell (see Raoult, *Ann. de Chim. et Phys.* [4] t. ii. p. 345, 1864), and states that Raoult finds that copper foil has higher electromotive force than electro-deposited copper by about $\frac{1}{200}$; and attributes it to the oxides of copper contained in it. He also confirms the invariability of E.M.F. with temperature at least between 10° and 50°; and states that with pure amalgamated zinc and electro-deposited copper, solution of saturated sulphate of copper and solution of sulphate of zinc, containing one part of crystals to one part of water = 1·35 sp. gr. at 20°, the electromotive force is 1·124 electromagnetic units. This, corrected by the Cambridge value of the B.A. unit, is 1·109 volt.

Sir W. Thomson (p. 245 of "Papers on Electricity and Magnetism") finds the electrostatic measurements of a Daniell's cell to be ·00374. The nature of the solutions and electrodes are not given. Taking the value of *v.* as 3×10^{10}, we have the E.M.F. as 1·12 B.A. volt, which, reduced to true volts, gives 1·105 volt.

Lord Rayleigh gives the ratio of a Daniell set up with amalgamated pure zinc, electro-deposited copper, and solutions of sulphate of zinc and copper, each of sp. gr. 1·1. Five observations of the ratio of this cell to that of a known Latimer-Clark cell at 16° C., taken as unity, gave ·7702, ·7710, ·7705, ·7698, ·7702, mean ·7703; and since the Clark is 1·435 volt, this gives the Daniell as 1·105 volt.

Latimer Clark (*Journal* Society Telegraph-Engineers, January, 1873) gives it as 1·11, which, reduced to true volts, is 1·095; and Dr. Alder Wright (*Proceedings* Physical Society, London, Vol. VI., p. 292) gives the value of a normal Daniell set up with solutions of the same molecular strength, preferably of strength *m* M SO_4 100 OH_2, when *m* is near 2—that is with copper sulphate nearly saturated, and zinc sulphate of equivalent molecular strength, and pure amalgamated zinc plates and electro-deposited copper—as 1·114 B.A. unit, or 1·099 true volt.

None of these are very far from the value assigned to the standard cell described above, viz., 1·102 volt. with equidense solutions and metals as described.

LITERATURE.

Under the Rays of the Aurora-Borealis in the Land of the Lapps and Kvœns. By SOPHUS TROMHOLT. Edited by Carl Siewers. Two vols. [Sampson Low, Marston, Searle, and Rivington. 1885.]

One of the first of Nature's wonders to fascinate the eye of the beholder will ever be the aurora borealis. The only grand illustration of the phenomena that it has been the present writer's lot to witness was in years gone by, when one Sunday evening the villagers congregated together outside the school room—then used as a temporary church—and foretold in awe-struck tone how the sky indicated the sanguinary fighting in the Crimea. Days or weeks afterwards it was known that one of the sternest battles ever fought was in progress at the same time as the grand auroral display was seen in central England. From then till now any information concerning auroras has always been interesting and attractive. Doubtless the desire to obtain knowledge on this fascinating subject is widespread. The volumes before us are valuable from a twofold point of view. They not only deal with a purely scientific question, but describe the author's sojourn among a little known and a somewhat despised people. "It is (preface) not a scientific treatise, nor a novel, but merely a modest narrative of a year's sojourn in the distant regions of *Ultima Thule;* not related with pedantic prolixity or tedious erudition, but sketched, as far as in his power, with light and rapid strokes." Let us at once say that the major part of the work consists of an exceptionally readable narrative of a journey to the extreme north of Europe, and a year's residence among the Lapps, in order to investigate the auroral phenomena which are to be seen in all their perfection only in those regions. Notwithstanding our desire to learn about the aurora, we must confess that the author interests us just as much in his narrative as in his purely scientific research. The description is admirable, and in imagination we have experienced the first drive with a reindeer, and the hospitality of the Lapps—the actualities of either we would rather be excused. The work is filled with pleasant anecdotes, one of which we may venture to give. The author desired to see one of the traditional idols. He tried once and failed, because of the incapacity of his guide. The second time he was successful; coming, however, to the conclusion that the stone was merely a common boulder.

"That the stone nevertheless was an idol in heathen times there cannot be the least doubt, because that is proved by tradition, the locality so greatly favoured by Nature, and by the fact that not many years ago there were still large quantities of bones of sacrificed reindeer lying around it.

"As there was no particular reason for having the stone removed, I decided to take a photograph of it. Lars pointed out to me that the stone originally stood erect a few paces from where it now lay, and as I desired to take it in its original position, I requested him to assist me in moving it. After a good deal of toil, as it was very heavy, we succeeded with our three arms in getting it into a pulk and dragging it to the top of a little eminence, where it had no doubt stood in the Pagan days when the Lapps worshipped it as a god or a symbol of divinity.

"At that moment occurred what certainly may be regarded as a remarkable coincidence. Whilst engaged in moving the old god I paid no attention to the weather, which up to then was clear and bright. In the meanwhile it had, however, become rapidly overcast, and when I now looked up, heavy, threatening clouds came drifting over the sky, followed by sudden gusts of wind. I nevertheless unpacked my apparatus, but the wind increased every second, and in less than three minutes we were in the midst of a violent snow-storm. I had just screwed the camera on, and turned round to say something to Lars, when a violent blast overturned the apparatus—and the camera was smashed to atoms against a projecting stone. The whole was the work of a moment, and the incident is the cause of my not having an illustration of the Sieite to place before the reader.

"I looked at Lars Gaino. He shook his head gravely, and said that there existed a belief amongst his people that ill would befall him who meddled with the old gods. There was not one of his race, he said, who did not believe that this was the reason why I was nearly killed when I last visited the mountain, and he was quite sure that the old god had raised the storm and destroyed the wicked apparatus. He desired at once to leave the mountain.

"It seemed, indeed, as if there was something more in what Lars said, for as soon as we were again on our way down the clouds cleared, the sun shone brightly, and there was no more wind than in a cupboard. This fully confirmed Lars and his tribe in their belief.

"The old god was, I regret to say, not satisfied with the destruction he had already wrought, but attempted to drown me as we drove home on the river. It was dark and late, and I had let the rein of my animal be tied to Lars' pulk and gone to sleep. Suddenly I awoke through a violent shock, and, opening my eyes, saw water on both sides of the pulk. It had got into a hole in the ice, over which lay a thin layer of snow, and by the sudden stoppage the rein broke. Fortunately the pulk was a little longer than the hole, so I escaped with a momentary frightening and a cold bath.

"For the future I shall leave all Sieites in peace."

The *raison d'être* for noticing this work must not be forgotten. It, of course, is the confirmation given relating to auroras. M. Tromholt made his investigations at Koutokæino in order to obtain, if possible, a solution of the problem as to the height of the aurora borealis. Another observing station was at Bossekop, some sixty-three miles north as the crow flies. The observations made at these stations, north-south of each other, enabled the necessary data for the calculation to be obtained. The phenomena to be investigated is thus referred to: "The aurora borealis develops a richness of colour and display of light of which those who have only seen this phenomena in southern climes can form no idea. It is nearly always in the sky; as soon as daylight disappears it flames up, and is even transparent when the sky is perfectly obscured by clouds. It is not, as further south, confined to the northern horizon; it is seen in the zenith, and from time to time the waves of light roll symmetrically over the entire sky into the furthest corner of the heavens. That wonderful form of the aurora borealis known as the auroral corona, created by beams or streamers travelling upwards from all points of the horizon and meeting in one spot in the zenith, is also seen here nightly, while another of true Arctic character, the streamers, attains the most marvellous forms. From one side of the sky to another a drapery, woven of light and colour, is wafted; now here, now there, first one, then two, then several bands, one above the other, never at rest and never the same form, hither and thither the folds sway with a soft fascinating motion, as from one end to the other waves of light chase each other, over taking, crossing, meeting, while the lower intense border displays the loveliest colours of red and green, the upper one fading into the dark background." (Vol. I., pp. 89 90.)

It is not, however, till we reach Chapter X. that we find more than casual references to the author's work.

In this portion of the book the author commences by pointing out that writers have been too apt to form theories without any due knowledge of the facts relating to the phenomena. Thus, he says, "Without any knowledge of the phenomenon one compiler copies from another the correct with the incorrect, and in the course of time the auroral literature has become so inundated with what may be called 'traditional falsehoods,' that it would be a herculean task to cleanse these Augean stables." He describes the principal forms of the aurora, giving admirable illustrations here, as indeed in all other parts of the book, showing how the many different forms seen by observers are really to be reduced to a few fundamental ones, the variety being due to the difference in the positions of the observers. He combats many of the errors which have crept into the literature, such as the clicking noise said to be heard during the prevalence of these displays and the amount of light received from the aurora. As regards the latter, he maintains that though for a few moments the light may be very intense and cast an unusual brightness over the landscape, these intervals of luminosity are so brief that the light emitted is of no practical value to the inhabi-

Digitized by Google

tants of the Polar regions. So far as M. Tromholt is concerned he is very emphatic against any noise of any kind being heard during the auroral display. We cannot enter into questions relating to the disturbance of aurora or the height; suffice it for us to say that on the latter point M. Tromholt—so far as his investigations have gone—seems to place it as about from 70 to 80 miles. Thus, he says (p. 259, Vol. I.), taking the average of 18 measurements: "The average height of the lower edge will be 70·2 miles, a result in perfect harmony with later observations." According to our author, the aurora borealis has three distinct periods, daily, yearly, and eleven-yearly; and he considers that these periods are connected with phenomena far beyond the earth's sphere, viz., the so-called solar disturbances (p. 265). The author almost refuses to be led into discussion of theory, pointing out that, though the knowledge obtained by scientific investigation has perhaps enabled us to see what the aurora borealis is not, at present we are totally unable to say what it is; but he admits that the phenomena is probably of an electrical character, and that the theory which seems to deserve most adherence is that advanced by Prof. Edlund, of Stockholm (p. 286). Our space will prevent us saying more upon these very interesting volumes, though we must not forget to state that they are exceedingly well illustrated, and accompanied by a map showing the routes and the localities visited during these investigations. The book will be of interest to the geographical and ethnographical student hardly less than to the electrical.

THE KAUFFER AND GOLDNER BATTERY.

On July 7, at 12 midnight (says an American contemporary) a battery of nine cells was started lighting two 8 candle-power lamps, six minutes on and six minutes off, day and night, the interruptions being accomplished by the aid of an ordinary 24-hour clock. This was continued until July 20, at 10 a.m., when the lamps had been burning a total of 152 hours. The object of this arrangement was to get the 152 hours inside of twelve days, while in practice they would be spread over six weeks. It was found on July 20 that the battery was by no means exhausted, so without any renewal of the depolarising liquid it was started on a consecutive run. At the end of the 152 hours ½lb. of zinc had been consumed in each cell, making the cost of zinc for the nine cells 45 cents. The inventors, Messrs. Kauffer and Goldner, state that the work put upon the battery in the test described was harder than it would have been if running, according to their original claim, four hours a day for a period of 38 days. The test has been watched with much interest, and was carried out by parties other than the inventors themselves.

THE INTERNATIONAL TELEGRAPH CONFERENCE AT BERLIN.

The opening meeting of the International Telegraph Conference took place at noon on Monday, the 10th instant, in the large lecture hall of the Post Office Department in the Artillery Strasse. Thirty-three States and 17 cable companies were represented. In all 72 delegates were present. England is represented by Mr. C. H. B. Patey, and Messrs. Fischer and Benton, of the Post Office Telegraph Department; France, by M. Fribourg, Director of Telegraphs, and MM. Lorin and Brunet; Austria-Hungary, by Baron von Watenwyl, Director-General, and two Councillors of the Telegraph Department; Russia, by General von Besack, Chief of the Telegraph Department, and two assistants; Italy, by Signor d'Amico; Spain, by Señor Aquilino Herce and Señor Coromina; Switzerland, by M. Frey; Turkey, by her Ambassador at Berlin; and all other European States by the principal officials of their Postal and Telegraph Departments. Of extra-European countries the following are represented:—Algiers, Brazil (Senhor Capanema), Cochin China, the Dutch East Indies, Egypt (Mr. Floyer), Japan, Persia (Colonel Smith), and Siam (Prince Prisdang, assisted by Mr. Wilberforce Wyke); and also British India (Colonel Bateman-Champain and Mr. C. H. Reynolds), and the following British Colonies:—Cape Colony, Natal, New Zealand, South Australia (Mr. C. Todd, the Postmaster-General), Victoria, New South Wales (Mr. E. C. Cracknell), and Tasmania (Mr. J. Henniker Heaton). The two last-named colonies notified their adherence to the Union only a few days before the opening of the Conference. Besides these official representatives, the following fifteen large cable companies, which occupy an international position, are also represented by special delegates:—

Company.	*Delegates.*
Eastern, Eastern Extension, Australasia, and China, Eastern and South African, Black Sea	Mr. John Pender, M.P. (chairman); Sir James Anderson (managing director); and Mr. Lewis Wells.
The Anglo American	Mr. Henry Weaver and M. Jules Despecher.
Submarine	Sir Julian Goldsmid, Bart. (chairman); Herr G. von Bunsen.
Indo-European	Mr. W. Andrews (managing director); Mr. F. Moll (secretary).
Great Northern	Capt. E. Suenson, of Copenhagen (managing director); Capt. W. de Hedemann (company's agent, in St. Petersburg); and Mr. F. C. C. Nielsen (manager of London office).
German United	
Compagnie Française	
Direct United States	Mr. John Pender, M.P. (chairman); Mr. J. W. Fuller (secretary and traffic manager).
Brazilian Submarine	Mr. Thomas Fuller (managing director).
Direct Spanish	Sir James Anderson (chairman) and Mr. C. Gerhardi (manager).
West India and Panama	Mr. W. Andrews and Mr. Henry Weaver.
Western and Brazilian	Major A. Wood (managing director).

The present Conference is the seventh of its kind. The first International Telegraph Conference met by invitation of the Belgian Government at Brussels in 1858, and adopted the fundamental regulations of the International Telegraph Convention. The second conference at Paris in 1865 amended and completed these regulations, and also adopted a resolution fixing the meetings of the conference at regular intervals in one of the European capitals. At Vienna, in 1868, the first extra-European countries (Asiatic Russia and British India) were admitted to the Union, the International Convention was finally adopted with 67 articles; and the International Telegraph Bureau at Berne was established. At Rome, in 1872, the Convention was further amended, and delegates of the cable companies were first admitted. The fifth conference, at St. Petersburg in 1875, passed new statutes and a general reduction of the tariff; and the sixth, at London in 1879, adopted the general word-tariff for international telegraphic intercourse. At all of these Conferences each State, although represented in most cases by several delegates, was entitled only to one vote, while the cable companies had no voting powers. The proceedings of the seventh Conference, which began on Monday, is conducted, like all the former ones, in the French language, as also the protocols and official reports of the Conference. The German Postmaster-General, Dr. von Stephan, Secretary of State, is the president. The main subject to be discussed by the present Conference is the general tariff question, and the regulation of international rates and charges, which has already occupied the attention of former Conferences. The States which favour a considerable reduction of rates still appear to be in the minority. Russia particularly opposes all proposals for reducing the tariff, as involving a great deficit in the receipts, and a large number of the other States, together with the cable companies, follow the same policy. The following proposals, however, will be discussed and voted upon by the Conference.

1. Germany proposes to establish a uniform tariff for all Europe, similar to the common rates now in force throughout the Universal Postal Union, of, say, 50 centimes fee for each message, and 20 centimes per word; or 10 centimes between countries bordering on each other. Messages by submarine cables to be subject to special rates. Germany also wishes to abolish the free transmission of date and time as hitherto. 2. Austria-Hungary also proposes a reduced tariff and a new system of settling accounts between the members of the Union; and also moves for a reduction of rates for newspaper messages. 3. England proposes to abolish all messages containing only the address and signature, but no other contents. 4. Belgium wishes to limit single words in extra-European messages to fifteen letters and five figures. 5. The Netherlands move to abolish the fixed number of words for prepaid reply messages. Another proposal is to levy charges, not as hitherto, on the number of words, but on that of the letters and figures. Besides the foregoing measures of administration, it

Digitized by Google

is also proposed to lay a number of technical questions relating to the latest results of telegraphic and electrical science before the Conference. For this purpose a series of highly interesting and important experiments will be carried out in the Central Telegraph Station in the Oberwallstrasse, the large apparatus hall of which probably surpasses in completeness those of all other Continental capitals. These experiments, which promise results of great scientific importance, will also be attended by the best authorities on electricity and telegraphs, viz., Mr. Werner Siemens, Mr. John Pender, M.P.; Sir James Anderson, Sir Julian Goldsmid, M. Jules Despecher, Captain Suenson, and others.

Dr. von Stephan opened the Conference after a speech in which he welcomed the delegates in the name of the Kaiser, and stated that this Conference would continue in common the labour of further perfecting the powerful means of communicating thought and extending civilisation which science has secured for mankind. Mr. Patey, one of the English delegates, representing all the others, briefly expressed their thanks for the welcome accorded to them, paying a complimentary tribute to Dr. Stephan, whom he proposed as president. Herr Hake, a director in the German Post Office, was elected vice-president, and the bureau was composed of M. Curchod, director of the International Telegraphic Bureau at Berne, with Herr Eschbaecker, secretary of the Bureau International, and Herren Linz and Neumann, of the German Post Office, as secretaries. Dr. Stephan referred to those members of the last conference who had died, amongst whom was Sir William Siemens. He also paid a warm tribute to the memory of the late Mr. Fawcett, at the mention of whose name the assembled delegates rose from their seats in token of respect. Speaking of the work that lay before the delegates, Dr. Stephan said that the London Conference established the principle of the word-rate, and it was to be hoped that the Conference which had just met would be able to record as the result of its labours another step in advance, particularly in the direction of bringing the telegraph into the service of a still larger public, and increasing its accessibility to all, even to the less wealthy classes of the community. With the maintenance of that spirit of conciliation which had been manifested at all conferences hitherto, and had made it possible to unite in the adoption of a common code of principles such a vast number of telegraph systems spread over the whole earth and governed by such diverse conditions of organisation, he doubted not that any new difficulties presenting themselves would be surmounted in the course of the forthcoming interchange of views.

Mr. Fischer, another of the English delegates, then gave an account of England's administration since the last Conference, after which Director-General Kielson (Norway) gave a review of the results of former Conferences. Professor Curchov, head of the International Bureau, read a report upon a proposal relative to the compilation of statistics of electrical measurements, and the effects of atmospheric currents and thunderstorms.

Two committees were afterwards formed, one to consider the tariff question, and the other the regulations, &c., these committees comprising eighteen and ten members respectively.

In the Committee on Tariffs, consisting of delegates of Germany, Austro-Hungary, Belgium, Denmark, Spain, France, Great Britain, Italy, Japan, Luxemburg, Norway, Netherlands, Portugal, Russia, Sweden, Switzerland, and Turkey, the Austrian delegate, Baron Brunner, has been appointed President, the Italian delegate, Signor Amico, Vice-President, and the French delegate, Director-General Fribourg, Referee. The fact that a German delegate was not appointed chairman is regarded as ominous of the rejection of the proposal made by Germany in favour of a sweeping reduction of charges. An American delegate on Tuesday made a very eloquent speech in support of the German proposal, but it is believed that the opposition of Russia, Turkey, and the great cable companies will be fatal to the German scheme. The other Committee, which has to deal with the regulations on technical and administrative matters, consists of delegates of Germany, Belgium, Brazil, France, Great Britain, Roumania, Sweden, Portugal, Russia, and British India. The President is Director Hake, of Berlin; the Vice-President, the Brazilian delegate, Baron Capanema; and the Referee, the Belgian Director, Delarge.

Renewed doubts are expressed as to the success of Germany's proposal for the introduction of a reduced European tariff, as this could not very well harmonise with the interests of the private English companies, to speak of nothing else, and it is understood that on this ground more particularly the British delegate will be forced to reassert the negative standpoint assumed by England at the London Conference. The only solution of the difficulty, *The Times* remarks, would be a guarantee on the part of the Continental Powers, or some of them, that under the proposed new system the revenues of the English companies should not be less than they are at present, but little hope is entertained that a compromise of this kind will be arrived at. One delegate for each State is entitled to vote. The rest, whether representing States or companies, have only a deliberative voice. The chief feature of the hall in which the delegates meet is a large telegraphic map of the world, which has been specially prepared for the purpose by the helpers of Dr. von Stephan.

On Monday next the delegates will be entertained at a banquet in the Zoological Gardens by the United German Telegraph Company, while they will likewise be treated to an aquatic excursion and a supper by the City of Berlin.

AWARDS AT THE INVENTIONS EXHIBITION.

Gold Medals.

Adamson, Daniel, and Co., "Wheelock" automatic cut-off engine.
Bell, John, and Co., treatment of asbestos.
Buckton, J., and Co., testing machine with autographic indicator.
Cardew, Captain, voltmeter.
Crompton, R. E., and Co., improvement in electric lighting appliances.
Crookes, William, radiometers, &c.
Crossley Brothers, gas engines.
Davey, Paxman and Co., engines and boilers.
Doulton and Co., general exhibit of pottery, &c.
Edison and Swan United Electric Light Company (Limited), Edison-Swan systems of electric lighting.
Electrical Power Storage Company, improvements in secondary batteries.
Fielding and Platt, high-speed engine.
Galloway, W. and J., and Sons, engines and boilers.
Goulard and Gibbs, successful working out of a system of distribution of electricity by induced currents.
Greenwood and Batley, high-speed horizontal engine.
Hathorn, Davey and Co., domestic motor.
Heenan and Froude, "Tower" spherical engine.
Henley's, W. T., Telegraph Works Company (Limited), excellence of cables.
Hick, Hargreaves, and Co., "Corliss" engine.
Hicks, J. J., improvements in thermometers, and other philosophical instruments.
India Rubber and Gutta Percha and Telegraph Works Company (Limited), india rubber and gutta percha.
Jenkin, Professor Fleeming (the late), telpherage.
Kitson and Co., Parson's high-speed engine.
M'Kenzie and Holland, railway signals, points, and crossings.
Phosphor Bronze Company, phosphor bronze alloys.
Planté, G. (France), secondary battery and scientific research.
Ransomes, Sims, and Jeffries (Limited), machinery.
Saxby and Farmer, railway signals and safety appliances.
Scott, Ernest, Ashton's positive actioned power meter and continuous indicator.
Shaw, Professor W. S. Hele, sphere and roller mechanism for transmission of power.
Shaw, Professor, W. S. Hele, improved integrators.
Siemens Brothers and Co., excellence of electric lighting arrangements.
Sterne, L., and Co., gas engines.
Swan, J. W., incandescent lamps.
Sykes, W. R., combined electric interlocking and blocking system for railways.
Thomson and Houston, systems of electric lighting. (Exhibited by Laing, Wharton, and Down.)
Varley, S. A., designing the first self-exciting dynamo machine.
Warne, W., and Co., india rubber.
Watkin, Major H., R.A., ingenuity in devising and applying practically scientific and accurate instruments to various military purposes, and the electric light for powder factories.
Watson, Laidlaw and Co., self-balancing centrifugal machine and hydro-extractor (Weston's patent); self-balancing electro-centrifugal machine and hydro-extractor (Watts' patent).
Westinghouse Brake Company (Limited), automatic air-brake and passenger communication for railway trains.
Wilde, Henry, discovery of the indefinite increase of the magnetic and electric forces from quantities indefinitely small.
Willans and Robinson, Willans' compound engine and electric governor.

Silver Medals.

Allen, W. H., and Co., high-speed engine and dynamo.
Alley and Maclellan, high-speed engine.
Andrew, J. E. H., and Co., gas engines.
Arundel and Co., Moscrop's continuous engine speed recorder.
Asbestos Company (Limited), asbestos packing.
Bernstein Electrical Lamp Company, incandescent lamps.
Boake, A., and Co., manufacture of sulphurous acid and sulphites.
Bower, George, process for rendering iron rustless.
Brin Frères, improvements in the production of oxygen and nitrogen gases.
Chapman and Messel, improvements in the manufacture of anhydrous sulphuric acid.
Chipperfield, R., good workmanship of engineering models.
Condy, H. B., manufacture of permanganates, hyposulphates, &c.
Consolidated Electric Light Company, system of using secondary batteries.
Deakin, Parker, and Co., Acme high-speed governor.
De Ferranti, S. Z., electric meter.
De Gruyter Clock Manufacturing Company, application of torsion to the measurement of time.
Delany Synchronous Multiplex Telegraph System, multiplex telegraphy.
Electric Sun Lamp Company, electrical exhibit.
Elwell and Parker, dynamo machine.
Faraday and Son, electrical fittings.
Fergusson, H. A., Lalande-Spence battery.
Gamble, Jos., and Sons, manufacture of chlorate of sodium, &c.

Digitized by Google

Gaussen, D., "V.W.H." corrugated vulcanised india rubber for various purposes.
Gerard and Co. (Limited), lamps and dynamos.
Glover, W. T., and Co., cables.
Goodfellow and Matthews, high-speed compound tandem engine.
Groves, William, construction of electrical and philosophical apparatus.
Gülcher Electric Light and Power Company (Limited), electric lighting apparatus.
Harper, —, patent electrical block system.
Harrison, Cox-Walker, and Co., electrical exhibit.
Howard and Sons, pharmaceutical preparations.
Immisch, M., improvements in electric motors.
Jablockkoff and General Electricity Company (Limited), Jablochkoff system of electric lighting.
Kendall, J. A., gas battery.
London Water Meter Supply Company, rotary meters and "Daussin" domestic motor.
Manganese Bronze Company, manganese bronze.
Marshall, Sons, and Co., high-speed engine.
Mather and Platt, high-speed engine and dynamo.
Maxim-Weston Electric Light Company, electrical exhibit.
Miller, Leslie B., electrical exhibit.
Muspratt, James, and Sons, improvements in the manufacture of chloride of potassium.
Nicholson, W. N., and Sons, steam engines.
Parkes, Alexander, insulating materials.
Parsons, Hon. E., electric governor and dynamo.
Pilsen-Joel and General Electric Light Company (Limited), Pilsen lamp.
Rigg, James, models of machine construction.
Robey and Co., improved Robey winding engine and horizontal fixed engine.
Salomons, Sir David, Bart., electrical appliances and philosophical instruments.
Scott, Ernest, and Co., machine for extracting iron from other substances by means of electro-magnetism.
Smith, Rev. F. J., ergometer and integrating instruments.
Smith, M. Holroyd, electric tramway.
Smith, J., and Sons, electric time balls.
Standard Time and Telephone Company (Limited), method of synchronising clocks.
Stephen, J., synchronic call.
Swan, Alfred, electric safety lamp.
Thurston and Co., electric billiard marker.
Traill, W. A., electric tramway.
Trouvé, G., electrical appliances.
Voss, Robert, induction machine.
Welch, E. J. Cowling, and W. Parker Smith, automatic brake.
Woodhouse and Rawson, electrical exhibit.
Yeates and Son, standard pressure gauge, &c.
Young, John, speed indicator.

Bronze Medals.

Allin, S. S., signal wire compensator.
Almqvist, Fridolf (Sweden), governor and speed indicator.
Andrews, J. D. F., and Co., electrical exhibit.
Anglo-American Brush Electric Light Corporation (Limited), electric lighting apparatus.
Beynon and Cox, patent gas engine.
Botten, H., electrical exhibit.
Brown, A. C., electrical exhibit.
Cassel, H. R., method of extracting gold from refractory ores by electrolysis.
Cobbett, W. Wilson, cotton machine belting.
Cordner, Allen, and Co. (Limited), electrical exhibit.
Coxeter and Nehmer, electrical exhibit.
Dale, H. and E. J., electrical exhibit.
Danchell, F. H., electrical exhibit.
Davis and Timmins (Limited), electrical exhibit.
Delepine, S., microtome.
Electric Signal Company (Limited), system of railway signalling.
Electro-Amalgamator Company (Limited), electro-amalgamator.
Fisher and Mieg (Austria-Hungary), hard porcelain.
Gant, R. B., electrical exhibit.
Globe Electrical and Engineering Company, electrical exhibit.
Goolden and Trotter, electrical exhibit.
Gray, J. W., and Son, electrical exhibit.
Harling, W. H., improvements in mathematical instruments.
Hockey and Co., Hockey's patent rotary engine.
Holmes, J. H. and Co., electrical exhibit.
Irish, W. E., electrical exhibit.
Jack, James H., electrical exhibit.
Jeffrey and Blackstone, portable vertical steam engine.
Joel, Henry Francis, electrical exhibit.
Kato Jukichi, porcelain lamp stands.
Korting Brothers, gas engine.
Lee, R. A., electrical exhibit.
Lorrain, J. G., electrical exhibit.
Lundberg, André Peter, electric lighting.
Macdonald, J. H. A., electrical exhibit.
Mackie, W., electrical exhibit.
March, Octavius, electrical exhibit.
Marshall, J. T., and Co., compound semi-fixed engine and boiler.
Moore, George, clock with electric alarum attachment.
Mosses and Mitchell, vulcanised fibre.
Munden, William John, gas engines.
Munro, John, electrical exhibit.
Ogden, Ralph, Manchester automatic expansive steam engine.
Oldfield and Walton, link belting.
Paterson and Cooper, electrical exhibit.
Perkins, A. M., and Sons, high-pressure engine and boiler and evaporative surface condenser.
Perry, A. H., electrical exhibit.
Phillips, F. C., electrical exhibit.
Pinchbeck, J., rotary steam engine.
Richardson, John, steam engine indicator for taking continuous diagrams.
Richardson, Koolman, and Isger, electro-plates and moulds.
Riley, John, electrical exhibit.
Rogers, Francis, M., electrical exhibit.
Scott-Moncrieff, W. D., steam engine governor.
Sellars, J. C., electrical exhibit.
Sennett, A. R., and Co., electrical exhibit.
Shepherd, C., improvements in electrical and sympathetic clocks.
Shippey Brothers, electrical exhibit.
Smith, T. Taylor, electrical exhibit.
Stewart, Charles W., electrical exhibit.
Thompson, Dowsing, and Rew, electrical exhibit.
Thorpe, H., electrical exhibit.
Timmis, I. Augustus, railway signals and points.
Trott, H., and Fenton, electrical exhibit.
Van der Weyde, electrical illumination of the sitter in photographic portraiture.
Vulcan Manufacturing Company, electrical exhibit.
Wilson, J. Veitch, and Co., improvements in the manufacture of lubricating oils.
Wood, Miss, geometrical ruler.

Society of Arts Medals.

Crookes, William, F.R.S., for his improvements in apparatus for the production of high vacua, and for his invention of the radiometer. *(Under the Fothergill Trust.)*
Crossley Brothers, for the Otto gas engine. *(Under the Howard Trust.)*
Hathorn, Davey, and Co., for their domestic motor. *(Under the Howard Trust.)*

Diplomas of Honour

which have been accorded only to Government Departments and public institutions:—

Japanese Government Education Department, Tokio, Professor Ewing's seismometers and other scientific instruments.
Japanese Government Telegraph Department, excellent workmanship and design of electrical and telegraph instruments.
Kew Committee of the Royal Society, system of testing watches, instrument testing, &c.
Physical Society of London, collective exhibit.
Royal Meteorological Society, meteorological apparatus.
Royal Engineers' Establishment. Chatham, (1) employment of cheap mirrors for the electric light, (2) application of the vibrator, (3) Cardew's voltmeter, (4) toughness and lightness of the material employed for military balloons and its capability of retaining hydrogen gas, (5) the use of tubes for the storage of hydrogen gas under high pressure for balloon inflation.

CITY GUILDS EXAMINATIONS.

The following is a list of the names of those gentlemen who satisfied the Examiners at the late May examinations:—

Electric Lighting.

Bacot, Edmund A., London.
Bennie, Hugh O., Glasgow (2nd, £3, and bronze medal).
Bigger, Fred. C., Glasgow.
Bigg-Wither, Frank H., London.
Bowron, Geo., London.
Briscoe, Albert E., Birmingham.
Bryan, Frank, Manchester.
Burton, Jas. E., London.
Chatterton, Alfred, London.
Coote, Ernest R., London.
Crawshaw, W. S., London.
Dalby, Edward C. B. E, London (4th, £1, and bronze medal).
Davidson, Louis, London.
Duffitt, George, London.
Filer, Frank E., London.
Fisken, Jno. B., Glasgow.
Fulton, Thos. C., Glasgow.
Fussell, Joseph H., Nottingham.
Gutman, Ludwig, London.
Hird, Arthur, Leeds.
Jenkins, Hy. C., London (2nd, £5, and bronze medal).
Kober, Charles, Glasgow.
Lea, Frank B., Manchester.
Leake, Walter, Manchester.
Marks, Herbert T., London.
Marshall, Geoffrey, Glasgow.
McMillan, Jno., Glasgow.
Mitchell, Geo. A., Glasgow.
Moon, Jno. S., London.
Morton, Wm. D., Glasgow.
Newbury, Fred. E., London.
Pyall, Wm. A., London.
Raine, Abraham D., London.
Sanderman, Jas., Glasgow.
Schmitz, Herman E., Leeds.
Seward, Willis G., London.
Slater, Arthur W., London.
Shaw, A. H., Manchester.
Sheard, Arthur H., London.
Snell, Albion T., London.
Spence, W. Lawson, Manchester.
Stocken, A. L., London.
Swan, Howard, London.
Thomas, Bertram, London.
Thomas, Eustace, London.
Tonge, Jno. H., London.
Turvey, Wm., London.
Wardell, Thos., Glasgow.
Wallich, Horace, London.
Wallis, T. M. W., Nottingham.
Wilson, Ernest, Leeds.
Wilson, Willie H. de M., London.
Wood, Harry, Manchester.
Woodward, J. H., Manchester.
Young, Benjamin, Belfast.

Telegraphy.

Aldworth, Jno. R. O., Cardiff.
Baguley, Joshua, Manchester.
Beach, Hy. S. W., London.
Bell, Henry S., Dublin.
Bennett, G. F., London.
Bennett, H. W., Nottingham.
Billingham, G. W., Birmingham.
Blackburn, Richd. S., London.
Brown, Wm., Aberdeen (4th, £1, and bronze medal).
Brooker, Arthur (2nd, £3, and bronze medal).
Butler, F. W., London.
Butler, Wm. H., London.
Campbell, Duncan, Glasgow.
Carter, Edwd. T., Bristol.
Chapman, Albert, Manchester.
Clayton, Birmingham.
Collinson, T., Newcastle-on-Tyne.
Cochrane, Jas., Manchester.
Connell, Geo. W., London.
Connolly, Wm., Dublin.
Crombie, Jas., Glasgow.
Curran, Patrick J., Dublin (3rd, £2, and bronze medal).
Delahunty, Timothy.
Dorman, Geo. H., Birmingham.
Ferguson, Jas., Newcastle-on-Tyne.
Fogarty, Jas., Dublin.
Fraser, Andrew, Aberdeen.
Fraser, James, Aberdeen.
Gaiter, John, Aberdeen.
Gifford, James, Glasgow.
Greenwood, Arthur, Bradford.
Haigh, Joseph S., Bradford.
Hall, Geo., Manchester.
Harrison, Wm. S., Manchester (1st, £5, and silver medal).
Hendrie, Robt., London.
Hills, Wm. F., London.
Hodgkinson, Arnold, Manchester.
Kennedy, Wm., Aberdeen.
Leonard, Wm., Dublin.
Levingstone, Joseph, Dublin.
Lloyd, Edgar W., Nottingham.
Macfee, Jno., jun., Glasgow.
Mansbridge, Geo. F., London (2nd, £5, and bronze medal).
Marshall, Jno. W., Manchester.
M'Candlish, Albert, Manchester.
M'Lachlan, Robert J., Glasgow.
Mitchell, Jas., Dublin.
Murray, Wm. F., Dublin.
Noble, Wm., Aberdeen.
Philpott, Jas. J., London.
Pickering, Jas. R., London (1st, £3, and silver medal).
Pigg, Jas., Newcastle-on-Tyne.
Plummer, Thos., Wexford.
Pollard, Fredk., London.
Prince, Wm. T., Wolverton.
Rickwood, Hugh, Manchester.
Saul, Frances Mary, Belfast.
Smyth, Wm., Dublin.
Taylor, Chas., Dublin.
Taylor, Jas. F., Manchester.
Tremain, Francis, Plymouth.
Tucker, Wm. S., Liskeard.
Turner, Jno. W., Plymouth.
Wilkes, Albert, Bradford.
Wilson, Hugh, Glasgow.
Winn, Chas. W., London.
Wood, Henry G., London.
Worsley, W. A., Manchester.

Electro-Metallurgy.

Brown, Geo. A., Birmingham (2nd, £3, and bronze medal).
Buchan, Alexander, Glasgow.
Buckeridge, H. L., London.
Bush, Wm., Newport, Mon.
Clarke, Chas. W., Birmingham.
Coldwell, R. N., London.
Dryhurst, Jno., Birmingham.
Gower, Alfred R., Birmingham.
Hurtley, Wm. H., Leeds.
Kinvig, J. W. B., Neath.
Macaulay, Malcolm.
Parker, Williamm Joseph, Birmingham.
Partridge, Wm. J., Birmingham.
Taylor, Robert, London.

Electric Instrument Making.

Fishenden, Edward G., London.

LEGAL.

United Telephone Company (Limited) v. Bassano and another.

In the High Court of Justice, before Mr. Justice North, on Wednesday last, this action was mentioned, his lordship reserving the delivery of his full judgment until after the Long Vacation. The hearing occupied the Court for several days during last month (reports of the proceedings appeared in *The Electrician* from week to week), the main issue being as to the infringement by the defendants of that portion of the Edison telephone which is known as the "transmitter," and the patent for which is the property of the plaintiffs.

The Attorney-General, Mr. Aston, Q.C., Mr. Moulton, Q.C., and Mr. Micklem were for the plaintiffs; Mr. Bigham, Q.C., Mr. C. Plumptre, and Mr. John A. Hamilton for the defendants.

His LORDSHIP said that, although he had not been able to find the time to write out his considered judgment, he would without further delay state that he had decided the case in favour of the plaintiffs, and he therefore granted them an injunction to restrain the infringement, and an order for delivery up of the offending machines.

The plaintiffs' solicitors undertook that the latter should not be destroyed during the vacation.

COMPANIES' MEETINGS.

The National Telephone Company (Limited).

The fifth annual ordinary general meeting of the shareholders was held on the 7th inst. at the offices of the company, 11, Queen Victoria-street, Colonel R. Raynsford Jackson, the chairman of the Company, presiding.

The notice calling the meeting was read by Mr. WILLIAM B. CAMPBELL, the secretary.

The report, which was taken as read, recommended a dividend at the rate of 2½ per cent. per annum on the ordinary capital for the second half of the year, in addition to the interim dividend for the first half of the year at the rate of 2 per cent. The accrued interest on the debentures, and the usual dividend of 6 per cent. on the preference shares, was also provided for.

The CHAIRMAN said: Gentlemen, I shall move the adoption by the shareholders of the Directors' report, and shall occupy your attention only an extremely short time, because the reports and accounts of the Company are complete in themselves, and put you in possession of all that it is necessary you should know respecting its affairs. I will, however, for a reason which will afterwards appear, call your attention to the increase in the gross revenue of the Company. You will see that on the 30th June, 1884, the gross revenue had reached £57,271. 15s. 2d., and that on the 30th June last it had reached £70,943. 11s. 3d. You will see, therefore, that there is a considerable increase in the gross revenue, and I am happy to say that the increase in the net revenue has been relatively greater. The net revenue for 1884 was £15,227. 0s. 5d., and for the year ended 30th June last £23,658. 10s. 3d. I have only called your attention to these figures because I wish to point out to you that no increase of the revenue of a telephone company can take place without an expenditure of capital. A telephone company is in a different position to almost any other undertaking in that respect. Take, for example, a railway. When a railway has been constructed at a given expenditure for the railway itself and for the plant, the traffic may be large or it may be small, and it may grow very considerably without the investment of additional capital. On the other hand, in a telephone company, if you obtain an additional number of subscribers, you can only connect them with the telephone system by an outlay for wires, standards, plant, &c., which necessarily involves the investment of capital. So, if you wish for any large increase of the revenue, you can only obtain it by corresponding investments of money. You may therefore, I think, safely assume that if a telephone company is properly conducted, and if its capital is soundly invested, then the amount of capital devoted to the development of its business is a fair criterion of the success of the company. I beg to inform you, although most of you, I think, will have received the circular containing the resolutions which will be proposed at a meeting to be held next Tuesday, that on that day a proposal will be put before the shareholders for an increase of the capital of this Company, and the effect of your sanction to the issue of that additional capital, and of its investment, will be doubtless to increase the prosperity of the Company, and to add to the dividend on the ordinary shares. The capital expended during the last year was £53,290. 17s 1d. That was a larger amount considerably than in the previous year, and I think the shareholders may naturally inquire why the larger amount has been spent. You are aware that the license of the Postmaster-General, under which the Company carries on its business, was altered last year, and that larger powers were given to the companies. Amongst those powers was the right to erect trunk wires in substitution of those previously rented from the Postmaster-General, and to have its own wires to connect town with town. The Company has largely availed itself of the privilege, and spent about £10,000 in doing so. Of course we have not as yet received a satisfactory return upon that expenditure, but the revenue is growing. We have two kinds of trunk traffic—namely, that derived from the ordinary rentals and that from those who pay for fee messages. The latter revenue is steadily increasing from week to week, and there is every prospect of its attaining, in the course of time, a large development, and being a valuable source of income to the Company. When we took over Messrs. Graham's telephone business in Glasgow, he had about 200 subscribers, and it was part of our bargain that he should have the right to erect and maintain our wires in Glasgow and within a radius of twenty-five miles around. But we found that contract disadvantageous, and all the work done under it extremely costly. We therefore entered into negotiations with Messrs. Graham, and bought the contract from them. The purchase of that contract cost us something over £7,500. I congratulate the shareholders upon the completion of that transaction. The effect has been to diminish, to a very great extent, the cost of working the Glasgow system; in mere maintenance alone the saving from that cause has been very large, and the saving in the cost of construction is so considerable that we have undertaken works in connection with our Glasgow district which we certainly should not have ventured to construct had that contract been in existence. You are aware we have acquired considerable additional territory from the United Telephone Company; an expenditure of about £2,200 was involved in connection with the acquisition of that territory. The expenditure proper for the increase of our ordinary revenue was £34,000, and the result of that outlay has been, I think, extremely satisfactory. I only know, so far, of one item of expenditure of importance in the current year. You are aware that we had a serious opposition in Dundee, where there was a rival company called the Dundee and District Telephone Company, and in order to carry on our contest with that company we were obliged to reduce our tariff to the low figure of £5. I need not tell you that we lost money heavily during the continuance of the contest with that company. When I was last in Scotland I succeeded in making an arrangement by which that business was conveyed to us upon payment to the local company of £8,500. By our arrangement with the United Company we are not allowed to possess instruments, but have to use the telephones of the United Company. That company, therefore, took over the instruments, and purchased them from us. So the actual cost of the purchase of the Dundee and District Telephone Company was not excessive, and the effect will be a considerable increase of our revenue from that town, where I have no doubt the company will henceforth possess a valuable telephone property. Dundee is connected with many of the surrounding places by trunk wires, and I do not suppose that there is any telephone system more perfect than that in Dundee and the vicinity. It is connected with Perth, Arbroath, and Forfar, and is about to be con-

Digitized by Google

nected with other places. A good deal has been said about the telephone tariffs, and many complain that they are unduly high; but those who make that complaint speak, I think, in ignorance of several important facts. Some of them say that the telephone charges in this country are the highest in the world. They are not aware, perhaps, that there are more telephones in the United States than in all the rest of the world put together. When the telephone was first introduced there, a great many exchanges were started upon low tariffs, and the companies thought they were making very large profits, but in the course of time they found the expenses so much greater than they anticipated that, instead of earning profits, they were losing money, and the effect was a general increase of telephone tariffs in America. I think our subscribers would be somewhat disagreeably surprised if in this country (where we are said to adopt the highest rates) we were to adopt those current in America—that is to say, £35 per subscriber, which is the rate charged in New York, Philadelphia, and other great American towns. The fact is you cannot adopt the same tariff in every town. The cost of working the telephone varies according to an infinite variety of circumstances. In some towns you are obliged to adopt a high tariff, and in others you can work it lower. As far as the National Telephone Company is concerned, it has been its aim to give its services upon economical terms to the subscribers. Therefore, in some places you will find the tariff is remarkably low, and that is due to the fact that we have been able to make it so without disadvantage to the Company. In other towns it is necessarily higher, as the expenses in those towns are greater. I do not think it necessary to dilate further upon this subject, or, indeed, upon any of those matters which interest the shareholders, because as I said in the beginning, our report seems to deal with everything which is of genuine interest. I will therefore say nothing more, unless in answer to questions which may be put by shareholders present. I move the adoption of the report.

Mr. J. P. BIGELOW seconded the motion.

Mr. GEORGE PUGH: With regard to the reserve fund, how is that invested?

The CHAIRMAN: The reserve fund is not specially invested. It is a means of setting aside a certain amount instead of investing it.

Mr. PUGH: Will that be used in the business?

The CHAIRMAN: That will be used in the business; yes.

Mr. PUGH: Then it is only nominally a reserve fund.

The CHAIRMAN: In that sense you may say it is only nominally a reserve fund. It will be used in the business. It is better to use that portion of the earnings in the business rather than to divide it and require further capital. Contingencies are constantly arising which may require expenditure, and it is desirable to set aside a portion of the earnings in this way from time to time.

Mr. PUGH: I understand the value of a reserve fund, but I do not see its value when it is used in this way—in the business.

The CHAIRMAN: Your suggestion is one that the money should be taken out of the business and invested.

Mr. PUGH: Then it would form a reserve fund.

The CHAIRMAN: Your suggestion is one which the Directors will be prepared to consider the same as they would any suggestion from any shareholder, but this is the first time we have set aside anything towards a reserve fund, and it is our intention to continue setting aside certain sums to reserve fund, so as to prevent our spending everything earned by the Company.

A SHAREHOLDER: Undivided profits you had better call it.

The CHAIRMAN: Well, there was a difference of opinion as to whether it should be simply carried forward or set aside as a reserve fund, but the general opinion was that it was better to set it aside as a reserve fund, because then it is regarded as an amount that you cannot touch. Mr. Pugh, you must bear in mind we do not obtain our capital from the public at less than six per cent. If we invest our reserve fund we shall probably not get above four per cent., so that the effect of investing it would be that you would lose two per cent.

Mr. PUGH: I understand it is merely the nucleus of a reserve fund.

The resolution for the adoption of the report and accounts was then put to the meeting and carried unanimously.

The CHAIRMAN moved that Mr. John Bruce, of Edinburgh, be re-elected a director.

Mr. S. D. WILLIAMS seconded the motion, which was put and carried.

Mr. PUGH moved the re-election of Mr. W. A. Smith, of Glasgow, as a director, which was seconded by Mr. S. D. WILLIAMS, and carried.

Mr. BIGELOW moved the re-election of Mr. Jeremiah Garnett, of Manchester, which was seconded and carried.

On the motion of Mr. CARGILL, seconded by Mr. PUGH, the auditors, Messrs. Quilter, Ball, and Co., were re-elected.

On the motion of Mr. BIGELOW, seconded by Mr. NESS, a cordial vote of thanks was passed to the Chairman.

The CHAIRMAN said: I beg to thank you for the vote you have just passed. It will be the endeavour not only of myself as Chairman of the Company, but of all the Directors, to do all that is possible in the interest of the Company, and I have great satisfaction in saying that it is utterly impossible for the Chairman of any Company to be supported by a more energetic and intelligent Board of co-Directors, and I think, perhaps, it is somewhat of an omission that the vote should apply to the Chairman of the Company alone, and I would suggest that some shareholder in the meeting should move that it should be extended to the Directors of the Company. Our Directors, when they come to town, come from great distances. They have been elected and chosen for their position on the Board very much on account of their knowledge and influence in particular districts, and one and all of them give a great deal of attention to the interests of this Company in those districts. The prosperity of the Company is very largely increased by the intelligence and supervision they give to its interests in the various centres of the Company.

On the motion of a SHAREHOLDER the vote of thanks was extended to the Directors generally in accordance with the suggestion of the Chairman.

The proceedings then terminated.

An extraordinary general meeting of the National Telephone Company was held within the offices of the Company, 11, Queen Victoria-street, on Tuesday last, Colonel Raynsford Jackson presiding.

The SECRETARY (Mr. W. B. Campbell) having read the notice convening the meeting,

The CHAIRMAN said that having dealt so fully at last Friday's meeting with the subject for consideration to-day, it was not his intention to preface the proposing of the resolutions with any further observations. He would therefore at once move "That the capital of the Company be increased by the issue of 15,000 new shares of £10 each."

Mr. J. P. BIGELOW seconded the motion, which was carried unanimously.

The CHAIRMAN next moved, and Mr. J. S. HARRISON seconded, "That such shares be called Second Preference Shares, and that the holders thereof (subject to the payment of the preferential dividend on the original Preference Shares), be entitled to a cumulative preferential dividend at the rate of 6 per cent. per annum. After the Ordinary Shares have received a dividend at the rate of 6 per cent. per annum out of the profits of each year, the Second Preference Shares and the Ordinary Shares shall participate rateably, according to the amounts paid up thereon, in any surplus profits."

The motion was also agreed to *nem. con.*

On the motion of the CHAIRMAN, seconded by Mr. W. A. SMITH, it was also agreed "That the Second Preference Shares shall not confer any right of voting at any General Meeting of the Company, and in the event of the Company being wound up, the surplus assets thereof shall be applied, in the first place, in repaying to the holders of the original Preference Shares the full amount paid up thereon, and, subject thereto, in repaying to the holders of the Second Preference Shares the full amount paid up thereon in priority to any payment in respect of the Ordinary Shares of the Company."

This concluded the business.

NOTES.

AMERICA IN 1884.—During the year 1884 there were granted in the United States 1,074 patents for electrical inventions.

THE EARTHQUAKES.—A Reuter's telegram, dated Simla, August 14, says that shocks of earthquake are again being felt in Cashmere.

SUGGESTED.—A practical result of the recent visit of a scientific body to Lincoln would be the electric lighting of Lincoln Cathedral.

NEW ZEALAND.—It is believed that the old cable across Cook's Strait is broken. The cable had been down for 19 years, and had three wires.

TALL!—According to a Texas paper the corn stalks in that State are so tall and large that they are being used as telegraph poles by the Baltimore and Ohio Company.

AT THE OPERA IN PARIS.—The work of installing the electric light in the Theâtre de l'Opera, in Paris, is proceeding merrily. The inauguration is expected in October next.

THE ELECTRIC LIGHT AND ATHLETICS.—Eight electric arc lights have been placed in the Union Base Ball Park, St. Louis, U.S.A., to enable athletic sports to be carried on at night.

PROPOSED CENTRAL STATION AT DIJON.—It is proposed to establish a central electric lighting station to supply 500 lamps in the town of Dijon. The Edison Company have the matter in hand.

LONG DISTANCE TELEPHONY IN HUNGARY.—Satisfactory trials of long distance telephony have recently been carried out in Hungary between the towns of Csorna, Gallya, and Hereny, a distance of 110·36 miles.

THE TELEPHONE IN ROME.—The Italian Minister of Public Works has consented to the formation of the Società Romana Co-operativa dei Telefoni, thus uniting the two rival companies which have for some time existed in Rome.

HOSPITALITY.—The Town Council of Elgin have decided to entertain at the public expense 200 members of the British Association, shortly to assemble at Aberdeen, and to drive them to all the neighbouring places of interest.

THE ELECTRIC LIGHT FOR WAR SHIPS.—The largest of the new ships, the "Camperdown," barbette, is to be lighted throughout by electricity. The work, which will be carried out by Messrs. Siemens, assisted by the Dockyard staff, has been commenced.

THE TELEPHONE IN BELGIUM.—At 11 a.m. on the 9th proximo, at the Bourse de Commerce, Brussels, the contract will be let for the establishment and working of a telephone system in the town of Iseghem and its suburbs. The caution money is £400.

TELPHERAGE IN PHILADELPHIA.—The "telpherage" system is being experimented with in Philadelphia. Two cables are used, one above the other, the packages being suspended from the upper and steadied by the lower, and the cables serving as conductors.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th August are £2,141, as compared with £2,382 in the corresponding period of 1884. The April receipts, estimated at £7,790, realised £7,890.

THE EXPERIMENTS at CREIL.—The experiments at Creil will probably be concluded some time in the beginning of next month. The initial E.M.F. has, it is said, been reduced to 4,500 volts, but it yet remains to be seen if the insulation will resist so heavy a strain during ten consecutive hours per day.

LIGHTING THE GUILDHALL LIBRARY.—The Guildhall Library is shortly to undergo a thorough repair. Some dissatisfaction having been expressed at the present mode of lighting, hopes are felt that the City Lands Committee will consider the advisability of illuminating the library with the electric light.

MARRIAGE.—The *Morning Post* announces that a marriage has been arranged between Mr. D. Jardine-Jardine, only son of Mr. James Jardine, of Dryfeholm, Tinwald, and Torthorwald, Dumfriesshire, and Miss Mary Angela Bright, second daughter of Sir Charles Bright, of Bolton-gardens.

ELECTRIC LIGHTING IN THE NORTH OF ENGLAND.—The Edison Company, in addition to the Art Galleries mentioned in our last issue, are lighting the Manchester and Salford Bank, a large portion of Messrs. I. and T. Watts' Manchester warehouse, besides several gentlemen's houses, and other and smaller work in the same district.

ENTERPRISE IN AMERICA.—The Schuyler Electric Light Company, of Hartford, Conn., have obtained the contract for lighting the city of Richmond. The contract is for five years; and provides for lighting the city in such a manner as will make it one of the most brilliantly illuminated cities in the United States. That is saying a good deal.

THE TOMMASI RELAY.—This relay continues to give satisfaction in France. Trials which have recently been made of the relay between Paris and Toulouse, a distance of 483·6 miles, gave satisfactory results with 8 Callaud cells for the Morse instrument and 12 cells for the Hughes type-writer. The power used in ordinary working is, we are informed, about 125 cells.

NEW CABLES AND LAND LINES.—An American contemporary is informed that the Central and South American Telegraph Company has secured a commission to establish cables between Buenos Ayres and Rio de Janeiro, and land lines between Buenos Ayres and the Pacific side, thus securing continuous and independent telegraphic communication between the United States and Brazil.

ELECTRIC LIGHTING IN ITALY.—The municipality of Vazallo have recently decided to illuminate the town by electricity. The system to be adopted will be that of Cruto, and the streets will be lighted with 70 incandescent lamps. The current will be furnished by two dynamos driven by a turbine, as abundant water power is at hand in the torrent Sesia. Besides the public lamps, the dynamos will supply from 90 to 100 lamps in private houses.

NARROW ESCAPE OF THE EMPRESS OF AUSTRIA.—According to news received from Ischl, the Empress of Austria has had a somewhat narrow escape from what might have been a serious calamity. At five o'clock on the morning of the 13th, which is about the hour when the Empress takes her morning bath, her bath room was struck by lightning, the electric fluid knocking down Her Majesty's attendant, who was preparing the bath, and violently striking the parquet flooring.

A NEW APPLICATION OF THE INCANDESCENT LIGHT.—It is said that the incandescent light has been applied to the internal illumination of the telemeter by a committee of the German army. The lamp is placed in a recess normal to the main lunette of the telemeter, and between the eye and cross wires. The light of the lamp passes through a small hole in the wall of the lunette, and illuminates the cross wires. This

Digitized by Google

illuminating of the wires is found to double the distance that the telemeter will measure.

A CONVENIENT ARRANGEMENT.—An American railway company has introduced a new and very accommodating feature on the limited trains. The guard on each of these trains is supplied with a large package of envelopes, each of which is weighted with lead, so that they may be tossed from a moving train to the station by passengers who wish to forward telegrams before the train reaches its next stopping place. On the envelope are printed directions for the telegraph clerk to forward the despatch at once.

EXTENSION OF AN ELECRIC RAILWAY.—The electric railway, which has been in operation since April, 1884, between Moedling and Brühl, in the suburbs of Vienna, is about to be extended to Hinterbrühl; its length will thus be increased from 3 to 4·5 kilometres. The system adopted is that of Messrs. Siemens, by which the current is produced at a fixed point and transmitted to the motors of the cars by metallic conductors along the route. The power is at present generated by five dynamos, each giving thirty amperes, with a difference of potential at the terminals of 500 volts.

AUSTRALIA AND CABLE RATES.—Intelligence from Victoria reports that the committee of the Melbourne Chamber of Commerce had decided to request the Postmaster-General to endeavour to get the Governments of the various colonies to co-operate with him in trying to induce the Eastern Extension Company to lower the rate charged for telegrams between Australia and New Zealand. They had also decided to seek the co-operation of the Chambers of Commerce in New South Wales, S. Australia, New Zealand, and other colonies in urging the respective Governments to take action in the matter.

A ROYAL TRIP.—The Princess of Wales, and the Princesses Louise, Victoria, and Maud left Charing-cross on Wednesday evening by special train *en route* for Gmunden, the seat of the Duke of Cumberland, in Upper Austria. At Dover the royal party were met by Major-General Hon. P. Feilding, C.B., commanding the South Eastern District; Colonel Sir Cromer Ashburnham, K.C.B.; and the other members of the general's staff, by whom they were escorted on board the "Invicta," Captain Dane. The landing stage and the approaches were thronged with spectators, and were illuminated by electricity from the steamer.

IRON TELEGRAPH POLES.—Iron telegraph posts have been introduced with great success in Switzerland, and are now being extended daily. They have been already put up on Swiss railways a distance of 350 miles. In Prussia they have been placed experimentally on the railway from Weissenfels to Gera, and on the line between Berlin and Potsdam. As iron is now so cheap, it is considered that in a short time they will altogether replace the old wooden poles in Germany, that cause so frequent interruptions to telegraphic communication from rotting or being blown down by every high wind, especially in exposed situations.

THE TELEGRAPH IN SOUTH AMERICA.—The American Telegraph Company have opened telegraphic communication between Chillan, Talcahuano, Concepcion, Coronel, and Lota, and it is expected that the line in course of construction between Chillan and Talca will be completed by the end of the present month, which will place the port of Valparaiso in direct communication with the southern part of the Republic. A telegraph line is to be erected between Arica, in Peru, and Lapaz, the capital of Bolivia, the tariff to be two Bolivian pesos per word. The line is to be completed within six months. The Peruvian telegraph line is now in operation to Casma.

STRONG STATEMENTS.—Suit has been entered in the United States Court at Memphis on the 10th inst., by the Pan Electric Telephone Company against the American Bell Telephone Company. The bill filed charges that the Bell Company's patents interfere with the Pan Electric patents, and are, to that extent void; that the Bell Company has slandered and misrepresented the patents and inventions of its opponents; that the Bell telephone in use is not the one described in its original patent, which is used only to litigate with; that Bell was not the first and original inventor of the art, it being known to and described by Phillipp Reis, of Germany, who died in 1874.

THE ELECTRIC TRAMWAY AT BLACKPOOL.—Recently a special meeting of the directors of the Blackpool Electric Tramway Company was held, to take into consideration the general affairs of the company. Afterwards, Mr. M. Holroyd Smith, the engineer, ran two cars, crowded with people, to and from the shed to the promenade, an itinerant brass band playing on one of the cars. The smoothness in running and the facility with which the cars were started and stopped were admired, and the experiment showed that the cause which prevented the line being passed by the Government Inspector did not lie with the company. It is expected the line will be ready in about three or four weeks. Up to now, over 21,000 persons have ridden upon the car.

THE TELEPHONE IN TONQUIN.—The telephone system in Tonquin, extending from its centre at Hanoi, has already reached a development of about 160 miles. The main lines are three in number. The first of these is from Hanoi to Haiphong, following the course of the Red River and the Bambous Canal. This line, which is in connection with two submarine cables—one to Saigon, and the other to Hong Kong—was finished at the end of 1883. The second is from Hanoi to Hong-Hoa, by way of Son-Tay (37·2 miles); while the third is from Hanoi to Phu-Lang-Thuong, a distance of 28 miles. Phu-Lang-Thuong will serve as a junction for the two lines now in course of construction, one going to Kep, and the other to Chu. The number of messages circulated upon the three lines amounted during the first eleven months of 1884 to 151,000.

AN ENTERPRISING SCHEME.—It is said that a number of telegraph operators of St. Paul, Minn., have incorporated the Operators' Telegraph Company, with a capital stock of $10,000,000. It is intended by those who have the project in hand to extend the wires of the new company all over the country, and to compete with the Western Union Telegraph Company. The design is to make the company co-operative, and it is intended to enlist all the operators in the United States in the enterprise. It is claimed that stock to the amount of $100,000 has already been taken, and the work of construction will be at once begun as soon as $500,000 worth of stock has been subscribed for. The first line built will be from St. Paul to Chicago. It is thought that the requisite amount can be secured in six months' time, and that by spring the work will be prosecuted with vigour.

SCIENCE AND ART DEPARTMENT, SOUTH KENSINGTON.—The list of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships, May, 1885, is as follows:—National Scholarships: William Burton, Manchester; Philip L. Gray, Southampton; Charles Lang, Johnstone, N.B.; Thomas Clarkson, Pendleton, Manchester; William Kelsall, Bradford; Henry Sowerbutts, Manchester; Frederick Chattaway, Birmingham; William Scudamore, Northampton; Frederic W. Lanchester, Southampton; Thomas H. Holland, Helston; Harold E. Hey, Man-

Digitized by Google

chester ; William Blackmore, Sheffield. Royal Exhibitions: Harry E. Hadley, Worcester; Hugh O. Bennie, Glasgow ; James Young, Belfast ; Arthur J. Moulton, Preston ; Harold C. Coote, London ; Robert H. Unsworth, Pendleton, Manchester; Sidney H. Woolhouse, Weaste, Manchester. Free Studentships: David Wilkinson, Preston ; Henry P. Motteram, Small Heath, Birmingham ; Albert E. Briscoe, Birmingham ; Orlando J. Preston, Bristol ; James M'Kenzie, Glasgow ; Philip C. Coultas, Bristol.

POST OFFICE VOLUNTEERS.—The men of the 24th Middlesex, Post Office Volunteers, numbering 450 strong, returned to town on Saturday last, after a week's camping out and drill at Aldershot, under the command of Lieut.-Colonel du Plat Taylor. The weather during the greater part of the week was fine and warm, and although, as usual, there were some cases of sickness among them, the men on the whole return improved in health and vigour. On Friday the members of the Telegraph Signalling Corps were examined in flag-signalling by the Signalling Officer of the Wiltshire Regiment, the result of which has not yet been announced. Some of the telegraphists of the Reserve force who went out to Suakim with the last contingent have now returned to England, but are still encamped at Aldershot, probably with the view of recruiting their health before being discharged. But it was with much surprise and some indignation that the Post Office Volunteers found that their comrades, several of whom were invalided, had been placed at Borley Bottom in charge of a number of sick horses, suspected of being infected with glanders. This treatment of our volunteers after the hardships of the Suakim expedition is felt to be unfair, as well as impolitic.

SUCH IS LIFE!—The death lately occurred at San Francisco, in a state of destitution, of Johnny Skae, who some few years ago was estimated to be worth ten millions of dollars. He was employed at Virginia city as an operator in the California Telegraph Company when the four Bonanza kings—Flood, O'Brien, Mackay, and Fair—were developing their operations connected with the silver mines in California and Virginia city. They communicated with each other in cipher. Skae discovered the key to this cipher, and became aware long in advance of every one else of the marvels which were to astonish the public. All the money he could command or borrow he invested in shares of the two mines; and when the allotment was finally settled, and public excitement had somewhat cooled, it was found that the telegraph operator was worth $3,000,000. But he was not content, and speculated largely in much less safe investments, so that when the commercial crash came soon afterwards it quite ruined him. He disappeared from view altogether until about a year ago, when a policeman in San Francisco found him lying on the street at night hopelessly drunk. The man who some years before was worth ten millions of dollars, upon being searched was found to possess only a few small coins.

AN IMPORTANT ACTION.—Judgment was entered on July 24, in the United States Superior Court, against the Western Union Telegraph Company and in favour of James H. Goodsell, for $240,159.11. In appears in January, 1881, Mr. Goodsell, as president of the National Associated Press, made a contract with the Atlantic and Pacific Telegraph Company for the dissemination of news. The contract came into effect on Feb. 1, 1881, but on Feb. 3 the Atlantic and Pacific Company fell into the hands of the Western Union Company, which assumed to carry out its contracts. The Western Union Company in 1882 charged Mr. Goodsell greater rates, and stopped the service because he refused to pay them. In July, 1882, Mr. Goodsell brought suit against the Western Union Company to recover $22,000, which, he alleged, the company had collected from different newspapers for his service, and had failed to account to him for. He also asked for damages to the extent of $650,000 for a breach of contract. The Western Union Company alleged that the contract was invalid and fraudulent, and that a new arrangement had been made and carried out, but that finally Mr. Goodsell abandoned the work. For this they put in a counter claim for $15,000 damages. Of the judgment entered $220,306 is for damages and $16,777.42 for money due, the rest being interest.

THE ELECTRIC LIGHT IN BRAZIL.—A Brazilian daily paper, in commenting upon an installation recently put down in Para, says:—"Due to the perseverance and efforts of Mr. Carlos Monteiro e Souza, we witnessed a trial or exhibition of the apparatus which took place both at Merces-square and at the large commercial house of Messrs. S. Aguiar and Co. When the machinery was set in motion at the first of these places, the square was instantaneously flooded with light as brilliant and soft as the tropical full moon on a cloudless night. At the same instant the same effect was produced in the establishment of Messrs. S. Aguiar and Co., on the Rua da Imperatriz. The machinery is set up in a building, 32 × 13ft. A vertical (six horse-power) steam engine is used to run the dynamo. This little machine, which weighs only 600 pounds, has a pulley eight inches in diameter, which makes 1,400 revolutions per minute, while the drive wheel of the engine makes 245. The lamps and dynamo are of the Thomson-Houston system, the property of a large and enterprising company of Boston. The machinery was set up by the excellent machinist, Henrique Paiva, proprietor of the extensive shops on Merces-square. Mr. Carlos Monteiro e Souza, now an enthusiastic apostle of electric lighting, is forming a stock company in Para to furnish arc and incandescent light in the provinces of Para and Amazonas. It is said that he is soon to return to the United States to contract for the apparatus needed by the company."

THE NEW YORK UNDERGROUND WIRE COMMISSION.—The commission appointed to compel the telegraph, telephone, and electric light companies to take down their poles and place their wires under ground, in New York, held its first meeting for organisation at the Metropolitan Hotel, on 26th July. President Loew offered a long preamble and resolution, declaring that under the law it was the duty of the commission to cause all telegraphic, telephonic, and electric light wires to be put under ground, and that the commission proposed to do the work for which it was appointed as speedily as possible. The law requires that plans and maps, with estimates of cost, shall be filed by the companies with the Board within 60 days after its passage, or before 14th August, and if they do not do this the commission is authorised to adopt a plan of its own. It is the purpose of this Board, the preamble says, to cause the wires to be placed under ground, and the secretary is instructed to notify all persons or companies owning or controlling the wires above ground, that the Board will receive at the Metropolitan Hotel any plans, maps, or methods proposed for its approval, and that it requests that such plans be submitted as soon as practicable before the expiration of the 60 days prescribed in the law. The resolution was passed. The following, proposed by Mr. Hess, was also adopted:—"Resolved, that the owners, lessees, or occupants of houses be requested to refuse permission for the placing of any telegraphic, telephonic, or electric wires over or on their respective buildings, without first securing a permit

Digitized by Google

from this Board." Another resolution offered by Mr. Hess, requesting the companies to offer to the Board at its next meeting any plans which they may have for placing new wires above ground, was passed, and the commission adjourned.

OBITUARY.—The death is announced at Perth, Western Australia, of Mr. FLEMING, Superintendent of Telegraphs. We regret to have to announce also the death, at Santa Cruz, Teneriffe, on the 22nd of July last, of Mr. R. BALKWILL, of the Silvertown Company's submarine cable engineering staff. Mr. Balkwill had been in the Canary Islands since the end of 1883, and subsequent to that date had done a considerable amount of work in connection with the system of the Spanish National Submarine Telegraph Company; these operations included the putting down of underground land lines to connect the shore ends of the cables with the offices at Santa Cruz, Teneriffe; Las Palmas, Grand Canary; and Arrecife, Lanzarote; also the construction of stone cable houses in Lanzarote and Teneriffe, and various operations of lesser importance. Mr. Balkwill accompanied the expedition from the India Rubber Company's Works which laid the cables of the West Coast of South America Company, extending from Lima to Valparaiso, and also the later expedition which laid those of the Central and South American Telegraph Company, connecting Lima with the Isthmus of Tehuantepec in Mexico. He also has laid at different times various lengths of underground cable in connection with the Direct Spanish Telegraph Company's system, both at Falmouth and at Bilbao. Mr. Balkwill, who died of typhoid fever after an illness of only twenty-six days, at the age of thirty-eight, is deeply regretted by all who had the pleasure of knowing him. The death is also announced at Castellon de la Plana, Spain, from cholera, of Don NICHOLAS GIL DOBZ, a member of the Spanish Government Telegraphs. He was for some time stationed at the Las Palmas office of the Spanish National Submarine Telegraph Company, and was very popular with his English companions.

PROPOSED ELECTRIC LIGHTING AT NEWCASTLE. — At a recent meeting of the Newcastle City Council Alderman Newton moved the sealing of a memorial to the Lords of the Treasury, asking for sanction to increase the power to borrow money in respect of the Public Library from £22,000 to £25,000. He said £1,800 of the extra £3,000 for which they wanted borrowing powers was for the final completion of the library, and £1,200 was for the lighting of the library with the electric light. They did not propose to adopt the electric light at once, but desired to make provision so that in the event of its being deemed desirable at some future time to adopt electricity they would be able to do so without having to make another application to the Lords of the Treasury. If they could get the electric light at the same price as the gas, it would be a great saving to the Corporation, inasmuch as the gas was very prejudicial to the bookbinding, whereas the electric light was not so. However, his motion did not commit them to the adoption of the electric light. That would not be done without the special vote of the Council.—Mr. W. Smith seconded the motion.—Alderman Barkas moved that that portion of the memorial which referred to the £1,200 for electric lighting should be struck out. The electric light would be much more expensive than the lighting by gas. The latter cost at present £114 per annum. The electric light would cost about £370. Mr. Goolden seconded the amendment. After some discussion a vote was taken. On the amendment 17 voted for and 17 against; it was therefore not carried. The original motion was then put, and it was negatived by 20 to 16. It was agreed, however, that the memorial, so far as related to the £1,800 for general purposes, should be sealed, the opposition being entirely concentrated on the £1,200 for electric lighting.

SOME NEW EXPERIMENTS.—An observation of M. Felix Lucas upon the radiation of incandescent carbon has recently been communicated to the Academie des Sciences. The author begins by recounting how with inoxidisable metals heated in air the radiations, at first obscure, become more and more luminous as the temperature is raised. Thus, according to M. Pouillet, a temperature of 525° C. corresponds to a just visible red; and that of 1,500° C. to brilliant white. An analogous phenomenon is observed if carbon is heated, being previously placed in a vacuum to prevent combustion. When sufficiently heated, the carbon becomes a veritable lamp, thus showing the existence of a relationship between the temperature and the brightness of the radiations from the body. With a view to determine this relationship in precise terms, M. Lucas prepared an arrangement of apparatus whereby he could heat in vacuo (by the current from a De Meritens machine) some specimens of ordinary arc lamp carbon, 5 mm. in diameter, manufactured by M. Carré. He obtained formulæ by which he was able to calculate the temperature of the carbon corresponding to any observed intensity of current and illuminating value. By this means he was able to trace how the illuminating power increased with the heat from the first visible glow at 1,000° C., valued at only 3 carcels, rapidly up to over 300 carcels, and then slower, until at a temperature of 4,500° C., the luminous radiations were equal to 413 carcels. Up to this point, therefore, although the heat had been only increased in the ratio 1:4·5, the luminous intensity was increased in the ratio 3:413. Now, however, a curious phenomenon appeared. An increase of temperature from 4,500° to 4,750° C. only increased the light from 413 to 420 carcels; and a further increase of temperature to 5,000° C. actually had the effect of lowering the light to 413 carcels, or the same intensity as that produced at a temperature 500° lower. It is noteworthy, as contrasted with this, that the increase of temperature from 3,125° to 3,520°, or only 395°, doubled the light emitted from the carbon. Thus, after a certain point, increase of temperature has a lessened effect in developing light, until, beyond the maximum of 4,750°, heat ceases to provoke more luminous radiations, and even reduces their visual value. Consequently, in stating this most striking conclusion, M. Lucas expresses the opinion that it is probable that calorific radiations, at first obscure, then successively luminous from red up to white, finish by passing beyond the violet end of the spectrum, and thus cease to be visible. Heat may therefore be invisible because of its intensity as because of its feebleness.

A VOLTAIC CELL WITH A SOLID ELECTROLYTE.—"I believe that there has never hitherto been made a voltaic cell with a solid electrolyte which was capable of generating the smallest sensible current—at least at ordinary temperatures. Sir William Thomson found that when warm glass was placed between plates of zinc and copper, the existence of an electromotive force was indicated by an electrometer in connection with the metals, and Profs. Ayrton and Perry extended the observation to the cases of paraffin wax, gutta percha, india rubber, and shellac. But it is needless to say that with electrolytes of such enormous resistance no current could be generated of sufficient strength to be detected by any galvanometer, however delicate. On June 27 I exhibited to the Physical Society a little cell consisting of plates of silver and copper, between which was contained a mixture of one part of copper

Digitized by Google

sulphide with five of sulphur. When this cell was connected with a reflecting galvanometer it produced a current by which the spot of light was at once deflected off the scale, copper being the positive pole. The electromotive force was found to be ·07 volt, and the internal resistance 6,537 ohms. The current, therefore, though far more than merely sensible, was small. Attempts were made to reduce the internal resistance by diminishing the proportion of sulphur contained in the mixture, but it appeared that as the sulphur was diminished the electromotive force was also diminished, until, when there was no free sulphur at all, the cell failed to produce the smallest measurable current. It occurred to me that the sulphur owed its efficacy to the fact that it formed a film of silver plate by direct combination. I therefore made a cell thus :—A thin layer of copper sulphide was spread upon a copper plate and compressed into a compact mass against a surface of polished steel. A layer of silver sulphide was then spread upon the copper sulphide, and the cell was completed by pressing a silver plate upon the silver sulphide. The current which this cell produced through the shunted galvanometer was considerably stronger than that generated by the cell first described; but still the result was not quite satisfactory, and there seemed to be indications of short circuiting, which I thought might possibly be due to the penetration of particles of copper sulphide through the layer of silver sulphide. The silver plate was therefore removed from the cell, and having been brushed over with a weak solution of sulphur in bisulphide of carbon, it was heated over a gas flame, and soon became covered with a uniform and continuous coating of sulphide. The heating was continued until all the free sulphur was evaporated. When the cell was reconstructed with this prepared plate it produced a current of 6,800 micro-amperes through an external resistance of ·2 ohm, and was able to deflect the pivoted needle of an ordinary coarse galvanometer. The dimensions of the cell are as follow :—The copper and silver plates measure 2½in. by 2in.; the thickness of the two layers of sulphide (strongly compressed) is about 1-20in.; the E.M.F. is ·053 volt, and the internal resistance is therefore about 7 ohms. This cell seems to be exactly analogous in its action to a Daniell cell in which plates of copper and zinc are immersed in solutions of copper sulphate and zinc sulphate. Silver is probably the best (or only) possible metal for the positive plate, but some other metal might perhaps be substituted for the copper with advantage."—Shelford Bidwell, in *Nature*.

ELECTRICITY AND THE NAVY.—Speaking of the recent inspection by the Lords of the Admiralty, *The Times* says :—"It only remains to state, by way of conclusion, that remarkable progress has been made during the past twelve months in the general adoption of electric light apparatus in nearly all sorts and conditions of men-of-war, so far as search lights are concerned, though only a limited number are as yet fitted. The machines selected are also suitable for the internal lighting of the ships by the incandescent system, and there can be little doubt that the superior comfort and even the necessity of electric lighting will be soon universally recognised in a practical manner. There have been complete installations on board the Indian and other troopships, the torpedo ram, "Polyphemus," and the "Colossus," and there are to be similar installations in the "Collingwood," "Edinburgh," and "Impérieuse." At the beginning of the year a carefully conducted trial of a week's duration of the "compound wound" dynamos, known as the Victoria, was carried out in the "Colossus," which fully demonstrated that electric lighting on board ship, in addition to many other advantages over oil and candles, also possesses in a striking degree that of economy. These experiments, which were continued uninterruptedly day and night, were based on the actual requirements of a ship at sea, and doubtless hastened the decision to fit dynamos in all our fighting vessels. The cost of systematic trials of this kind has to be borne by the Admiralty. But the trials have already borne good fruit for the navy and country generally, and will amply repay the nation in the long run by reducing the expense of the lighting apparatus and the expenditure of fuel. It is also worth alluding to the other numerous and important electric appliances which have found a home on board our vessels of war. The ships are navigated from armoured towers or other protected positions, where are placed every requisite for fighting or navigating purposes. The commanding officer must be able to communicate readily by voice pipes with the battery or turrets, with the engine rooms, magazines, and various other parts of the ship. But it has been thought expedient in some ships to supplement the ordinary means of communication by telephones, and different systems are under trial. The experiments must, however, extend over a considerable period and under different conditions before it can be absolutely decided which is the best method to adopt, or whether, indeed, telephones can be relied upon in such ships in cases of emergency. But it is also necessary that the officer shall not only be in a position to convey his orders from the tower to the engine room and fighting stations, but that he shall also be certain that his instructions are understood and obeyed. This is accomplished by a system of electric telegraphs and revolution indicators. Electric steering telegraphs and tiller indicators are also necessary parts of a perfect equipment, and in order to enable the commanding officer to have complete control of the guns and torpedoes, so that he may be able to discharge all or any of them as required, electric firing currents are fitted, by means of which he has only to press a key, and so complete the circuit, to fire the guns or eject the torpedoes at will. In turret ships it is, furthermore, important that the guns should not be fired when directed, as they must be while the turret is being rotated, towards any part of the superstructure, or when they are depressed in some positions towards the deck. To prevent accidents arising from the non-observance in the heat of action of the precautions against accidents automatic electrical arrangements have been devised, by which it is simply impossible for the guns to be fired when at the 'dead points.' Additional electric combinations are necessary to enable the guns to be fired from the turrets instead of from the conning tower. These tend to further complicate matters on board, and without enumerating in detail other costly electric fittings of a man-of-war, we have only to add that auxiliary conning stations are provided in case of disaster occurring to the main positions, to show how absurd and misleading it is to compare, as is sometimes done, the cost of constructing an armoured with that of a merchant ship." One of the points still under consideration as regards the "Inflexible," previously visited, is the expediency of completely lighting her by electricity. Their lordships' experiences on board the "Colossus" must have removed any vestige of hesitation on their part as to the transcendent superiority of the latest system of illumination, as the "Colossus" is actually ready for sea with the exception of the trial of her guns. When, on their lordships going on board, the whole of the interior spaces were lighted by incandescent lamps the effect was so extremely brilliant that the visitors could not refrain from expressing their satisfaction. Among the estimates of the various departments of the Admiralty the following items appear :—For extension of electric shop, £700; lightning conductors, £900.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.

BY OLIVER HEAVISIDE.

(Continued from page 231.)

Simultaneous Conduction Current and Elastic Displacement.

In the ordinary intercourse of Man with his environment he is more or less accustomed to overlook, ignore, or treat as non-existent all phenomena whose recognition is not of immediate practical utility to him. (Plato, on the Celestial Harmony.) For instance, very few people are even aware, until their attention is forcibly called to it, of the multitude of most singular optical phenomena that occur in the everyday use of the eyes, some of them very difficult of explanation. Their perception would not be of immediate utility to the average man. They are therefore left unnoticed, as if they were not, until even recognition of them becomes difficult. The phenomena occur, and are seen by the eye mechanically, but the mind's eye is blind to them.

Most electricians, in a somewhat similar manner, are accustomed to confine their attention to only one part of the wonderful phenomena occurring during the existence of a conduction current. They may think of the wire, of its resistance, the current in it, and the E.M.F. causing it. Or possibly, in a more advanced stage, they may think also of the heating of the wire, and of external work done, as in driving a motor, with the necessary consideration of conservation of energy as regards the amount of work done. Still, however, it is the current in the wire that is the first object of attention, and what goes on outside it is ignored. This is perfectly natural, for what we call the strength of the current is the one thing that is, in the steady state, practically altogether independent of the external conditions; whilst again the steady state is of great importance, and may be brought under calculation with comparative ease. We are aware of the existence of an external magnetic field, and also of an electric field, or of an electro-magnetic field having two sides, the electric and the magnetic. They vary under different external circumstances, but as the steady conduction current is independent of them they are ignored. This independence, which is really a fact of an extraordinary character, is, by habit, taken for granted, and ceases to have anything remarkable about it.

If we have a closed circuit with a steady impressed force in it, there results a steady current in the circuit, whose strength is calculated from the data relating to the wire itself, and is independent of the distribution of matter around, provided we do not disturb the insulation at the immediate surface of the conductor. If we bring a mass of iron near the circuit, or in general alter the distribution of external matter as regards its permeability to magnetic induction, there results merely a momentary disturbance of the conduction current. When this has ceased, the current is just as it was before, although the external state has been considerably altered, there being in particular a different magnetic field, and a change in the distribution of the rays of energy converging to the wire. This, with the similar transient disturbance of current by motion of a magnet or another closed current, comprises what is ordinarily understood by the induction of currents. Only the magnetic energy is concerned, in the main.

There are also the inductive effects due to alterations, not of the magnetic permeability, but of the electric capacity outside the wire, or by altering the external electric field. The current induced, or the alteration made in the previously steady current, is, as in the case of magnetic induction, transient only, and no disturbance is produced finally in the distribution of current. (Except indirectly, as by altering the structure of the wire itself, and its conductivity.)

The effect of surrounding a wire supporting a current with soft iron is to decrease the current temporarily. On the other hand, the effect of surrounding it with gutta percha is to increase the current on the whole temporarily, it being increased in that part of the circuit next the source more than it is decreased in the other part. If in the former case T be the increase made in the magnetic energy, the battery does 2T less work than if the iron had not been brought to the wire. In the latter case, if U be the increase made in the electric energy, the battery does 2U more work than if the gutta percha had not been brought to the wire.

Both the inductions, electrostatic and magnetic, are in simultaneous action always. In a large class of cases, however, especially with condensers, the magnetic induction is of comparative insignificance. In another large class, as of coils containing iron, and circuits closed, the electrostatic induction is negligible. In intermediate cases, when neither is negligible, we have very complex effects. But in all cases there is no permanent effect on the distribution of conduction current, however greatly the electric and magnetic fields outside the circuit are permanently altered, and likewise the manner of transit of energy from the source to the parts of the circuit away from the source. In brief, when the impressed forces are given, the conductivity conditions alone determine the steady state of the current. And, although it is not at once seen, the same is true whatever electric capacity (or permeability) the conductor itself may possess, so that there is interior electric (or magnetic) energy. The latter is recognised. Also, the electric capacity of very bad conductors is known. But there is little or no information regarding the capacity of good conductors, though, for various reasons, I believe in its existence. The coefficient of permeability μ is known to never vanish. That of conductivity k has an enormous range, and may perhaps also vanish altogether—for instance in planetary space, if nowhere else. Similarly, the coefficient of electric capacity c may have a larger range than it is at present supposed to have in bad conductors. We tacitly assume $c=0$ in good conductors in general.

It will be understood that in thus speaking of the electric capacity (specific) of a conductor, we do not in any way refer to the Capacity of a Conductor of electrostatics, which is really the capacity of the surrounding dielectric, by all analogy with usage in the corresponding conduction problems. We refer to the specific capacity of the material of the conductor for elastic displacement in itself. This has, of course, nothing to do with the nonconducting dielectric outside. It is sometimes said that the specific capacity of a conductor is infinite. This is a mischievous delusion. It is tolerable, for mere mathematical purposes, sometimes to assume $c=\infty$ in a conductor, and ignore its conductivity altogether; *i.e.*, do away with the conductor, and substitute for it a dielectric of infinitely great specific capacity. We may, similarly, sometimes conveniently replace a voltaic cell (mathematically) by a condenser of infinite capacity and constant difference of potential. Or, we may consider a modern accumulator as a condenser for limited purposes, in spite of the obvious radical difference in their physical nature. But the absurdity of considering a conductor as of infinite specific capacity is readily seen. For although we may, by increasing greatly the specific capacity of a dielectric, imitate, in some respects only, a conductor, yet as specific capacity refers to elastic displacement, such displacement must afterwards subside when allowed to, which is wholly different from the behaviour of conductive displacement, which has no tendency to return. The proper condition is not $c=\infty$, but $c=0$ (unless we know there is elastic displacement in the conductor, as we do when it is badly conducting), with the auxiliary condition, k finite. Conductive and elastic displacement are wholly distinct things, and may be combined in any proportions. The former dissipates energy, the latter stores it.

In the following is an investigation of the general problem of steady impressed electric force and electrification in space with any distributions of electric capacity and conductivity. So far as I know, it has not hitherto been fully treated, but only piecemeal, and under limitations. For instance, Maxwell's treatise does not consider impressed force in the dielectric at all, and the capacity of conductors but imperfectly. Nor, again, is the determination of the state of the dielectric due to currents in conductors treated, which presents some curious peculiarities. Also, it is of advantage to deal comprehensively with the matter, since in practice we really have this simultaneous conduction and elastic displacement, either at the same or at different places, but connected. Being too long for one section, the following will continue it.

Given k and c the electric conductivity and capacity for

Digitized by Google

conduction current C and elastic displacement D at every point of space, and also the distribution of impressed force e; find the steady state, or, rather, show how it is determinate. E being the electric force, we have

$$C = kE, \quad \text{div.}C = 0, \quad \text{curl}(e - E) = 0, \quad . \quad . \quad (86)$$
$$D = cE/4\pi, \quad \text{div.}D = \rho, \quad \text{curl}(e - E) = 0, \quad . \quad . \quad (87)$$

for the full statement of conditions at a point. First, the linear relations, viz., Ohm's law and Faraday's (or Thomson's or Maxwell's). The second of (86) expresses that the conduction current is continuous everywhere, and the second of (87) defines the electrification density ρ in terms of the displacement, viz., its divergence, the proper measure of the discontinuity of the elastic displacement. The third conditions are identical. They express that the actual force E is the sum of impressed e and of a polar force F, such that curl F = 0. If $c = 0$ at a certain place we have only (86) to consider; if $k = 0$ then only (87); if neither vanishes, then both. Also, there will usually be surface conditions, which will come later.

First imagine $c = 0$ everywhere, and k finite everywhere, that is, an infinite conductor whose conductivity nowhere quite vanishes, and of no capacity. Then we may write either

$$\text{div.}k(e + F) = 0, \quad \text{curl}F = 0, \quad . \quad . \quad . \quad . \quad (88)$$

and determine F; or else

$$\text{div.}C = 0, \quad \text{curl}(C/k - e) = 0, \quad . \quad . \quad (89)$$

and determine C. It is obvious that the first of (88) has any number of solutions for F; we must then show that one (and only one) of them satisfies the second of (88), thus fixing F. Or, it is obvious that the second of (89) has any number of solutions for C; we must then show that one (and only one) of them satisfies the first of (89) thus fixing C. Thus, since the first of (88) expresses that C is closed, choosing any closed C settles F. Or,

$$kF = \text{curl}\,A - ke$$

is the general solution, wherein A is any vector whatever. Similarly the general solution of the second of (89) is

$$C/k = e - \nabla P$$

wherein P is a perfectly arbitrary scalar.

Now, whatever F and f may be, if $F_1 = F + f$

$$\Sigma F_1 k F_1 = \Sigma(F + f)k(F + f) = \Sigma FkF + \Sigma fkf + 2\Sigma Fkf$$

the Σ indicating summation through all space. But if F satisfies both of (88) whilst f satisfies only the first, the third summation on the right vanishes. For F is polar, and kf is closed, so that, by the elementary property of the polar force, $\Sigma Fkf = 0$ for any one infinitely small tube of kf, and therefore for all. Thus we are reduced to the first and second summations on the right side. The first is fixed, the second may vary, but is necessarily positive, every element of it being positive. Hence $f = 0$ makes the summation $\Sigma F_1 k F_1$ a minimum. But F_1 is any solution of the first of (88), whilst F is a solution of both, so we prove that any solution F_1 of the first which also satisfies the second of (88) makes $\Sigma F_1 k F_1$ a minimum. But this quantity has a minimum, for it is necessarily positive unless $F_1 = 0$ everywhere. Hence there is a solution of (88), viz., F, when $f = 0$. There cannot be two solutions. For, if F and F + f be both solutions of (88), we must have curl$f = 0$ and div.$kf = 0$, and therefore $\Sigma fkf = 0$, which can only be by $f = 0$, making F the sole solution.

We may treat (89) similarly. Let C satisfy both conditions, whilst C + γ satisfies only the second, so that γ satisfies curl$\gamma/k = 0$. Then the total Joule heat per second is

$$\Sigma(C + \gamma)k^{-1}(C + \gamma) = \Sigma Ck^{-1}C + \Sigma\gamma k^{-1}\gamma + 2\Sigma Ck^{-1}\gamma.$$

Here the third summation on the right vanishes, because C is closed and γ/k polar. The second summation is necessarily positive, therefore $\gamma = 0$ makes the heat a minimum. This closes the current, making C + γ become C, satisfying both conditions. As the minimum is necessary, the necessity of a solution of (89) follows, and that it is unique is shown by $\Sigma\gamma k^{-1}\gamma$ vanishing when γ is closed and $k^{-1}\gamma$ polar, requiring that $\gamma = 0$, if we assume that C and C + γ are both solutions of (89)

As regards (88), we may state the result thus. There is one distribution of polar force F, a linear function of which, namely, kF, has a given distribution of convergence, conv.kF = div.ke. Or there is one distribution of force E differing from e by a polar force alone, a linear function of which, namely, kE or C, is continuous everywhere. As regards (89), we may similarly state that there is only one closed current C, a linear function of which, namely, C/k or E, has a given distribution of curl, viz., curl C/k = curl e.

Or, assuming that Ohm's law and the continuity of the current are always obeyed, let C vary. Then $\Sigma Fk F$ is made a minimum by that one distribution of C which makes F polar. And, assuming that Ohm's law is obeyed, and also that F is always polar, let F vary. Then ΣEC, the heat, is made a minimum by that one distribution of the current that is completely closed.

The gist of the above, and also of the more abstruse and complex demonstrations that may be given, is expressed by the theorem $\Sigma FC = 0$, or, a polar force, F, does no work on a closed flux, C, arising from the property of a polar force that its total round any closed curve is zero. Given first Ohm's law, the linear connection between the actual electric force and the current density, and also that the current must be closed. If the impressed force be so distributed that it alone is sufficient to satisfy Ohm's law and continuity (that is, when div. $ke = 0$), the force e is the actual force and the current is ke. But should this condition not be complied with by the impressed forces it is clear that an auxiliary or complementary force, F, is required which, together with e, shall make up the actual force E to satisfy continuity and Ohm's law. The question, then, is, how is this complementary force to be found? Any number of F's may be made up, but only one of them is completely polar. We then have $\Sigma FC = 0$, and the total heat expressed by

$$\Sigma EC = \Sigma eC = \Sigma eke - \Sigma Fk F.$$

It is naturally suggested by this making of the total heat equal to the activity of the impressed forces, that we examine the effect of subjecting the complementary force, not to being polar, but to satisfying $\Sigma FC = 0$, or $\Sigma eC = \Sigma EC$, which is possible in other ways than by a polar force. Thus, knowing that F uniquely determined polar satisfies this condition, and supposing that E, C, and F represent the real solution, let us alter the current in any manner, keeping it closed, also obeying Ohm's law, and finally keeping the heat per second always equal to the activity of the impressed forces. Let f be the alteration in the complementary force, then kf is the alteration in the current, and is closed. Also the alteration of ΣeC is Σekf. But, by our final restriction above,

$$\Sigma(F + f)(C + kf) = 0, \text{ or } \Sigma f(C + kf) = 0,$$

which reduces to

$$\Sigma ekf = -\Sigma fkf$$

on putting $C = k(e + F)$, and then $\Sigma Fkf = 0$, F being polar and kf closed. But Σfkf is positive, hence Σekf is negative. Hence ΣeC is reduced. That is to say, any change made in C from the real current, subject to Ohm's law, continuity and conservation, decreases the heat and the (equal) activity of the impressed forces. Hence, in the real case, the impressed forces work as fast as ever they can, and this is by having the auxiliary force polar.

Taking a simple linear circuit, to exemplify, we find that there are only two solutions, the real, and C = 0. Both satisfy conservation (meaning $\Sigma eC = \Sigma EC$), but no other current will. But we need not be misled by C = 0 being, in this case, the only other solution than the real. For if we introduce a shunt, making three wires joining two points, and have an impressed force in only one of the wires, we may create additional solutions without number. For two simple circuits can be made containing the impressed force, furnishing two extreme solutions, in which no change from the real current is made in the current in one or the other branch not containing the impressed force. Between these extremes, by changing the current in all three branches suitably, we get any number of other solutions, in all of which continuity, Ohm's law, and conservation are satisfied. The heat varies from zero up to a certain maximum, which occurs in the real case; then the auxiliary force is completely polar, or has

Digitized by Google

a potential. Of course, did we ever find a seeming departure from the proper distribution of force related to the known impressed force, we should naturally ascribe it to *other* impressed forces, and so come back to potential again.

(To be Continued.)

BEHIND THE SCENES AT HER MAJESTY'S THEATRE.

The performance of the "Excelsior" ballet at Her Majesty's Theatre is an interesting one, viewed from a scientific as well as from a theatre goer's standpoint. In the first place, the story it unfolds and the moral that it teaches are both intimately connected with the traditions that guide us and the aspirations which urge us all to constant application and to renewed research. The second point of interest is a purely technical one, viz., the essentially practical application in this country of the arc light to purposes of stage illumination and stage effect. When installing the electric light, with all its accessories in a theatre, two great difficulties have to be met and to be overcome. The possibility of such requirements has not been contemplated in the construction of the building, and space, therefore, is limited. The engine and dynamo must be stowed away in a hole or corner, and yet in some position where they can be got at, and which meets with the approval of the insurance people. That is one difficulty. The second is perhaps less easily dealt with. The arcs must be at the wings, in a convenient position for handling when required, and yet so arranged as to be out of the way of the performers, scene shifters, scenes, and the various paraphernalia which cumber up almost every available inch of space at each side of the stage. These difficulties, suffice it to say, for the present have been surmounted, without expense, and by no other means than ingenuity and perseverance.

The opening tableau of the ballet is entitled the "Spirit of Darkness." The stage represents a Spanish town in ruins. A funereal night—a lugubrious silence only interrupted by the sounds of a bell inviting prayers for those who are condemned to perish at the stake. The Inquisition is all powerful. Terror reigns on all sides. The Genius of Darkness is rejoicing; he holds at his feet, conquered, a woman in chains. It is "Light!" "Thou," says he, "who wert at one time the glory, the progress, the civilisation of the whole world, behold what my power has effected! Where are the splendours of past ages? I now reign, and shall reign for evermore. Never shalt thou break thy chains." Suddenly Light revives. A mysterious power imparts to her a new life, her countenance brightens up, her chains fall off before the bewildered gaze of the Spirit of Darkness, and in prophetic tones she says to him:—"Thy reign is over, and the Future is mine. Thou shalt no longer spread discord and hatred among Mankind. Men shall soon speak to and understand each other from pole to pole. Thou shalt lie crushed by sublime discoveries, gigantic works, unexpected marvels." "No," cries the Spirit of Darkness; "I believe not in these marvels of the Future. And even were they realised I shall stand forth to combat and annihilate them." "Look," says Light; "look, and prostrate thyself before the Genius of Humanity." The scene is transformed; Light and Civilisation are united on the Terrestrial Globe in the Palace of Genius and Science.

The second tableau is called "Light," the scene being the palace of Genius and Light. In this palace, dazzling with riches and splendour, are gathered together the glories of all ages. In letters of gold are inscribed all the great works of modern times. Steam power, the Telegraph, the Isthmus of Suez, Mont Cenis. A new existence is opening for Mankind.

At the conclusion of this tableau, "Light" (Signorina Desovino) bears aloft a very ingeniously constructed portable arc lamp, the first we have had the pleasure of seeing. (Fig. 1.) It is a very neat and very effective apparatus, striking its own arc, giving a light of some 3,000 candle-power, and burning for about four minutes for each arc formed. We are not at liberty to disclose the details of its construction, but we cannot forbear to congratulate Mr. Shepherd, the electrician, upon the admirable manner in which his simple invention fulfils the required conditions.

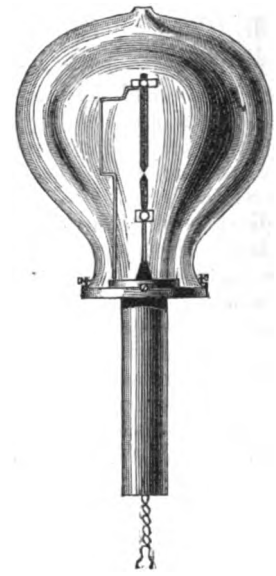

FIG. 1.—The "Excelsior" Hand Arc Lamp.

The third tableau represents "The First Steamboat," followed by the fourth tableau, representing "The Prodigies of Invention"; while the fifth depicts "The Discovery of Electricity." In his laboratory at Como, Volta, absorbed in thought and full of anxiety, is seated before his instruments. He is working, seeking, but cannot find. Something is still wanting to complete the wonderful discovery that is to transform the face of the Earth. A new thought flashes through his mind; he tries new experiments, and the electric spark appears. He falls on his knees, and offers up his thanksgivings to God. The Spirit of Darkness rushes towards the battery to destroy it, and receives a strong electric shock. He recoils. He remains for a while confused, paralysed—then darts forward again; but the Light interposes, and shows him the effects of this marvellous discovery.

The apparatus used for the demonstration of the "electric spark," or rather "arc," is of the simplest kind, it having been

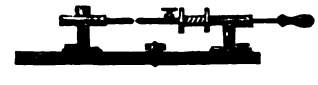

FIG. 2.

devised and constructed by Ernest Moy, nephew and pupil of Mr. Shepherd, and a lad apparently of sixteen years or so of age. This youngster acts, not only as assistant electrician, but is mechanician, stoker, engineer, and so on—a responsible and evidently capable person.

The sixth tableau, "Electricity," is laid in Telegraph-square, Washington. Light and the Spirit of Darkness are borne to the Central Telegraph Office at Washington. A crowd of little telegraph messengers come running out of the office. Light is triumphant and the Spirit of Darkness takes to flight blaspheming.

The remaining five tableaux continue to illustrate the progress of civilisation and the final defeat of the Spirit of Darkness and Ignorance; but for these it will be sufficient to mention that in the last tableau "Light," mounted upon a lofty pedestal, and bearing in her hand the "Excelsior" arc, crowns a very effective scene, and closes a fine performance. The light given by the ten arcs at the wings throughout the evening was extremely good, but not quite up to our idea of what should have been given by 20,000 candles. The so-called 2,000 candle-power lamps are probably nearer 600 candle-power than the former amount. The most remarkable thing about this installation, however, is the practical, the rough and ready manner in which it is worked. A good serviceable engine—an

Digitized by Google

8 horse-power Clayton and Shuttleworth portable—is stowed away in a narrow space adjoining the stage entrance, leaving just enough room for the dynamo, a piece of ¾in. india rubber tubing (feeding the boiler from a hydrant near by), and the engineer. The 8 horse-power is fitted with an enormous chimney, 70ft. in height, and a feed-tank of Lilliputian dimensions. There are no resistances whatever in the circuit, and not a switch-board or switch in the theatre; the leads being taken direct to the lamps, and any alteration such as would be caused by the extinction of any of the lamps being compensated for by "slowing down."

Just before the commencement of the performance an electric bell, actuated by the gasman at the wing above, notifies the youthful electrician to "stand by"—standing by, in his case, meaning the rapid adjustment of a brush to the dynamo; while a second ring has the effect of producing the burst of light which is such a valuable adjunct to spectacles of the "Excelsior" kind. The lamps used are the Maxim-Weston, arranged by Mr. Shepherd, whose knowledge of the application of the electric light to stage effect is probably unique.

We may mention that the whole of the work has been carried out in accordance with the Phœnix Fire Office rules, and has received the approval of Mr. Heaphy.

CORRESPONDENCE.

THE KAUFFER AND GOLDNER BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Like very many of the statements put forward in relation to batteries for electric lighting, the paragraph relating to the "Kauffer and Goldner" battery, quoted from an American source in your last issue, is somewhat difficult of mental deglutition. It would seem to imply that 2,432 candle-hours were obtained by the consumption of 4½lb. of zinc. Now, a pound of zinc cannot possibly be made to generate, even under theoretically perfect conditions, more that 1·14 horse-power hour; and 4½lb. of zinc could not, therefore, generate more than 5·13 horse-power hours. No result obtained in practice could even approach this figure. We are therefore called upon to believe that 2,432 candle-hours have been obtained by the expenditure of considerably less than 5 horse-power hours, presumably with an incandescent lamp. It would be interesting to know what lamp was used.—Yours, &c., DESMOND G. FITZGERALD.

DOUBLE-POLE SWITCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It was with pleasure I read in one of your contemporary's last week's issue a letter by Sir David Salomons advocating the use of double-pole switches in installations generally, and more especially where accumulators are employed.

Notwithstanding the many obvious advantages in favour of such switches they have been but little used in England, although in America, where electric lighting has taken such a firm hold, experience has demonstrated not only the desirability, but in many instances the actual necessity of using them.

Whether in large isolated plants or in central station lighting, the larger the number of lamps and the more extended the net work of wires so much greater has been the resulting gain.

The same remarks apply quite as much if not more to the use of double-pole "safety cut-outs," the additional facility in localising faults much more than compensating for the slight extra cost, and they have the cordial approval of Mr. Musgrave Heaphy from a fire insurance point of view.

That the advantages obtained are not of a mere hazy but of a material character is proved by the fact that in all the installations made by the Edison Company in America nothing but double-pole cut-outs and switches are employed.

An efficient switch must always be an important factor in a good installation, and in spite of the multifarious claims to perfection, it is only too well known that but very few switches will stand the test of time. In a double-pole switch considerable difficulty is experienced in constructing one that will fulfill all the requirements of strength, room for wires, good contact, and sharp "make and break," &c., and yet will at the same time be neat and not cumbersome.

The double-pole switches, which have been now extensively used for some time in America, are manufactured by Messrs. Bersmann, Edison, and Co., who manufacture all the Edison electrical fittings. Messrs. B. Verity and Son having been appointed their special agents in England, and being convinced that in a short time only double-pole fittings will be employed, have brought them under the notice of numerous electricians. A considerable number have been supplied for the large installation at the Hotel Metropôle, and they have the assurance of the electrical engineer, Mr. Holloway, that with such an extensive run of wires, and with workmen continually damaging them, the double-pole safety cut-outs more especially have been of immense service to him in coping with such difficulties.

In all the installations and wiring that our firm is at present carrying out, such as the Naval and Military Club, and the Criterion, &c., nothing but double pole fittings are being used, and I for one am sure that this is a step in the right direction of improved efficiency.—Yours, &c., JOHN B. VERITY.

A SILENO-DIFFERENTIAL RECORDER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Thanking you for the description of my patent Sileno-Differential Recorder, I wish to draw your attention to the fact that I have succeeded in overcoming an objection often raised against it that in the event of earth currents moving zero the apparatus would cease to work properly. This I have done by adopting an improvement suggested by Mr. N. Blackwood-Price, Superintendent of the Eastern Telegraph Company's Station, Trieste, by which the possible error of a moving zero is completely eliminated. I intend to bring my apparatus before the public at the next electrical exhibition of importance. Kindly insert this notice as appendix to the description of my apparatus you have given.—Yours, &c.,

VON TAUND-SZYLL.

SOURCE OF ERROR IN WEIGHING SMALL QUANTITIES.—A curious source of error in weighing delicate quantities has, according to our American namesake, latterly been discovered by a German, Mr. Hennig, of Wurzburg. Owing to a supposed error in results, Mr. Hennig made careful investigation, and found that the scales he was making use of were affected by the electrical condition of the rectangular glass shade which covered and protected the balance. The lever of the balance carries small sliding weights, called "riders," by which to obtain more delicate divisions than can be arrived at by arbitrary weights in the scale pans, and he found that wiping the glass shade above these produced sufficient electricity to raise them from the beam. Rubbing the shade lightly with a linen dusting cloth displaced the zero pointer several lines, while with silk or woollen cloth this error was materially less. The amounts of error thus engendered are shown as follows:—After the first rubbing of the shade the electrical charge held balanced 600 milligrammes, and at the end of two hours still balanced a weight of 10 milligrammes; while with silk or woollen rubbers, under identical conditions of the atmosphere, the charge was balanced by 150 milligrammes and 70 milligrammes respectively. The charge was dissipated by a Bunsen flame, instantaneously applied. Mr. Hennig purposes remedying the difficulty by attaching to the under surface of the glass shade a metallic grating with an earth connection, so that an accidental charge will be disposed of before it can do mischief.

TELEGRAPH CONFERENCES.

The final results of these periodic Conferences are of the greatest importance to civilised nations. There is a danger, however, especially to be feared when private interests are considered, seeing that these private interests, as we have before pointed out, can only have a vote at second hand. It is not to be expected that all differences will be settled by any number of conferences—at any rate till the Millennium has arrived. Nor must we forget that two distinct questions, scientifically and commercially, have to be considered. The first concerns the land lines, or the land telegraphic system, belonging to the various States; the other, that of the cable system, belonging practically to private companies. No doubt there has been a good deal of friction relating to the transmission of telegraph messages by land lines across the various frontiers; but very much of this has already been remedied, and what is evident at this Conference is that the settlement of many of these minor differences among the States and the Companies, which correspondence has failed to effect, will be arranged. These periodic meetings bring together the principals who control the various systems, and what was difficult, owing to distance, and could hardly be arranged by correspondence, becomes easy when it is possible to meet together and verbally exchange opinions. The result of all Telegraphic Conferences hitherto held has been to formulate certain rules and tariffs generally acceptable to those interested, and although as yet the Conference now sitting has not decided any single point, all the subjects are being well ventilated, and the instructions and opinions of the eighty delegates are being understood by each other, so that there is no reason to apprehend that the Berlin Conference will fail to establish some marked improvement in telegraphic operations.

With regard to the German proposition for a uniform tariff, which we referred to in our last issue, there seems to be very little doubt that it will not meet the approval of the delegates. The land lines are principally owned by the various Governments, and too many of the States are already struggling under the effect of a great deficit in their receipts for telegrams, so that such States as Russia, Italy, France, Austria, &c., are not prepared to accept any proposals by which they would increase that deficit to any appreciable extent. It may be, however, that some slight concessions could be made towards the proposal, more, perhaps, in a conciliatory spirit than from any real agreement with the principle. The main feature of all the discussions, both at the general Conference and at the numerous small gatherings, has been the question of how far the States and the Companies can be persuaded to reduce their tariffs, and how far could the principle of uniformity be adopted. It has, we understand, been strongly urged that all the States, feeling confident that the principle of the uniform tariff is correct, should of themselves adopt such a tariff, and leave those who do not at present adhere to this conclusion to further consider the question at some future time, and adopt it when practicable. We are inclined to think that a universal uniform tariff is an impossibility, and that some other basis of agreement will be found.

It is said that there are one or more projects believed to be generally acceptable, which will in the first place be considered by a sub-commission. The Companies have long known that a general reduction of their rates would be among the proposals to be urged, and subject to the various States, India, and the Colonies bearing their due share of the burden, the delegates have declared their readiness to advise their various Boards to agree to a substantial reduction of tariff. The reduction that the Companies can consent to depends in a great measure upon the definition of code language and the nature of the restrictions which shall regulate Press telegrams, if the latter are still to be accepted at reduced tariffs. Our readers know full well that the art of coding messages has arrived at almost a state of perfection; still, some people may not be aware that cases are known in which sentences consisting of over 120 words have been sent by means of one single code word. The pioneers of submarine telegraphy have had to meet and to overcome, for the benefit of their shareholders, the loss to revenue which they could not foretell, but which has arisen because of the coding system.

These commercial questions have been put forward again and again; but there is another view of the matter which, as yet, has not been duly considered. It is that so far as cables are concerned there is a limit, and a limit very soon reached when compared with land lines, to the number of signals that can be transmitted in a given time. When we deduct the time occupied by repetitions, and the time occupied by messages relating to the companies' own affairs, we can easily determine the maximum number of words of a given length that can be transmitted per day, and can as readily determine the price which should be paid per word, if such a maximum number of messages could be obtained. Hitherto a reduction of tariff has always resulted in a loss of revenue, and though we may talk a good deal about the interests of the public, simplicity of regulations, uniformity,

Digitized by Google

and general reductions, all these mean reduction of the revenue of the companies, leaving them the hope which "springs eternal in the human breast"—the hope of augmented traffic resulting from the changes. The whole subject is one which gives the gravest anxiety to the representatives of the Companies now at Berlin. When the general taxpayer has to pay the losses which result from Government business there is no end to the purse; but it is quite a different matter when private companies are compelled against their own convictions to attempt to comply with a system the benefits accruing from which are benefits principally to a class quite able to take care of itself, and quite able to pay for the services it requires.

SHIP-LIGHTING BY ELECTRICITY.

BY W. H. SNELL, A.S.T.E. AND E.

The electric lighting of ships engaged in the passenger service has become so general and is so highly appreciated by travellers that steamship owners are discovering the necessity of adopting this method of illumination even for second or third class vessels. The writer proposes to offer some remarks and suggestions which are likely to be of interest to owners of steamships who have adopted or are about to adopt the electric light upon their vessels. These remarks will aim at being of a very practical but quite untechnical character, and will to a large extent embody the experience which has been gained while having charge of an extensive series of installations on ship-board. These installations comprise altogether nearly thirty dynamos (of different types), several thousand glow lamps, and a few arc lights.

Among these ships is one which I believe was the very first to be lit by electricity, and it says much not only for the firm who undertook the work, but also for the method itself, that the original arrangements continue to work satisfactorily down to the present time. Nevertheless, as may easily be supposed, any modern installation will differ very widely, in almost every detail, from this early specimen. In certain departments of electric lighting—as, for instance, in the supply of electricity from house to house—we may still look for great advances, but this is certainly not now the case with regard to ship lighting. While it would be too much to assert that absolute finality has been reached, yet it is quite certain that no very great improvement remains to be made in any important detail. The only substantial gain that may fairly be expected in the near future would arise from a reduction in the price of glow lamps. But as the cost of lamps comes under the head of working expenses, we can take advantage of such reduction whenever it may come.

When any given ship is to be lit, the first question to be considered is to find room for the engines and dynamos. The position selected should be as cool and well ventilated as possible, should either be a part of the engine room itself, or readily accessible from that room, and should admit of steam connection with the donkey as well as with the main boilers. In a new ship a space upon the main or spar deck immediately forward of the engine room usually fulfils these requirements as far as possible. In vessels already built it is frequently possible to appropriate the oil room, which generally occupies the position above described. If there is no available space 'tween decks it will be necessary to get down upon the floor of the engine room, or in the last resort to cut a space out of the coal bunkers. But in this case it will usually be difficult or impossible to make use of the donkey boilers; the temperature will be much higher, and the machines more exposed to dirt and accident. The connection with the donkey boilers is only *necessary* when it is desired to use the the dynamos while in port, but if (as I fully anticipate) electricity is by-and-bye used on ship-board for other purposes than lighting, such facilities may come to be considered indispensable. For this and for other reasons I would venture to say, "Don't put your machines on the floor of the ship if you can possibly have them higher up."

Having determined the best position for the machines, consider next the choice of engines and driving gear. This selection will largely depend upon the amount of space available and upon the speed at which the dynamo has to be run. This speed may be anything from about 300 revolutions per minute up to 1,000 per minute, or even higher. We will consider this point more in detail later. But supposing for the present that we know the required speed, we have (principally) four available methods of driving the dynamo.

(1.) By coupling direct to a high speed engine.

(2.) By rope gearing with grooved pulleys.

(3.) By a short belt run over a tightening pulley.

(4.) By friction gearing.

An internal cog wheel gear has also been tried with some success, but of this plan the writer cannot speak from experience. One would suppose that the noise would often be very objectionable.

(1.) The first plan has much to recommend it, especially where space is limited. The absence of gearing in any shape or form also entirely obviates one possible cause of break down. There is more than one pattern of high-speed engine which works with remarkable smoothness and gives wonderfully little trouble, frequently running for months together without being overhauled. The consumption both of oil and steam in this class of engine is relatively rather large, but on a big ship the cost of steam for this purpose is not a matter for very serious consideration, although it cannot be altogether overlooked. In the earlier forms of high-speed engine the quantity of oil required was sometimes rather alarming, but in the later patterns this has been reduced (in all cases that have come within my knowledge) to very reasonable limits. When this plan is adopted it is a decided advantage to make use of a flexible coupling between the shafts of the engine and dynamo. One advantage of this form of coupling is that it tends to compensate for any small want of truth in setting the machines in line.

(2.) The system of driving by cotton rope gearing requires considerably more space, but it permits of the employment of a somewhat more economical class of engine. It is necessary in this case that the machine be mounted upon a sliding bed, to permit of the ropes being tightened whilst running. The ropes should always be protected by being boxed in as far as possible. They may be kept in good condition by being liberally treated with a mixture of black lead and tallow—as there are usually upwards of 10 or 11 turns of the rope there is little or no slip even with the grease. The ropes should, of course, be frequently examined, and should be renewed long before there is any chance of their being outworn. A case came to my knowledge in which, from lack of the precautions here mentioned, a rope gave way, and lashing around a dynamo destroyed the machine.* Still, with reasonable care, I believe the method to be quite trustworthy. In the two instances under my charge there has never been any trouble of any kind with the ropes.

(3.) The third method of driving, that of a short belt passed over a tightening pulley, should also prove satisfactory enough when properly applied. So far as my own experience goes I am only acquainted with one set of two machines fitted with such gear, and they were under my charge only for a short time. In this case link belting was employed, and some trouble was caused with one of the machines by the belt breaking more than once. But this particular case was probably not a fair test of the method. The whole installation had been unsatisfactorily laid out, and I had reason to believe that, owing to defective insulation, the dynamo was doing far more work than was bargained for. Link belting is certainly the right thing to use in this case, where the belt is bent in each direction.

(4.) The fourth method is that of friction gearing. The arrangement introduced by Messrs. Siemens Brothers and Co., in which the dynamo pulley is faced with papier-machie and runs upon a larger wheel upon the engine shaft, gives excellent results. I am not aware up to what power it has been

* I was shown pieces of the machine in a hamper, but was not able to investigate the facts.

Digitized by Google

worked successfully. I have not used it for transmitting more than about 6 horse-power. This gearing should be boxed in, or some day an oil can will be placed upon the wheel just as the machine is about to be started; such an incident would produce much inconvenience.

We will next consider some of the points of a good dynamo for ship lighting. First, it is desirable that it should be "compound wound," in order that it may be self-regulating; that is, in order that the same current may be supplied to each lamp, no matter what number of lamps may be burning. It therefore follows that we should prefer a continuous-current machine to one giving alternating currents, as the latter cannot be made self-regulating—at least not in this simple way. It is true that very good results have been obtained in ship-lighting by alternating machines, but the special advantages claimed for them—such as absence of sparking—are now equally well secured by almost any modern continuous current machine for incandescent work. Electrically speaking there is very little to choose between the six or eight different machines of the leading makers. They none of them convert into electricity much less than 80 per cent. of the power supplied at the pulley. It is chiefly important to be satisfied that the mechanical construction is good, that the machine is capable of standing a certain amount of rough usage, and also that it can make a run of at least eighteen hours without overheating. For a reason to be mentioned later it is also desirable that the insulation resistance between the wires and the frame of the machine should be as high as possible. This point is of much greater importance in ship lighting than ashore, although it is not one upon which a purchaser can very readily satisfy himself. The armature should be capable of being easily removed and replaced by the engineers of the ship. It is, or should be, very seldom necessary for this to be done; still, it is as well to carry a spare armature in case of accident. The commutator (that is, the small copper bars which are set around the armature shaft at the end opposite to the pulley) should be an inch or so longer than the width of the brushes which bear upon it. And the brushes should be capable of being slightly shifted in their holders along the line of the armature shaft. By this means, if the position of the brushes is slightly altered at frequent intervals, any grooving of the commutator is obviated. If, as is preferable, there are two brushes side by side it is desirable that the brush holders should be capable of independent adjustment. Unless this is secured it will be necessary always to use brushes of almost exactly the same length in each holder. Possibly in some later machines this point is of less importance than formerly. I have usually found a plain flat brush made of copper wire much cheaper, and more easily adjusted by the men, than those made of copper strips with slant cut ends. The flat brush can be used down to the stump, while the other cannot; it is, however, necessary that the men should understand that it is not desirable to economise in brushes at the expense of the commutator.

Continuous current machines have armatures approximating towards one of two types, usually known as the disc and the drum. There are several well-known machines of each type, between which it may be difficult to make a selection. If in any case all other things are substantially equal, it is, perhaps, well to choose the disc type, mainly on the ground that the armature is more accessible for repairs, more likely to have a true balance, and more easily ventilated. Still, there are very fine machines with drum pattern armatures.

In order that the rolling of the vessel may not have a prejudicial effect upon the bearings of the armature shaft, it is desirable that the machine should be set with its spindle fore and aft, and not athwart ships. It should also be noticed whether the oiling is likely to be efficient under any probable list that the ship may receive. A special oil is made for use with dynamo machines. This oil is free from the acid which is usually present in machine oils, and which tends to affect the insulation of the coils.

As we have already said, if the machines are "compound wound" practically the same amount of current will pass through each lamp, no matter how many lamps may be burning. This, however, supposes that the dynamo is always driven at the same speed. If the speed increases to any extent, the current through each lamp is increased possibly so much as to destroy the filament. In any case the result will be to shorten the life of the lamp. Now there are two causes which tend to vary the speed of the engine. The first is a change in the steam pressure; the second is any alteration in the load, that is in the number of lamps alight. In order to compensate for change of steam pressure, the engine must be fitted with a governor sufficiently sensitive to maintain the proper speed within the permissible limits under any probable variations of pressure. And in ship-lighting, if the governor is capable of doing this, and if other things are properly arranged, we need not trouble ourselves very much about the second source of irregularity in speed. In giving this as my opinion I am perhaps diverging from the views expressed by some of the highest authorities. But the case usually considered is one in which, from my point of view, the other things alluded to above were *not* properly arranged, or at least not as well as they probably might have been. There are, in fact, two conditions which must be fulfilled in order that we may dispense with an automatic regulation of speed, so far as variation in the load is concerned. The first condition is that the circuits should be arranged so that every dynamo supplying any state room lamps should also supply a certain number of "ship" lamps. Now, the state room lamps, including those in the officers' berths, alone are liable to be turned "off" or "on" at pleasure. All other lamps which I call "ship" lamps can very easily be placed under the charge of some one, who alone should be entrusted with the duty of switching the lamps on or off. The lamps in the saloon, smoking room, ladies' cabin, engine room, stokehole, passages, &c., will almost all be lit at dusk, and will only need to be extinguished at some given time.

Most of these lamps will be turned on or off in batches, and not one at a time. Under these circumstances it is only necessary that the lamps should not be switched off until warning has been given to the man at the engine. He then *first* slows down the machine so as to perceptibly diminish the light; this acts as a signal to the other man that he may now proceed to switch off the lamps, and the driver finally readjusts the proper speed. By this simple plan it is impossible for the engines to race when the load is diminished. As for the state room lamps whose use is left at the discretion of the passengers, by taking care that as far as possible they are supplied by machines which are *also* running ship lights, we have a guarantee that the load will never be unexpectedly increased or decreased except by a certain small ratio. The maximum value of this rate per cent. is known, and in practice of course we never get more than two or three lamps extinguished at once, so that the speed can easily be kept right by the man at the engine.

From what has been already said it will be understood that a tachometer, to indicate the speed at which the engine is running, is an indispensable part of the equipment. These instruments require, however, to be carefully cleaned and oiled at regular intervals if their indications are to be relied upon. It is very desirable to check them occasionally with a counter or speedometer. It is also necessary to run a pilot lamp from each machine; the lamp and the tachometer then to a certain extent act as a check upon one another. If, however, the lamp should become over bright while the tachometer does not indicate an increase of speed, it is better to believe in the lamp. I once heard of a man who was of a different opinion. His tachometer having struck work he drove up the machine until the lives of several lamps came to a sudden and untimely end. Such a man should be promoted at once to another sphere of labour.

Before we quit the engine room there are still one or two points that may be mentioned. It is better to employ at least two separate machines rather than to rely altogether upon one. Then, if an accident does happen to either machine we can still keep the saloon and the engine room lit up. It is often convenient in large installations to employ two machines of equal size, together with one smaller one. We can then use the small machine alone for the lamps which are kept burning all night, or for such work as running an arc light upon some special occasion.

Digitized by Google

As to the best speed for ships' dynamos it should be remembered that very slow machines are as a rule not so efficient as those which run faster. "Very slow" may be taken to mean anything less than 400 revolutions per minute. However, anything up to 800 revolutions, or even higher, may be accepted.

We will now proceed to consider the "wiring," which is one of the most important parts of an installation. It is most essential that the wires should be of sufficient size, and that they should be thoroughly well insulated and sufficiently protected *in every part of the ship*. If they are not large enough some of the heat which ought to be generated in the lamps will appear in the wire instead. If the insulation is not good enough, not only is there a leakage of current, but in the presence of moisture the wires tend to corrode. It is, however, quite a simple matter to provide most thoroughly against each of these dangers. The proper sizes of wires so as to unite economy with perfect safety are now thoroughly well understood. The insulation of the wires may also be relied upon so far as the electric properties are concerned. It is, however, desirable to insist upon the use of an insulation specially prepared to withstand the action of damp and sea salt. But even when this class of wire is employed it is very desirable that the wire should be protected as far as possible from exposure to sea water. In some early installations this protection was very effectively secured by enclosing every wire in iron piping. This plan has, however, so many disadvantages that it is impossible to recommend it. It is very expensive, it takes about five times as long to put up, it is not nearly sufficiently flexible, and when the wires are once safely enclosed it is next to impossible to get at them again. The only places where tubing is sometimes really necessary is in the engine room and stoke hole. Even there I much prefer to use an insulated conductor, bound around outside with a strand of galvanised iron wire. This plan was first introduced by a Glasgow firm, and it is a distinct improvement. In other parts of the ship, wherever, from damp or other causes, wooden cleating is not a sufficient protection, lead cased wire may be used with great success. In the Royal Navy they are now trying the plan of sinking the wires in wooden grooves, and filling in with white lead or some similar composition. This method may be expected to answer in places where the wires once put up are never likely to be disturbed; but in the merchant service, so far as my own experience goes, such finality is frequently unattainable, and for one reason or another the wires have often to be reached. I therefore much prefer, whenever any special protection is required, to have the protection attached to the wire itself, and I have found the lead covering to answer every purpose. It is not very expensive, it resists salt water, and it is easily removed at any point when a joint has to be made, and as easily replaced.

It may be worth while in this place to draw attention to the necessity of seeing that all the wires, brackets, switches, &c., are attached only to the permanent fittings of the ship. To those who are acquainted with the exigencies of the merchant service this will not seem a superfluous recommendation. I have known a case in which a new ship was fitted with about 500 lights. About 100 of these were placed in the state rooms and passages on the lower deck, and were attached to the wooden partitions in the usual manner. But as soon as the ship commenced running it was found necessary to use the lower deck for stowing cargo upon the outward voyage. For this purpose every vestige of the state room fittings was removed at the home port and replaced at the foreign port on each voyage. It was therefore necessary to supply an almost entirely new set of fittings for the lower deck, and to attach the whole to the iron beams or other permanent structures. Of course much expense would have been saved had this been done in the first instance.

Another thing which requires special care in this connection is in passing the water-tight bulkheads. This is a point at which no liberties can be taken, and the wiring should be arranged so as to traverse these partitions at as few points as possible. For the largest cables a stuffing box may be employed, but it is usually sufficient to pack the cable with wood, which can then be swollen. Upon the main deck it is sometimes best to go *over* the bulkhead instead of going through it. For this reason, among others, I distinctly prefer the "single" wire system in which the current returns to the machine through the skin of the ship. We have therefore little more than half as much wiring to put up, and, of course, the cost is proportionately less. In common, I believe, with most electricians I looked upon the single wire system with much distrust when it was first introduced. But also in common with almost all who have had experience of both plans I am now prepared to give it a decided preference. The advantages alleged in favour of the double wire are that the total insulation of the system is considerably higher, and that the chance of "short circuits" is very much reduced. But if other details are properly arranged, the chance that a "short circuit" will occur, or that it should do any harm if it does occur, may be equally disregarded upon both systems. I am acquainted with a ship in which one part was wired with double wires, and at a later date the lower deck was fitted with single wires. As a matter of fact the only troubles as to insulation that have occurred have always been with the double wires; and this has, I believe, been the experience of others under similar circumstances.

When a single wire is used it is necessary to connect the other terminal of the lamp to the ironwork of the ship. For this purpose a connection is made between one side of the lampholder and the metal work of the bracket. If the bracket is attached directly to the ironwork this is all that is required, but if not an uncovered copper wire is taken from the bracket to the nearest convenient point, and there secured between two copper washers which are threaded upon a $\frac{3}{8}$in. screw tapped into the iron. It will then be impossible for any one to obtain sparks from any part of the bracket while the current is on.

It was in view of the employment of this method that I said that it was desirable that the insulation between the brushes and the iron frame of the dynamo should be higher for ship lighting than for shore work. If, however, the dynamo is bolted upon a separate foundation, it is possible to insulate the whole machine from the ship more or less effectively. But obviously this cannot be done when driving direct from a high-speed engine, or by means of friction gearing, or in any case where the engine and dynamo are upon the same bed-plate.

As we have now got back to the engine room, we may consider next the switches and safety fuses which are there required. The particular pattern of switch-board which should be adopted will depend upon the size and character of the installation. It is desirable that facilities should exist for running any one of the machines upon any one of the circuits, and for making such changes rapidly when necessary. If, however, we have machines of different sizes, we must be careful to make it impossible to run the smaller machine upon circuits containing a larger number of lamps than it is meant to carry. It should also be impossible to place two machines upon the same circuit at the same time. It will usually be necessary to make use of some form of plug switch-board. In this, the connections are made by placing brass plugs in holes slightly countersunk on a system of cross-bars. The bars should be mounted upon a slab of slate, or some other incombustible insulating material. It is very necessary to adopt some plan for locking the plugs in their positions; there are several methods in use all about equally good. The plugs should be kept perfectly clean, and a spare set should always be at hand. Whenever possible, it is much better to slow down the machines before shifting plugs. For large machines it is best to have a good make-and-break switch in the main circuit as well as the plug board.

A safety fuse should be placed in the main circuit of each machine; it should always be connected between the machine and the switch-board. It is desirable that these main fuses should be of some form which, while preventing injury to the machines, will not be liable to cause unnecessary interruptions to the circuit. Such arrangements have not yet come into very general use, but there is no reason why they should not be insisted upon.

In other parts of the ship the switches are mainly of two kinds, those for single lamps, which frequently form a part of the bracket, and "section" switches, one of which is usually supplied for each distinct group of lamps, and is generally turned by a key. The essential thing to be required in these

Digitized by Google

switches is that they should always stand either full on or full off. Any switch which will remain in an intermediate position should be condemned, for it will very likely cause sparking. It is not desirable to have too many lamps upon one section switch; the lamps in the saloon, for instance, should be divided into groups of, say, 30 or 40, and each group should have a separate switch. It is customary to divide the state rooms in the same way into sets of 15 or 20, and to provide each set with a section switch in addition to those attached to the lamps. This plan requires more wire, but it presents several advantages. It enables us to cut out any part of the installation which may have received serious damage, so that it shall not interfere with the working of the remainder of the lamps. Besides this it obviates the use of a special set of wires for the "night light circuit." Those lamps which (in this part of the ship) are to burn all night may be connected with the positive side of the switch. These lamps are therefore still connected with the machine after the switch has been turned off. The plan has a further advantage, inasmuch as after turning on the section switch a light may be obtained in any state room if required at any time of the night. All switches should be carefully cleaned at intervals.

It may be taken as a general rule that wherever there is a switch there should also be a safety fuse; and the fuse should be upon the side next the machine. For lamp switches and for all section switches, except those of the largest size, the fuse may be of the simplest character. I have always found that lead wire answers the purpose admirably, although probably a thin strip of tin is better still, at any rate for section switches.

With regard to lamp brackets there is little to be said; their style will, of course, depend mainly upon the character of the ship's fittings. For the state rooms it is better to have bracket, fuse, and switch all in one piece. In the saloons it is a good plan to have three-branched pendants over the tables, so as to avoid throwing the shadow of the glass holders (which usually hang alternately with the lamps) along the tables. Until recently it has been the general custom to make the same bracket carry both oil and electric lights in the saloon. However, now that greater confidence is felt in the electric light, this is being abandoned, much to the advantage of the latter. If in any case it is still considered necessary to supply oil lamps, the brackets will of course have to be very much heavier articles. It is then desirable to see that a special metallic connection is made with a piece of copper wire between the bracket and the iron beam from which it is hung. If this is not done, after a voyage or two the lamps will often go in and out as the ship rolls, owing to the bracket not making good electrical connection with the iron. This remark of course applies only to the single wire system. In the engine room the brackets should be very short, so as to project from the walls as little as possible, and it is desirable to enclose them in wire protectors.

It is often desirable to have facilities for carrying portable lamps into certain parts of the ship. For this purpose the best plan is to have pairs of terminal screws (with switch and safety fuse) placed at convenient points. These terminals should be enclosed in a wooden box provided with a lock and key. When required a piece of flexible double wire cable is attached to the screws at one end, and the other end of the cable passes into the portable lampholder.

The essential points of a good lampholder are that it should make thoroughly good contact with the platinum loops without putting an undue strain upon them, and that it should be easily fixed or detached from the bracket. It should also hold the lamp with a somewhat elastic grip, so as not to transmit the vibrations of the ship to the filament of the lamp any more readily than can be helped. When a lamp has to be changed the holder should invariably be removed from the bracket with the lamp attached; and similarly the lamp should first be connected with the holder, and then the holder with the bracket. In large installations attention to this rule will save a lot of breakages. In hanging lamps, especially high-resistance lamps with long filaments, it is better to place them so that the plane of the loop lies athwart ships. This will obviate the tendency of the loop to swing with the rolling of the ship. The carbon of the loop is probably in a semi-plastic condition while hot, so that its period of vibration is lengthened sufficiently to enable it to respond to the roll of the vessel. At any rate, I have found that, with high-resistance lamps, in upwards of 75 per cent. of lamps which have been burnt out the loops have given way at the place where the greatest strain would have occurred had they been subjected to such vibration.

I have as yet said nothing as to the selection of the incandescent lamp itself, possibly because there is at present very little to be said. It will be some time yet before sufficient data will have been accumulated to enable any one to give a distinct preference to any particular make of lamp. In the meantime we can only say that all the leading makes are very good—some day we may hope they will all be still better. One caution may be given. It is quite impossible to judge the intrinsic value of a lamp by comparing the light which it gives with that given by another lamp, even if they are both hung upon the same circuit. Indeed, in that case the chances are that the duller lamp is really the better of the two.

Lamps are specified by their candle-power and their voltage. Other things being equal, the higher the number of volts the smaller is the current required to give the same light, and therefore as the number of volts is increased the size of the wires may be diminished in the same proportion.

For ship-lighting 80 or 100 volts is about the thing. As to candle-power, 16 or 20 candle lamps are generally used, but in the state rooms and other small rooms 10 or 12 candle-power is ample. If we use these smaller lamps we must, however, be very careful to see that they take the same number of volts as those of higher candle-power which are supplied by the same machines.

It will be understood that the number of volts given by the dynamo machine when running at its proper speed is a fixed quantity. The lamps must therefore be ordered with reference to the machine. If the lamps require a number of volts greater than that given by the dynamos, they will burn dimly, if less they will soon have their filaments destroyed by the excessive current which would traverse them.

Arc lamps are very seldom brought into regular use in the merchant service. It is, however, a very good plan to carry a pair of such lamps capable of giving about 600 candle-power. They are extremely useful when any urgent repairs are required outside the ship. For this purpose two pairs of leads should be taken from the machine room, one to each end of the promenade deck. They should there be attached to a pair of terminal screws, enclosed in a wooden box with a safety fuse and a switch. A good length of well insulated double-wired cable of the proper size should be carried; the lamps can then be suspended in any position where they may be required, and the current can be taken from the terminals on deck. It is not desirable to try to run an arc lamp from a machine which is supplying glow lamps at the same time. For many purposes—such as for discharging cargo at night—a lantern which will hold eight or ten glow lamps is just as good and less troublesome than an arc lamp.

With regard to the maintenance of the installation, it is well that some one on the ship should learn how to make a good joint in an insulated wire, and should be able to take down and properly replace any of the brackets, switches, or other small fittings. This is about all they need know. A box containing the tools and materials required for jointing wires can be obtained complete, and the proper method of jointing is easily learnt by an intelligent man. In addition to this a few other stores will have to be carried, such as lamps and lamp-holders, a few spare brackets, switches, and safety fuses of each sort in use; several sets of brushes for the dynamos, one or two coils of insulated wire (principally of the size used for single lamps), and including also some lead-covered wire; and a supply of small articles, such as staples, copper-binding wire, sheet lead, &c. In ordering lamps it is well not to get too many at once, as among a large number there are sure to be some in which the vacuum will deteriorate if laid by for any length of time.

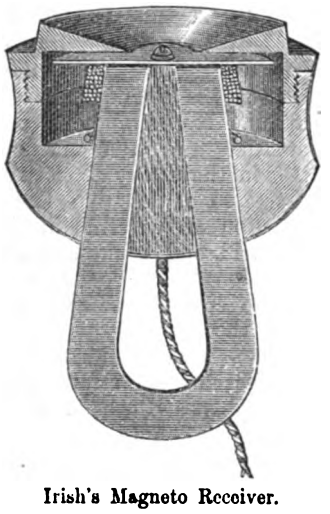
In concluding this paper I should like to repeat that these

Digitized by Google

remarks are not intended for the instruction or information of electrical engineers, but it is hoped that they may prove of service to the large and increasing number of those who are making use of the electric light on board ship.

A NEW MAGNETO TELEPHONE.

On Saturday last we had the pleasure of inspecting a new magneto telephone, the invention of Mr. W. E. Irish, of Sunderland. The receiver, as will be seen by our illustration, possesses two novel features. The diaphragm is *centred*, giving presumably a higher degree of sensibility, or vibrating surface, and the coil is wound round both poles of the magnet; a block of wood between them serving as a support to and holding the diaphragm. The reason for this latter arrangement is not easily seen if it be other than a departure from recognised forms of construction. On the occasion of our visit, however, it worked very well indeed; the articulation being distinct



Irish's Magneto Receiver.

and clear. The transmitter proper—for the receiver can be used for both purposes—differs in some slight degree from the foregoing. We have to regret, however, that want of space compels us for the present to hold over a more detailed description of Mr. Irish's very interesting apparatus.

INFLUENCE OF EXTERNAL RESISTANCE ON THE INTERNAL RESISTANCE OF VOLTAIC CELLS.*

BY G. GORE, LL.D., F.R.S.

The present series of experiments were made for the purpose of ascertaining whether the total internal resistance of a voltaic battery varied with the amount of resistance in the external part of the circuit, and whether such change, if any, consisted of an alteration of the amount of ordinary conduction resistance of the exciting liquid.

The mode of experiment employed was to take a circular glass cup, 6·0 cm. wide and 4·0 cm. deep, partly fill it to an uniform height in every case with a mixture of five minims of nitric acid per ounce of water, at atmospheric temperature; wholly immerse in the liquid at a distance of 2·0 cm. apart, and facing each other, positive and negative plates of perfectly clean metal, each 1·0 × 1·0 cm., suspended by means of a narrow vertical strip prolongation of each metal; these strips being connected with an ordinary astatic galvanometer of 6·5 ohms resistance, which had been carefully calibrated by means of electrolytic measurements.

Two series of experiments were made, viz., one with a zinc positive and a series of different native plates; and one with a platinum negative and a series of positive ones; during each experiment the liquid between the plates being rapidly stirred by means of a revolving vertical blade of ebonite, to prevent polarisation. The electromotive forces of all these voltaic couples were first ascertained by opposing their currents to those from a thermo-electric pile of about 300 German-silver and iron elements (see *Pro.* Birm. Phil. Soc., Vol. IV., 1884, Part 1, p. 129); and their strengths of current were determined by means of the calibrated galvanometer. The measurements of strength of current were made—1st, without any added external resistance; 2nd, with 100 ohms wire resistance suddenly switched into the circuit; and 3rd, with 1,000 ohms instead of the 100. The total resistances were then calculated from the electromotive forces and strengths of current. The following tables show the results:—

* Read before the Birmingham Philosophical Society, June 11th, 1885.

TABLE I.

Influence of External Resistance on Total Resistance of Voltaic Cells.

Aver. .	·8142	159·40	·00965	384·77	·00254	124·65	1615·90	·000507	455·52

With this series, in every instance except the one marked,* the total resistance of the cell was increased by adding external resistance; the addition of 100 ohms external resistance increased the resistance of the cell an average of 124·65 ohms; and the addition of 1,000 increased it an average of 455·5 ohms. The smallest original total resistances were usually with negative plates of the most corrodible metals, cadmium, lead, tin, iron, nickel, and copper, and the largest with those of the least corrodible metals; the largest increases of resistance were also with the latter class; aluminium was an exception owing to its acquiring a film of oxide. As the whole of these resistances were calculated from electromotive forces obtained during a state of balance of current, they are all more or less magnified, especially the large ones.

The second series of experiments were made in a similar manner, but with a series of positive plates and a single negative one. The same liquid was employed. The following are the results:—

In every instance except the one marked* the total resistance of the cell was increased by adding external resistance; an effect similar to that in the previous series. The addition of 100 ohms increased the cell resistance an average of 361·0 ohms, and the addition of 1,000 increased it an average of

Digitized by Google

1261·0 ohms. These increases were 4·49 times larger than those in Table 3 in the case of addition of 100 ohms, and 3·42 times larger in that of 1,000 ohms, if palladium and gold are omitted. The smallest original total resistances were again with the least corrodible, and the largest with the most corrodible metals. The average original resistance was 6·4 times greater, and the average strength of current was less than one-half that in Table 1, whilst the average electromotive force was slightly greater. The resistances of aluminium and of silver were usually large in both tables. The cases of large resistance in this table were greatly magnified in consequence of the circumstance already mentioned, and of the smallness of the currents.

In a paper "On Transfer Resistance in Electrolytic and Voltaic Cells," read before the Royal Society, March 19, 1885, I have shown by experiments that "with an electrolytic cell, using ·02 and ·0022 ampere strengths of current, no manifest difference of the ordinary conduction resistance occurred;" also that "a species of electric resistance, distinct from that of polarisation and of ordinary conduction-resistance, varying greatly in amount in different cases, exists at the surfaces of mutual contact of metals and liquids in electrolytic and voltaic cells;" and further, "that this species of resistance was largely reduced by increasing the strength of the current." From these facts I conclude that all the foregoing instances of total internal resistance consisted not of alterations of ordinary conduction-resistance of the liquid, but of what I have termed "transfer-resistance" at the surfaces of the plates. If, therefore, we deduct from each of the total resistances in the two tables, the ordinary resistance of the liquid, amounting to about 15·5 ohms, the remaining magnitudes represent, within certain limits of variation, "transfer-resistance," and the increases of such resistances by diminished strength of current caused by additional external resistance. According to this, the primary chief cause of the usual weakness of the currents; the much larger original resistances; and of the greater increases of resistance, in Table II. than in Table I., was the large "transfer-resistance" at the platinum negative plate. The smallness of the resistances in the cases in Table I., in which both the positive and negative plates were composed of easily corrodible metals forming readily soluble salts, was due to the small "transfer-resistances" of those metals.

Waltenhofen, Naccari, and Mazzotto have already shown in a limited number of cases that the total internal resistance of a voltaic cell increases with diminished strength of current (Wiedemann's Beiblatter, Vol. V., 1881, pp. 451, 529, 608), but do not appear to have ascertained that this resistance consisted in any degree of an alteration of resistance at the surfaces of the plates; the two latter investigators, however, have observed that in the case of several kinds of voltaic elements, total internal resistance was different when negative plates composed of different metals were employed (*ibid.*, p. 451).

LITERATURE.

Handbuch der Elektrotechnik. By Dr. Erasmus Kittler. [Stuttgart: F. Enke.]

Under this title, which might be translated as "Manual of Electrotechnics," the first half of the first volume of Dr. Kittler's long-expected book has at last made its appearance. The complete work is to consist of two volumes, and in an introductory note the publisher promises that it will be issued at latest within a year from date. The general scope of the book is sufficiently ambitious, inasmuch as it covers nearly all the applications of electricity for lighting purposes, for transmission of power, and for electro-deposition of metals. We reproduce the table of contents given in the publisher's prospectus:—Volume 1: Induction and Lines of Force, Theory, Principles of Continuous Current Machines, Electrical Measurements, with special reference to Continuous Current Machines; Description of various Systems, Theory of Continuous Current Machines, Alternating Current Machines and their Investigation. Volume II: Arc Lamps, Glow Lamps, Photometry, Electric Light Installations, Electric Transmission of Power, Secondary Generators, Accumulators, Application of Electric Machines in Chemical Industries.

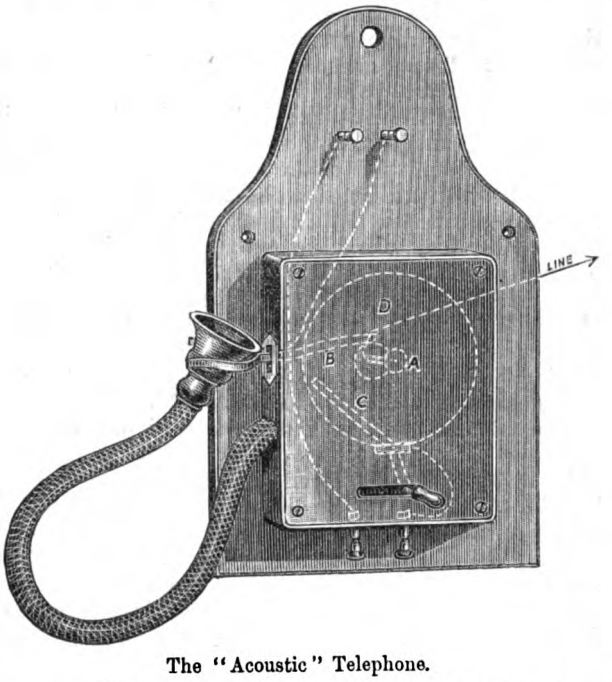
From the summary it will be seen that the author proposes to include in his book nearly all the practical applications of electricity, with the exception of telegraphy, telephony, and railway signalling. The first half of Volume I. contains about 300 pages, and treats of the subjects mentioned in the prospectus up to and including electrical measurements. The treatment is rather didactic than analytical or critical, and the reader cannot help being constantly reminded that the author occupies a professor's chair at the Technical school at Darmstadt, and is in the habit of making things plain to an audience of very mixed intellects. A teacher is bound to treat his subjects in a somewhat broader style, to repeat explanations, and to illustrate his meaning with numerous examples, lest some of his pupils may not be able to follow him. With an author this is not required, and although we would not go so far as to say that redundancy of language is a fault in a book, we prefer a terser style, and a more critical treatment, which we almost have a right to expect from the author's high standing in the German scientific world. The first chapter treats of the magnetic field, and of lines of force, which conception is rightly taken as the basis for all future explanations of the phenomena of induction and dynamo electric action. Nothing, however, is said about the magnetic potential and the magnetic shell; this most important factor in the theory of electro-magnets is only mentioned, but not treated at length. The second chapter deals with the induction of currents in linear conductors moving in a magnetic field, and is explained by a profusion of examples and illustrations. All possible combinations of induction between two conductors and a conductor and magnet are given, and the general question of self-induction is treated, but without entering into its theory. In this respect the author contents himself with referring the reader to the works of Helmholtz, Joubert and others. In the third chapter we find a very clear explanation of the currents generated in solid conductors moving in a magnetic field, and we would especially recommend this part of the work to those who have to do with the designing of dynamos. By the many illustrations given they will see at a glance what to avoid in the shape of continuous masses of metal. A short description of the ordinary induction coil and the part played by the condenser in connection with it brings us to the second section of the book, entitled "The Principles of Modern Continuous Current Dynamos." Here we find the usual explanations of the Gramme-Pacinotti and Hefner-Alteneck armatures given at great length, but nothing is said as to how the electromotive force created in any of these armatures can be calculated. The chapter is purely descriptive, the analytical treatment being probably reserved for the theory of continuous current dynamos, which, forming part of the second half of Volume I., will be issued in November next. A few practical hints for the construction of armatures, commutator, and brushes are added. In these the author is hardly explicit enough, and in one or two cases these practical recommendations are nothing more than rule of thumb. To cite only one case, when speaking of the density of current to be allowed in the wires of the armature, and also further on, when speaking of the magnet coils, Dr. Kittler quotes that long-exploded rule of Mr. Uppenborn, according to which in thick wires a current of two amperes, and in thin wires a current of three amperes per square millimetre, may be permitted. Is it possible that the author has never heard of the experiments and theoretical investigations of Prof. Forbes, who more than two years ago has already shown how the density of current in a coil can be determined with due regard to permissible heating? In another place Uppenborn is again quoted—and this time confirmed by no less an authority than Waltenhofen—for a rule of thumb which is not only unscientific but absolutely wrong. We refer to the rule that the exciting power around the field-magnets of a dynamo ought to be proportional to their cross-sectional area, viz., 110 ampere turns per square centimetre. Although the author mentions in a foot note that Ross denies the validity of this rule, he does not throw any further light on this most impor-

Digitized by Google

tant question, and the humble student is left to settle as best he may whether Waltenhofen, Uppenborn, or Ross be right. Here, if anywhere, was a case to be taken up by the author in a critical spirit, who might have with advantage devoted a whole chapter to it. If, to make up for such liberality, he had omitted all that he said about the magnetic moment of bar magnets, and the well-known formulæ of Müller, Dub, Jacobi, and others, his book would not have suffered. These can be found in every book yet written on electro-magnets; but has ever anybody been able to utilise them in the practical design of dynamos? We believe not; and the reason is that we do not use straight bars in the construction of dynamos, but horseshoe magnets, and that it is not the magnetic moment of a bar, but the number of lines of force passing between armature and polar surface, which is of importance in a dynamo. This section of the book concludes with an interesting historical sketch of the development of modern dynamos. The third section, treating of absolute measure and the apparatus used in electrical measurements, is by far the best part of Dr. Kittler's book. Those who have visited the author in his laboratory at the Vienna Electrical Exhibition of 1883, and have noted the conscientious care and great accuracy of his measurements, will turn to this part of the book with the expectation of finding a valuable standard work of reference, and they will not be disappointed. In the first place the author gives a complete theory of the tangent galvanometer, inclusive of all the possible sources of error and the method for their elimination. He adds a very useful table of corrections for readings taken with the mirror galvanometer, by which much tedious calculation can be avoided. The sine galvanometer, astatic galvanometer, bifilar suspension, electro-dynamometer, and the absolute electrometer are exhaustively described, as are also the copper and silver voltameters. As regards the latter, we should have expected to find some reference to Lord Rayleigh's latest determination of the electro-chemical equivalent of silver, but the author is quite silent on this important subject. In copper-voltameters he recommends a density of current of 23 to 28 amperes per square foot. Rheostats and resistance boxes, standard cells and differential galvanometers, and their application to the measurements of resistances, are next described. The chapter on Wheatstone's bridge and its numerous modifications will be found particularly instructive. A question of great importance to the practical electrician is that of handy and fairly accurate instruments for the measurement of current and electromotive force. These might have been treated of at greater length. In all, the author devotes only 18 pages to practical volt and ampere-meters, and these few pages are occupied by description pure and simple, without a word of criticism or instruction regarding the use of the instruments. It is to be regretted that the author did not treat of these practical instruments at greater length, and give the reader the benefit of his experience. The book is well printed and profusely illustrated.

MECHANICAL TELEPHONES.

Very many years ago, at the time when youth is reckless, we remember having purchased, for the modest sum of one penny, an apparatus constructed of cardboard, parchment, and string, by means of which fond lovers were supposed to be able to breathe soft nothings in defiance of that cruel element, distance. Whether this was called a telephone or not we do not know; but it was an idea—an old one even then—and cost a penny. That was all that could be said of it. Since that time, however, science has made gigantic strides, and the idea which was evolved doubtless during the antediluvial period has within the last few weeks borne fruit—golden fruit—in, at all events, one quarter. The subject of our illustration shows one application of the idea. It is an apparatus which has been manufactured and sold by Messrs. Weedon and Irish for the last half-dozen years at a moderate sum. Its construction will readily be understood by our readers, it only differing from the toy in the materials used, and in the fact of its possessing a mechanical or electrical call and an ear-piece. We need hardly say that the golden fruit to which we have alluded has not fallen into the hands of this firm, but apparently into those of the promoters of the Mechanical Telephone Company, whose remarkable prospectus will have been perused by many with feelings of admiration for



The "Acoustic" Telephone.

its compilers, not unmixed with some apprehension for the public.

ELECTRIC LIGHTING IN SOMERSETSHIRE.

Ashton Court, near Clifton, the residence of Sir Treville Smyth, has recently been the scene of an extensive installation of the electric light. The following is a sketch of what has been accomplished under the personal management of Mr. S. Sharp:—

Motive Power.—A Crossley twin 6 horse-power gas engine, indicating 28 horse-power, fitted with a self-starter.

Dynamos.—Two Hockhausen shunt-wound machines, by Messrs. Edmunds and Goolden, of Halifax, each giving 105 volts and 85 amperes in external circuit, at 1,100 revolutions.

Accumulators.—Fifty-four of the Electrical Power Storage Company's glass cells, 23 L plates coupled in parallel with the dynamos and lamp circuit to act primarily as a regulator, also to supplement the engine power on special occasions, and to provide light in bed rooms and elsewhere, when the engine is not running. The battery will maintain seventy 20 candle-power lamps for eight or nine hours.

Engine Room Fittings. — The switch-board, a *specialité* of the above-named company, and made by them, is arranged with an accumulator switch, with "off," "on," and ammeter blocks, two dynamo switches, having a similar arrangement, and closing automatically the field before the main circuit, a regulator switch for adding cells as required, and, lastly, a lamp circuit switch. All these being connected to the positive terminals of accumulators and dynamos, there is no possibility of any inexperienced person making a short circuit if interfering with the switches. Voltmeters and ammeters are also affixed to the board. Two large Cunningham magnetic cut-outs (by Woodhouse and Rawson) protect the main cables.

Leads.—The mains, which are carried through the house a distance of 300ft. to the distributing board in the Buckhorn corridor, are calculated at the rate of 625 amperes per square inch, with the maximum number of lamps on, viz., 250.

Main Switch-Board.—Placed in a central position is a large and handsome switch-board, with mahogany case and locked glass door, made by Messrs. Paterson and Cooper. On its massive slate backing are fitted six Eidsforth switches, with as many Cunyngham magnetic cut-outs for the various sections of the house. Attached to the board is a Cardew voltmeter;

Digitized by Google

but in order that the engine driver also may know at all times the difference of potential at this distributing board, which is rendered necessary by the fact that the switching on the various rooms will be under the management of the butler, and the number of lamps alight may vary from 1 to 200, the positive and negative bars of the switch-board are put in connection with the engine room voltmeter. The driver then switches on or off one or more cells to maintain a constant pressure at the central point.

Arrangement of Lamps.—The lighting is almost entirely from the ceilings, and so arranged as to ensure an even distribution of light in any part of the rooms. In the hall, drawing room, and boudoir the lamps in the ceiling are arranged symmetrically, according to the designs of Messrs. Jackson and Graham, of London, who have executed the alterations and decorations of these portions. The ceilings of the south entrance, vestibule, and museum are the work of Mr. J. Long, builder, of Bath, under the direction of Major Davis, architect, of the same city. In the south entrance 20 candle-power lamps, with suitable glass shades, hang from the crowns of the richly-carved groined stone roof, and give ·2 candle-power per square foot at a height of 11ft. A pannelled oak ceiling has been erected in the museum; from certain intersections of the moulded ribs fifty-four 20 candle-power lamps are suspended, and yield a light of ·55 candle-power per square foot. The switches are enclosed in boxes let into the stone walls.

Turning from the south entrance to the conservatory, twenty wrought-iron foliated pendants with flowers, to receive the incandescent lamps, give finish to the light iron frame of the roof. These twenty lamps (20 candle-power) are equivalent to ·35 candle-power per square foot. The vestibule, leading into the dining and drawing rooms, has seven lamps as finials to the raised ornamentation of the ceiling, the illumination at the height of 12ft. being ·37 candle-power per square foot. In the drawing room, the panelling being of dark oak, a liberal allowance of light is required. The grouping of the lamps on the ceiling consists of four stars of five Bernstein 50 candle-power lamps, the intermediate spaces being occupied by 10 candle-power lamps. Each star of five has its switch concealed behind a movable panel, the 10 candle-power being governed by one switch.

On the walls of the dining room are four single wall brackets of severe design (from the Anglo-American Brush Electric Light Corporation), with shades, whilst the dining table is illuminated by a pair of screw-armed candelabra, glow lamps taking the place of candles. Under the carpet are let in two of Mr. Tayler's Smith's pin floor connectors. Flexible wires lead from these, through the table to the base of each candelabra, where a similar connector is provided with three pins.

In the study are single and double wall brackets of Faraday and Son. In the boudior a dozen lamps throw down their rays. Wall sockets of the Brush Electric Light Company, to take incandescent lamps, or plugs with flexible wires, are let into the walls of this room, as well as elsewhere, for reading or piano lamps. The brackets in the various rooms are by Messrs. Verity and Sons, of King-street, Covent Garden, and are very elegant.

The upper and lower corridors and landing are fitted with F. and C. Osler's wall brackets and globes. On one staircase hangs a massive chandelier, with four arms, each carrying a duplex oil lamp. The wicks are gone, and carbon filaments have taken their place. Through the glass globes the change is unnoticeable, but the action of a switch behind the panels reveals the secret. A turret staircase and sundry other places also have other lights. Fusible plugs in great number, in addition to the magnetic cut-outs for each section on the main switch-board and the magnetic cut-outs on the main cables, render the installation perfectly safe.

The following is a *resumé* of the lamps:—

	Volts.		Candle-power.
20 Bernstein	50	...	50
160 Anglo-American "Brush"	100	...	20
12 Anglo-American "Brush"	50	...	10
24 Anglo-American "Brush"	25	...	10
32 Woodhouse and Rawson	25	...	10

THE TELEGRAPH CONFERENCE AT BERLIN.

The Tariff Committee meetings have resulted in a recognition of the general principle that what is called the "Grundtaxe," or fixed preliminary charge, on every telegram before the cost of its transmission is assessed according to the number of words, should be abolished or simplified, as well as that terminal dues should be rendered uniform. These decisions, of course, will only form the basis of further discussion by the plenary conference itself, but still they point to the existence of a spirit of conciliation and compromise among the delegates which will probably enable the German Postmaster-General not to go wholly empty-handed away, though it is still regarded as certain that he will not succeed in achieving the acceptance of his proposals in their entirety. His scheme of uniform telegraph dues for all Europe was rejected by a majority of nine to seven.

The following is a list of the delegates of the various Governments represented at the Conference:—

Country.	*Delegates.*
Germany	Dr. von Stephan (Secretary of State); Mr. Hake (Director of the Second Division of the Department of Posts); Mr. Scheffler, Mr. Fritsch, and Mr. Le Sage.
Austria-Hungary and Bosnia-Herzegovina:—	
Austria	Dr. Brunner de Wattenwyl, Mr. Laurenz J. Wolschitz, and Dr. Charles Benesch (acting secretary to the Minister of Posts and Telegraphs).
Hungary	Mr. Koller de Granzow (Director-General of Telegraphs), and Mr. Francois Mokry.
Bosnia-Herzegovina	Lieut.-Colonel Oscar Parmann.
Belgium	Mr. F. Delarge (Engineer-in-Chief and Director of Telegraphs).
Brazil	Baron de Gapanema (Director-General of the Imperial Telegraphs).
Bulgaria	Mr. Ivanoff (Director-General of Posts and Telegraphs).
Denmark	Mr. Höncke (Director of Telegraphs), and Mr. C. C. Lund.
Egypt	Mr. Floyer (Inspector-General of Telegraphs), and Iskandar Bey Fahmy.
Spain	Mr. Aquilino Herce (Director-General of Posts and Telegraphs), and Mr. Vicente Coromina y Marcellan.
France	Mr. Fribourg (Director of Posts and Telegraphs), Mr. Lorin, and Mr. Brunot.
Cochin China	Mr. Brunot.
Great Britain	Mr. Patey (third secretary to the Post Office), Mr. H. C. Fischer (controller of the Central Telegraph Station), & Mr. Benton.
British India	Col. Bateman-Champain, R.E. (Director-in-Chief of Indo-European Telegraphs), and Mr. C. H. Reynolds.
British Colonies:—	
Victoria, Australia	Not represented.
South Australia	Mr. C. Todd (Postmaster-General and Superintendent of Telegraphs).
New Zealand	Not represented.
Tasmania	Mr John Henniker Heaton.
Cape of Good Hope	Not represented.
New South Wales	Mr. E. C. Cracknell.
Greece	Mr. Durutti.
Italy	Commander E. D'Amigo (Director-General of Telegraphs), and Chevalier Berliri (assistant).
Japan	Mr. Tadasuke Ishie (Director-General of Telegraphs), Mr. Takémoura (secretary), and Mr. Yoshida (secretary).
Luxembourg	Mr. Mongenast (chief of the Department of Posts and Telegraphs).

Digitized by Google

Country.	*Delegates.*
Montenegro	Dr. Brunner de Wattenwyl and Mr. Laurenz J. Wolschitz.
Norway	Mr. C. T. Nielson (Director-in-Chief of Telegraphs) and Mr. J. U. F. Bugge (assistant inspector of Telegraphs).
Holland and Dependencies	Mr. M. J. P. Hofstede (Director-General of Posts & Telegraphs).
Persia	Colonel Smith.
Portugal	Mr. Guilhermino Augusto de Barros (Director-General of Posts, Telegraphs, and Lighthouses).
Roumania	Colonel Pastia (Director-General of Posts and Telegraphs); and Mr. J. Jacovesco.
Russia	Mr. De Besack (Director-General of Posts and Telegraphs); Major General Ussow, & Mr. de Rossi.
Servia	Not represented.
Siam	H.H. Prince Prisdang, Mr. Luang Nai Tej (First Secretary of the Legation); and Mr. Wilberforce Wyke (Secretary of Legation)
Sweden	Mr. D. Nordlander (Director-General of Telegraphs); and Mr. H. E. Uddenberg.
Switzerland	Mr. Frey (director of Telegraphs).
Turkey	Her Ambassador at Berlin.
Bureau International	Mr. Curchod (director of the International Bureau), Mr. Eschbaecher (secretary), Mr. Neumann, and Mr. Linz.

The following is a complete list of delegates representing the cable companies :—

Company.	*Delegates.*
Anglo-American	Mr. Henry Weaver and M. Jules Despecher (representative of the company in Paris).
Black Sea	Mr. John Pender, M.P. (chairman), and Mr. Lewis Wells.
Brazilian Submarine	Mr. Thomas Fuller (managing director).
Central and South American	Not represented.
Commercial Cable	Not represented.
Compagnie Française	Mr. Henry Weaver.
Cuba Submarine	Not represented.
Direct Spanish	Sir James Anderson (chairman) and Mr. C. Gerhardi (manager).
Direct United States	Mr. John Pender, M.P. (chairman); Mr. J. W. Fuller, secretary and traffic manager).
Eastern	Mr. John Pender, M.P. (chairman); Sir James Anderson (managing director); Mr. Lewis Wells; M. Jules Despecher (company's agent in Paris), and Mr. Hibberdine (assistant).
Eastern Extension, Australasia, and China	Mr. John Pender, M.P. (chairman); Mr. Lewis Wells; M. Jules Despecher, and Mr. J. E. Hesse.
Eastern and South African	Mr. John Pender, M.P. (chairman); Sir James Anderson (managing director); and Mr. Lewis Wells.
German Union Telegraph and Trust	Dr. Lasard (director); Mr. Steinhardt, and Mr. Payton (secretary).
Great Northern	Capt. E. Suenson, of Copenhagen (managing director); Capt. W. de Hedemann (company's agent in St. Petersburg); and Mr. F. C. C. Nielsen (manager of London office).
Indo-European	Mr. W. Andrews (managing director); Mr. F. Moll (secretary), and Dr. Werner Siemens (representative of the company in Berlin).
London Platino-Brazilian	Not represented.
Spanish National Submarine	Count Th. d'Oksza (director) and M. Lucas Mariano de Tornos (company's agent in Paris).
Submarine	Sir Julian Goldsmid, Bart. (chairman); Mr. G. von Bunsen.
West Coast of America	Mr. Robinson Kendal (chairman).
Western Union	Mr. Henry Weaver.
West India and Panama	Mr. W. Andrews and Mr. Henry Weaver.
Western and Brazilian	Major A. Wood (managing director).

UNIFORMITY OF CHARGE FOR EUROPEAN TELEGRAMS.

The proposal of Germany that there should be one uniform word-rate for European telegrams arises naturally out of the past history of international telegraphy, and is almost suggested by the very existence of such a Congress as that which is now meeting. The object of a conference between different States on telegraphic matters is to facilitate international communication and to harmonise the principles upon which it is conducted. The adoption of a common code, and of uniform principles of telegraphic working, the settlement of detailed rules to be observed by every State, as to the mode of counting and charging for the contents of a message and the character of the services to be performed for the public, are all important applications of the principle of uniformity. And former Conventions have gone further than this. Some years ago it was agreed that the charges made by each State for messages originating in or destined for any part of its dominions should be the same without reference to particular locality. More recently the principle of a word-rate throughout the telegraphic world was adopted. With this basis to start from, and with the analogy of the uniform postal charge throughout Europe, it would have been surprising if the suggestion that there should also be one European word rate for telegrams had not been made, and there will be a general, though we think unreasonable, feeling of disappointment at the announcement that the Congress is not disposed to receive it favourably. There is a second branch of Dr. von Stephan's proposal which is quite distinct from the first, but which, if possible, is still more natural. Under the Postal Union arrangements all postage is prepaid, and each country keeps its own receipts, the existence of elaborate accounts being thus obviated. Under the Telegraph Conventions, on the contrary, each country accounts to the other for a portion of the charge upon each telegram. Thus, if a telegram is sent from London to Paris, Great Britain accounts to France for the charge which France has agreed to as her due on a telegram destined for her territory. Dr. von Stephan proposes that the principle of the Postal Union should be applied to telegraphy, and that each country should keep all payments it receives for telegrams despatched within its territory, paying all expenses of transmission. Although the senders of telegrams are not interested in this part of the question, it is obvious that it has an important bearing upon the effect of the whole scheme upon the revenues of the several States, and must consequently influence their representatives in the discussion at Berlin.

Unfortunately for the attainment of a uniform rate, telegraphic arrangements are complicated by the fact that State Governments are not the only agencies occupied in transmitting telegrams. There are no private posts in Europe, but there are private telegraph companies. The Continental Powers, like England, send the telegrams of their subjects within their own dominions, and if all telegrams passed only over land lines the States would have a free hand in telegraphic legislation. But submarine cables play an important part in European telegraphy, and the longer cables are nearly all in the hands of private companies. In laying submarine cables official caution followed private enterprise at a respectful distance, and no great amount of public money has been sunk in this species of investment. The cable companies have spent millions in linking together distant countries, and they naturally desire to reap the fruits of their venture and to pay a reasonable dividend to their shareholders. A public administration may be prepared to lose, or at least to risk, something over its telegraphs for the purpose of stimulating commerce and adding to the amenities of life, but a private company exists to earn money for its constituents. Hence the cable companies are naturally found on the side of caution when projects of telegraph reform are under discussion. They have expensive plant to keep up, and they protest that they cannot make sweeping reductions without being brought face to face with bankruptcy and ruin. The Continental nations are but slightly interested in the fate of the cable companies. A large number of foreign telegrams can be sent entirely overland. Germany, for example, touches almost every other Continental nation, and is cut off by the sea from Great Britain

Digitized by Google

and the Scandinavian Peninsula only. On the other hand, neither Germans nor any other Continental people have invested any appreciable amount of capital in cable enterprise. Great Britain is very differently situated. She cannot be reached except by the sea, and though the British Government is largely interested in the most important and direct communications with the Continent, many cables which are entirely in private hands leave our shores; and nearly all the money sunk in submarine telegraphs has been found by the people of this country. While, therefore, zeal for a uniform low-priced telegram is a comparatively cheap virtue on the part of Germany, England is compelled to pause and count the cost before she can give free rein to the same generous impulse.

It will, of course, be said that private interests should not stand in the way of public good, that those who invested in submarine cables did so for their own profit, and have no more right than Egyptian bondholders to the services of the State to save their pockets. It is hardly, however, State assistance which the companies ask; what they deprecate is active competition at the hands of a concert of European States. Let us consider what would happen if England overlooked entirely the views of the companies and embraced the German proposal. The companies are not represented on the Telegraph Congress. They are allowed to be present and to follow the discussions, but have no votes. The proposal for a uniform rate might therefore be carried notwithstanding their protests. The rate proposed by Dr. von Stephan consists of a fixed tax of 50 centimes for every message and a word-rate of 20 centimes per word, with an additional charge not to exceed 10 centimes per word, when correspondence is transmitted over a submarine cable. Thus messages from Great Britain to Spain, for example, would be charged at the maximum rate of 30 centimes or 3d. per word with an addition of 50 centimes or 5d. for each message. The present rate to Spain by line of the Direct Spanish Company, which has a cable from the Lizard to a point near Bilbao, and by that of the Eastern Company, whose line runs from Porthcurno in Cornwall to Vigo, as well as by the overland route through France, is 6d. The Congress has no power to bind the Direct Spanish or the Eastern Company to lower its charges. The only mode in which it could enforce its reduced rate of a trifle over 3d. would be by underselling the companies by means of the overland route. As far as this country is concerned there would be an initial difficulty in arranging with the companies who are interested in the direct cables to France and Belgium. This could only be done if these companies opposed the reduction, as they certainly would, by offering them some kind of compensation. But it would be impossible for the Government of this country, after compensating one private company for an apprehended loss of income, to be a party to an active competition with other private companies, with the avowed object of forcing a similar loss upon them. The demand for compensation on the part of the Direct Spanish and Eastern Companies would in the case we have put be irresistible, and a similar result would ensue in the case of other companies. Even if the Government were deaf to all appeals on the ground of fairness as between one company and another, there are reasons why it would be impolitic to destroy cable communications with distant parts of Europe. Such communications have before now been highly useful both to the Government and commerce of this country when overland routes were interrupted, and it is impossible to tell when such a state of things may recur. Moreover, our communications with the East are facilitated and guaranteed by the existence of sea lines skirting the coast of Europe, and it is not likely that the country would look favourably on any policy which tended to impair in any degree our telegraphic connection with India. Thus the Government would inevitably be landed, sooner or later, in the acquisition of the undertakings of all the cable companies so far as regards European communications; and the taxpayer would in all probability pay a great deal more than the property of the companies was worth, as he did on the purchase of the inland telegraphs, and perhaps be called upon to work a losing undertaking into the bargain.

It may, of course, be argued that it is from mere timidity that the cable companies are deterred from embracing a proposal which, by increasing their business, would, in the long run, give them a large profit. But there is no magic in uniformity of charge. If the actual expense of sending a telegram from London to Spain is more than the sum charged for the work, the result must be a loss; and the fact that the same charge yields a handsome profit on the despatch of a telegram between Berlin and Vienna will not make the loss any the lighter. The fact is the advantages of uniformity of charge only exist where an undertaking is in one hand, and the logical sequence to Dr. von Stephan's proposal would be that all the European States and cable companies should make a common purse. But so far is he from recommending this that he proposes to abolish all accounts and leave each country to keep its own receipts. One can hardly expect a dividend-paying company to embrace a proposal in blind faith that somehow or other it is to be for the benefit, although all considerations of pounds, shillings, and pence lead to an opposite conclusion.

There are other considerations bearing upon the German proposition. The Government of this country is itself interested in communications with the Continent, and would probably be a loser by the reduction of rates, though it would gain by the retention of all moneys paid in this country for the transmission of telegrams, since Great Britain sends more telegrams than it receives. To other countries the proposed abolition of accounts would be prejudicial, and hence it is that Dr. von Stephan's proposal meets with opposition from inland States. But for this country the main consideration must be the effect of the uniform rate upon the interests of the cable companies, and the consequences that any serious attack upon them must entail upon the relations of the Government to cable enterprise. Attractive as the German proposal is at first sight, it is probable that the interests of the public will be better served by a less heroic policy, which, while duly regarding the interests of those who have acted as pioneers in oceanic telegraphy, shall use the resources and influence of the great European States to enforce a continuous improvement in the conditions of international intercourse.—*The Times.*

LEGAL.

The Electro-Amalgamator Company (Limited).

In the Chancery Division, on Wednesday, before Mr. Justice A. L. Smith, vacation judge, an application was made on behalf of Mr. F. Horner Lyell, a creditor and shareholder, for a winding-up order. Counsel for the petitioner said the company had requested that the petition should stand over, and he asked that it should stand over for a fortnight.

The JUDGE: Let it stand over for a month. Then my brother Mathew will be here [laughter].

NOTES.

NOTICE OF INTERRUPTION.—The cable between Fao and Bushire is interrupted.

LONG DISTANCE TELEPHONY IN EGYPT.—The Government has authorised the establishment of a telephone between Cairo and Alexandria.

PERSONAL.—The Calcutta *Englishman* understands that Colonel Grierson will shortly go to Calcutta as Examiner of Telegraph Accounts.

INTERESTING.—M. Lazare Weiller, it is said, is about to make known the results of his experiments upon the electric conductivity of pure metals and of alloys.

AN ELECTRIC SEWING MACHINE COMPANY.—A company is being formed in America to run sewing machines by electricity on the Stockwell system, which is being now so successfully used in Philadelphia.

VOLK'S ELECTRIC RAILWAY.—Mr. Volk, whose electric railway is now laid at Brighton, has been invited to submit his scheme before the Southport Corporation with a view to its introduction on the Southport shore.

NEW TELEGRAPH OFFICE IN CHINA.—The Chinese Administration announce the opening of a new telegraph office at Hoihow. The rates are 1f. 25c. per word for local telegrams, and 2f. per word for foreign messages.

THE TELEPHONE IN FRANCE.—At Troyes there are 126 subscribers to the exchange, and at Saint Quentin 62. At Boulogne not much has as yet been done, but there is every probability of an extension being made at an early date.

THE ELECTRIC LIGHT IN MINES.—A new shaft is being sunk, and large additions to the plant are being made, at the Backworth and Ashington Collieries, Newcastle, one noticeable feature being the application of the electric light on the Maxim-Weston principle.

THE ALTERNATIVE CABLE TO THE CAPE.—Although the project of establishing an alternative cable to the Cape has for a long time remained in abeyance, there are rumours that a definitive decision favourable to the enterprise has at last been come to. It may be that by this time next year the cable will be in working order.

LAYING OF A DUPLICATE CABLE.—The Eastern Telegraph Company announce the laying of the duplicate cable between Zanzibar and Mozambique, by the ss. "Seine," belonging to the Telegraph Construction and Maintenance Company. The line has been laid with the view of improving the service and to guard against future interruptions of communication with South Africa.

TELEGRAPHIC COMMUNICATION WITH THE TORY ISLANDS.—About 100 gentlemen, comprising representatives of Glasgow, Liverpool, Belfast, and Londonderry shipowners, visited Tory Islands recently, and, having examined the Island, passed resolutions in favour of establishing telegraphic communication between the island and mainland, and urging the Government to afford this communication.

NEW TELEPHONE EXCHANGE.—Mr. H. C. Grahame, an energetic gentleman connected with the South of England Telephone Company, has just opened an exchange at Northampton, with a list of 20 subscribers and four private lines. As Mr. Grahame has succeeded so far in the short space of time, some three months, he has been in Northampton, it may safely be predicted that the exchange, ere long, will be in a fairly prosperous condition.

CATALOGUES RECEIVED.—Messrs. Cordner, Allen, and Co. issue a well-illustrated and comprehensive catalogue describing the various electrical apparatus manufactured by them. The catalogue also contains some useful tables relating to electric light cables and wires, as well as a copper wire resistance table, &c. Messrs. Harvey and Peak (successors to W. Ladd and Co.) have also issued a revised catalogue of electrical and mathematical apparatus.

SALES OF PLANT.—Particulars will be found in our advertisement columns of electrical and mechanical plant and stores about to be sold by public auction. The electrical plant consists of Ferranti, Brush, Gramme, and other dynamos; exciters, arc and incandescent lamps, installation fittings, cables, manufacturing plant, &c., the same being the property of the Hammond Electric Light and Power Supply Company, now in liquidation. A quantity of similar stores are also to be similarly disposed of by Messrs. Fryer and Son, at 252, Goswell-road, on the 1st and 2nd proximo.

TRAIN LIGHTING IN INDIA.—Mr. Winter, the telegraph engineer of the Madras Railway, has concluded certain very interesting experiments in connection with the lighting of trains by electricity. The batteries are to be worked by the engine of the train itself, but the difficulty was to keep the batteries working when the train stopped. After many patient enterprising experiments, Mr. Winter succeeded in constructing storage batteries in the train. When the latter stops, the connecting wire is hitched on to the storage batteries and the light maintained perfect during the stoppage.

MRS. GAMP AT SEA!—Captain Campbell, master of the steamer "Princess Beatrice," which runs between Larne and Stranraer, has related at Belfast a curious incident which has occurred on board this week. During a voyage it appears that the man at the wheel noticed the compass was so disturbed by something that he could not keep the vessel on her course. He reported the matter to the mate; and the captain, on making an investigation, discovered that the "gamp" of one of the passengers acted as a "very powerful magnet," and thus diverted the needle. And yet people will persist in carrying umbrellas!

GAIETIES IN BERLIN.—Perhaps the most sumptuous entertainment to which the delegates of the Telegraph Conference in Berlin have hitherto been treated was a garden party given on Saturday evening in their honour by Herr Geheimrath (brother of the late Sir William) and Frau Siemens, at their residence in Charlottenburg. Their drawing rooms and lawns, which were all beautifully illuminated with the electric light, were crowded with about 300 of the chief social and scientific celebrities of the capital, and the hospitality offered them was worthy of such a German prince of science as the brother of Sir William Siemens.

THE EXPERIMENTS AT CREIL.—According to *Le Bulletin International des Téléphones*, M. Marcel Deprez is perfectly satisfied with an initial E.M.F. of 4,500 volts. This reduction of course necessitates a proportional decrease in the quantity of energy transmitted to Paris; without that, to produce 200 h.-p. (French), or 147,000 watts, with 4,500 volts, the current strength would have to be 32·7 amperes, and the loss upon the line, of which the resistance is 100 ohms, would amount to 107,000 watts, or 145 h.-p. That would leave a maximum of 55 h.-p. disposable, neglecting the internal resistances of the generating and receiving machines.

TWO TELEGRAPHISTS DROWNED.—The bodies of Robert G. Cary and Herbert J. Steer, who were drowned by the upsetting of a boat in Southampton Water on Sunday evening, have been recovered close to the scene of the accident. The

Digitized by Google

inquest was opened at Elling, Lieutenant Jones, R.E., attending from Aldershot, the two deceased men belonging to his company. It seems they were engaged at Southampton on telegraph duty, and on Sunday afternoon went out in a boat with a fellow lodger named Smallbone, a railway guard. As they were changing seats the boat capsized, and the deceased were never seen afterwards. Smallbone was saved by some men who had pulled to the spot. The inquest was adjourned.

NEW PUBLICATIONS.—The syllabus of day and evening classes at the Mason Science College, Birmingham, contains, in addition to the usual list of the officers of the college, &c., the rules and regulations to be observed by students and which govern admissions to the college. A description of the various scholarships open for competition is also given, together with a table of classes, the dates of examination for degrees of the University of London, a note upon Government aid towards the instruction of science teachers, and other useful information. The Durham College of Science (Newcastle-on-Tyne) Calendar is a similar publication, containing, however, in addition to the information mentioned in the foregoing, examination papers of a much more extended nature.

LANCASHIRE AND CHESHIRE TELEPHONE COMPANY.—The fourth annual meeting of the shareholders of the Lancashire and Cheshire Telephone Company was recently held in Manchester. In moving the adoption of the report and statement of accounts the chairman (Mr. Charles Moseley) spoke in hopeful terms of the progress which the company is making and its prospects for the future. The new arrangement with the Post Office had greatly facilitated their movements, and negotiations were being made, or were contemplated, for establishing call offices at the post offices and railway stations throughout the district. The report was adopted, and a dividend at the rate of 7 per cent. was declared. It was also resolved to increase the capital by the issue of 30,000 new shares of £1 each.

THE ELECTRIC LIGHT FOR WAR SHIPS.—The Lords of the Admiralty have given to Messrs. Siemens Brothers and Co. the order to light the following ironclads, viz. :—The twin screw turret ship "Edinburgh," of 9,150 tons and 7,520 horse-power; the barbette ships "Warspite" and "Impérieuse," each of 7,390 tons and 8,000 horse-power; the "Collingwood," barbette ship, of 9,150 tons and 9,570 horse-power; and the "Rodney," barbette ship, of 9,700 tons and 9,500 horse-power. These vessels are to be lighted throughout with incandescent lights, and are to be fitted in addition with search lights for fighting purposes. The current will in each ship be supplied by three independent dynamos, each coupled direct to a Willans central-valve compound engine, capable of indicating about 35 horse-power at a speed of 400 revolutions per minute.

THE ELECTRIC LIGHT IN PORTUGAL.—Although the electric light is making its way steadily in every other European country, Portugal obstinately refuses to avail herself of one of the greatest blessings of modern civilisation. Her cafés, her hotels, and promenades are dim with bad gas, and redolent of the odours which invariably attend the injudicious use of that source of semi-darkness. In that little kingdom there is but one lamp (a Siemens arc), and one dynamo. These are installed in the ancient Tower of Belem, on the Tagus, and serve not only to light up the entrance to the river, but to enable a sharp watch to be kept upon the vessels in quarantine, and the Lazaretto upon the left bank. Electricity against disease. We can only hope that Portugal will further recognise the great sanitary and other advantages attending the use of this luminant.

GALLANT RESCUE BY A POSTAL TELEGRAPH CLERK.—According to a contemporary, on Saturday afternoon last a young child, whilst playing at the deep end of the ornamental water in St. James's Park, fell into the water, and soon after disappeared from sight; although a number of men were near the spot, yet no one ventured to render assistance. A postal telegraph clerk, named William Berriff, shortly afterwards arrived on the scene, and on hearing the circumstances, quietly put down his bag, and dived into the water with all his clothes on. He succeeded in bringing the child to shore, and, with some difficulty, the apparently lifeless child was restored to animation. The gallant fellow, after assisting to restore the infant to life, quietly took his departure, and turned up at his office near by. His colleagues were greatly surprised at his arrival in a thoroughly drenched condition.

THE ELECTRIC LIGHT IN HOSPITALS.—The Edison Company, which lately placed a plant at the Wauwatosa insane asylum, near Milwaukee, in accordance with a request from the authorities there, has introduced a novel arrangement for regulating the light of the lamps in the hospital and other places where a full illumination is not constantly needed. The desired result is effected in a very simple manner. The apparatus consists of five resistance coils of varying strength, which are cut in or out of the lamp circuit by means of a switch. A sixth contact cuts out the light entirely. The whole is mounted upon a small board which can be fastened on the wall or wainscoting, and is about 6 by 8 inches. The coils are enclosed in tin, and outside this is a wire cloth grating. It is also proposed to use these as heaters for the patients, by attaching them by a flexible cord, so that they may be utilised in a bed, chair, or as a footstool.

THE NEW JENNEY DYNAMO.—In the new Jenney dynamo the manner of connecting the armature coils with the commutator sections is somewhat novel. In order to provide a connection between the two which shall permit of their easy separation, the ends of the commutator sections are slotted in such a way that the wires from the armature coils can be forced into the slots of the sections; they are then held therein by a band, formed by winding a hemp cord on the outside of the connecting wires. This band serves to keep the wires in place, and to prevent their being broken by centrifugal force, and also serves to prevent copper dust or the like from entering the inside of the armature, which would short-circuit the coils. When it is desirable to remove any of the wires, the hemp cord is unwound, and they can be slipped out of the commutator sections without bending or injuring them in any way.

ELECTRIC INVENTIONS IN AMERICA.—During the quarter ending March 31st of the present year about 226 patents have been granted in the United States for electrical inventions. Amongst these Louis A. Berthon, Paris, claims one, "telephonic circuit and apparatus;" Brush three, viz., two "armatures for dynamos," and an "arc lamp;" Daft one, "electric railway;" Edison one, "chemical stock-quotation telegraph;" Hockhausen three, "automatic cut out, arc lamp, and focussing arc lamps;" T. D. Lockwood two, "battery, telephone, and electric signalling circuit;" W. M. Mordey one, "dynamo;" Philippart, of Paris, one, "secondary battery;" Reckenzaun one, "dynamo and motor;" Holroyd Smith one, "electric railway system and car;" Sprague three, "regulator for electro-dynamic motors, electro-dynamic motor, electrical indicator;" and, lastly, Weston four, *i.e.*, electric lamp fixture, manufacture of incandescents, dynamo, and system of generating and regulating electric currents."

SERVICES OF RESERVE TELEGRAPHISTS IN THE EASTERN SOUDAN.—The Postmaster-General has directed that the following extract from a report of the late Acting Director of

Digitized by Google

Telegraphs at Suakin, as regards the reserve men from the 24th Middlesex (Post Office) Volunteers employed with the Royal Engineers in the recent operations in the Eastern Soudan, be published for the general information of Officers of the Department:—"As telegraph operators these men are of the highest efficiency. As regards their conduct I can only say that on no occasion during the four months they were under my command had I the slightest cause to find fault. I found them at all times, under very trying circumstances, ready and willing to carry out orders, and to take their share in the roughest work—including the care of horses on the picket line, to which of course they were wholly unaccustomed—and I would be much obliged if you would bring to the notice of H.M. Postmaster-General the creditable way in which they conducted themselves."

THE BRITISH ARCHÆOLOGICAL ASSOCIATION AT BRIGHTON—The Mayor's *conversazione* was marked by the illumination of the Old Steine enclosures, the work being carried out entirely under the direction, and at the expense, of Mr. Volk, the electrician, who brought to his aid electricity, gas, and oil, and thus provided in various parts of the enclosures a very great attraction for the inhabitants. Gas standards were erected, and the jets were enclosed in pink-coloured globes, which cast a soft and pleasant light around. A large number of glow-worm lamps, of almost all conceivable colours, were scattered as it were about the grounds and twined around the fountain. The general effect of the illuminations was exceedingly bright and gay, and thousands of persons who visited the Steine to witness them were delighted with what they saw. At one period of the evening the fountain was put into play and the electric light thrown upon it from a powerful lamp at No. 1, Marine-parade, but the diffusion of the light could hardly be called a success. This was owing to the fact that the lamp could not be placed nearer, the rays being too greatly dispersed. Otherwise the arrangements were in every way satisfactory, and reflected great credit upon Mr. Volk.

THE ELECTRIC LIGHT IN CORN MILLS.—Messrs. Rishworth Brothers, corn millers, York-street, Leeds, have introduced the incandescent electric light into their mill, and the whole place is now illuminated by this means. The installation consists of 97 16 candle-power Edison-Swan lamps, the current for which is supplied by one of Crompton's patent wrought-iron dynamo machines of compound self-regulating type. The power is taken from their mill engine for the present by means of a belt. Near the dynamo are the switches for the main circuits, by means of which the various rooms are lighted or extinguished at pleasure. Here also are the cut-outs. In each room there is in addition one or two auxiliary switches for turning out such lights as are not regularly required. On each floor there is an ingenious arrangement in the shape of movable lanterns, provided for inspecting the interior of the various machines and gearing, and for use in places where a naked light or even a covered oil lamp would be dangerous. The lights in the offices are provided with suitable Venetian shades. The work has been done by Mr. Wilson Hartnell, M.I.M.E., consulting engineer, of Leeds.—The City Corn Mills, belonging to Mr. Alexander M'Dougal, Manchester, have also just been lighted with the incandescent light.

THE ELECTRIC LIGHT AND PHOTOGRAPHY.—Experiments were made on the 20th inst. at the Royal Gun Factories in the Royal Arsenal, Woolwich, in order to test the application of a new electric lamp, designed for making examinations and photographs of gun interiors. The system of scrutinising the bores of guns by means of electricity has only been a short time in vogue, and has proved of great value, but the want of an electric dynamo has prevented its general adoption at many places where it would have been of considerable use, and the authorities have now taken up readily a portable battery for the purpose of supplying the place of a dynamo in such cases. The battery, without being necessarily powerful, is chiefly serviceable on account of its constancy, as it can maintain a light of unerring brilliancy for a period of ten hours if requisite, and then enable the examiners to make their inspections with all the leisure they may desire. The experiment was to try the battery and a dynamo in competition. Two 8in. guns were placed side by side in the new boring mills, and photographs were taken of their interiors by both processes, the results, as far as could be judged by a cursory view, being equally satisfactory. Col. Tarleton, Royal Artillery, Assistant Superintendent of the Gun Factories, was present; the electric apparatus was directed by Mr. Angus, and Mr. C. O. Brown, of the Chemical Department, superintended the photography. In future it may be expected that reports of damaged guns sent in from distant stations will be accompanied by photographs, both internal and external.

A CURIOUS PHENOMENON.—A contemporary is informed that, at about midnight on July 29, a remarkable phenomenon was seen at Jönköping, Sweden, over Lake Wettern. A strong luminosity was suddenly seen in the north, where some very peculiar clouds—looking like icebergs—were observed almost to touch the water. From these clouds electrical discharges continually proceeded, imparting to them a bluish, phosphorescent light, somewhat ruddy near the water and intensely yellow at their sides. It seemed like a constant discharge of fireworks from the lake. It was remarkable that the light—as is generally the case with an electrical discharge in the atmosphere—did not assume the form of bunches of streamers, but at one time flared up intensely and at others formed narrow bands across the clouds. Above the latter there was a faint bluish reflection. The lake lay as calm as a mirror, and though an optical illusion was uncommon in these parts, the western shore seemed close to the town, while the eastern disappeared in the clouds. Except the electricity-laden clouds in the north the sky was clear, stars shone, and the full moon was bright. Below the latter the sky seemed faintly red, compared with the intense electric light. At Katrincholm the same phenomenon occurred in the north east. Here an intense glare was seen above a cloud, assuming the appearance of two gigantic lustrous trees, which remained thus for half an hour, when it changed into a variety of forms. There was no noise accompanying the phenomenon, which lasted in both places for about one hour. It is not probable that the phenomenon could have been of auroral nature on account of the brightness under a full moon.

THE ELECTRIC LIGHT FOR STEAMSHIPS.—The "Aquidaban," the new ironclad recently built for the Brazilian Government by Messrs. Samuda Brothers, and now lying in Millwall Docks, was completely lighted up by electricity on the evening of the 20th inst. Any one who has explored the depths of an ironclad can readily conceive the value of the incandescent lamps in such subaqueous regions In the admiral's rooms and the officers' quarters they are a veritable luxury; while for all work on deck, including the loading or unloading of stores, their capability of being grouped under a shade and used as a pendant light at any height or depth renders them of the highest utility. All these advantages are obviously obtained to the full in the arrangement of the 220 incandescent lamps with which

Digitized by Google

Messrs. R. E. Crompton and Co. have supplied the "Aquidaban." But for the purposes of an ironclad another adaptation of the electric light is of paramount importance, and Messrs. Crompton and Co., have therefore also fitted this vessel with two great search-lights—arc lights of 25,000 candle-power nominally, but of greatly magnified intensity when their beam is concentrated by the mirror arrangements of the lamp and projected, as it may be, for long distances on either side of the ship. One of those powerful lights is placed aft, and the other in an elevated position in front of the bridge. By a special invention the mirrors of the huge projectors, as well as the whole of the incandescent lamps, are so hung as to minimise the risks of fracture from the concussion caused by the firing of the heavy guns in the turrets. The dynamos driven by the compound Willans engine work with surprising gentleness and freedom from vibration. The trial run of the light was, it need scarcely be said, very successful.

THE ACCIDENT AT EARL'S COURT.—On the occasion of the Board of Trade inquiry, on Wednesday last, into the circumstances attending the railway collision which occurred on Sunday afternoon last near Earl's Court, John Brazier, who has been a signalman at Warwick-road box for two years, said he was alone in his cabin when the collision occurred. The down home signals were not easily seen from the cabin, but they were electrically repeated there. Everything was in good condition before the collision. The last train from West Brompton previous to the collision was the one due at Earl's Court at 2:37, and he lowered for it both home and distant signals on the wall road. Signals were put at "danger." He did not recollect looking at the electric indicator to see if the arms were responding to the levers, though he usually did. There was nothing that he felt in the movement of the lever to indicate that anything was wrong. After the collision the driver of the District train came up to the box and asked him if the driver of the other train had come out against his signals. Witness replied "No; it was you who came past the signal." To this the man rejoined, "My signal is off; look." Witness looked round and found that this was the case, but on looking at the electric indicator in the cabin he discovered that it showed the signal on. Mr. George Estall, resident engineer to the District Railway, deposed to visiting the scene of the collision shortly after the accident, when he found the down home signal on the Putney-road standing off, although the lever in the cabin was in its proper position of danger. An inspection revealed the fact that the vertical rod controlling the signal arm was broken. The rod was made of wrought iron, and was five-eighths of an inch in diameter. The metal was worn, but this was not visible. Charles Brown, telegraph foreman, said the electric indicators were last examined before the accident by a telegraph linesman, named Tombs, who would have reported to him if anything had been out of order. The inquiry was adjourned.

THE EARTHQUAKES.—It is reported from America that Cotopaxi in Ecuador began a serious eruption before daylight on July 23rd. Streams of lava, with ashes and stones, overwhelmed part of Chimbo, situated near Cotopaxi, and one hundred houses were destroyed. Guayaquil is 130 miles from Cotopaxi. The *Nacion*, of Guayaquil, reports that about 1 o'clock in the morning people were awakened by a heavy artillery apparently from guns of the heaviest calibre. The explosions followed one another with wonderful rapidity, sometimes causing a continuous roar, shaking the earth and causing the windows and the doors of the houses to rattle. A telegram from Chimbo to Guayaquil states that in that city, situated almost at the foot of the volcano, there was what the residents along the River Yana-Yacu call an aluvion. The phenomenon which these people understand by "aluvion" is really the stream of lava which descends the mountain sides, melting the snow with which it is covered, and pouring down a tremendous mass of lava, mud, stones, and all obstacles encountered in its progress. Investigation during the day showed that the shocks produced by the explosions during the night were exceedingly heavy. The smoke hung like a pall over the face of the country, and the steady fall of ashes thrown constantly out of the terrible crater intensified the darkness. Accounts from Latacunga state that the eruption began with a terrible storm. The damage done was considerable, but the number of victims is not known. A similar catastrophe occurred in June, 1877. According to a telegram from St. Petersburg to Scandinavian journals, dated August 4th, severe earthquakes have taken place at Tashkend and Wernoje in Russia. In Pishek every house suffered, and the new settlements Sukuluk and Belowodsk were destroyed. In the latter place the church fell in. It is stated that fifty-four persons were killed and sixty injured. The shocks continued to be felt several days, and there are great fissures in the earth.

THE WATERS RAILWAY SIGNAL.—The importance of electric signals in connection with railway service, says our American namesake, has directed the attention of many inventors to the subject. Their aim is to secure that absolute reliability which is apparently impossible under human oversight. A system invented by William T. Waters, of Atlanta, Georgia, comprises some novel and ingenious features. The operation of his block system is very interesting, and is designed to cover every necessary point in connection with the movements of railway trains upon either a single or double track system. It consists of a series of signalling stations which may be simply posts, with a metallic case containing the necessary mechanism to operate the semaphores. These stations divide the line into blocks, and each is provided with two distinct sets of signals. One set consists of semaphores for each direction, together with illuminated night signals for similar use; the second is a verifying signal, visible both day and night, operated from either direction, and recognised as a signal whenever seen. The first set consists of four semaphore arms or discs, mounted on rods pivoted within the signal box. Each pair of these discs form an advance and a rear signal. The night signals consist of lights in fixed positions, changed by transparent screens in connection with the day signals. The verifying signal is a revolving disc by day and a light by night, and the object of this portion of the system is to notify the engineer before leaving a given block, that his advance signal has or has not been diplayed at the farther end of the block he is then to enter. The verifying signal is the main signal of the system. The signal mechanism is operated by a reversible electric-motor provided at each post, which turns in either direction according to the circuit by which the transmitted impulse may arrive. The operation is entirely automatic, and is actuated by the movement of the train through the medium of a track circuit closer, or an insulated section of the rails as may be deemed most expedient. The signal posts are connected with an ordinary single wire by means of which the various movements are controlled. The signals are interdependent. One train can in no manner interfere with the signals of another; neither can a train, without adequate warning, approach nearer than the distance of one block to a post whose indications are already controlled by a previous train. These results are attained by a combination of electro-mechanical devices which have been arranged with a view to eliminating all possible elements of

danger, and at the same time providing a system which can be introduced at a reasonable expense.

THE BRITISH ASSOCIATION MEETING.—The arrangements for the visit of the British Association to Aberdeen may now be said to be complete. Apart from hotels and lodging houses —whose owners cannot after all be blamed for trying to make science pay—the hospitality of the Aberdonians towards the members of the Association will be quite as lavish as that of any southern city, Most of the notabilities intending to be present, and all the officials who care for it, will be the guests of the leading people in the town and neighbourhood. There will be several garden parties in Aberdeen during the week, while the number of excursions already arranged for is alarmingly large. On the Saturday of the first week, by invitation of Her Majesty, 150 of the members will be taken to Balmoral by water and coach, and lunch will be provided for them. These will be shown over the grounds. Besides this it is said that arrangements are under consideration for the presentation of a few representative members of the association to Her Majesty. On the same day as the Balmoral excursion, parties of from 30 to 150 will be taken to Haddo House, Dunecht, Dunnottar, Drum and Crathes, Finzean, Glentana, and Loch Kinerd. On the Wednesday of the second week a party of 25 will be taken to Braemar, lunched, and driven about. And on the Thursday 200 will be taken to Invercauld, while other parties will be made up for Haddo House and Braes o'Gight, Huntly Castle, Elgin and Lossiemouth, Portsoy, Banff and Duff House, Edzell and the Burn. It is thus evident that ample preparations are being made for the entertainment of the learned visitors. So far as concerns the actual work of the meeting, the various sections will be well accommodated in the buildings of Marischal College and various halls in the neighbourhood. In Section A, Mathematical and Physical Science, it has been arranged to have discussions on kinetic theories of gases and on standards of white light. Prof. Crum Brown has consented to open the discussion on the kinetic theories, and has drawn up a short abstract of points to which he proposes to allude. In Section B, again, arrangements have been made for two discussions in the Chemical Section, over which Professor Armstrong will preside. The one will be on the determination of the Molecular Weights of Liquid and Solid Bodies, the other on Electrolysis. It is proposed to have a series of critical papers read which shall embody, as far as possible and desirable on such an occasion, our knowledge of these subjects, and also indicate the directions in which investigation is specially required and may be most usefully carried on. These subjects have been chosen as being of general interest and of special importance to the chemist, and in the hope of inducing chemists and physicians to co-operate in attacking the many problems which await solution. Captain Abney will open the first discussion with a paper on the Spectroscopic Method. Professors Guthrie, Reinold, and Dilden, Mr. S. U. Pickering, Dr. Russell, and Dr. Armstrong will also contribute papers. Professor Lodge will open the discussion on Electrolysis, and Professor Schuster, Captain Abney, and Mr. Shelford Bidwell have already consented to contribute papers on portions of this subject. Mr. Baker presides over the Mechanical Section (G).

THE ELECTRIC LIGHT IN A BLEACH WORKS.—The *Textile Manufacturer* contains an account on installation recently put down at the Bleach Works of Messrs. J. Whittaker and Company, of Radcliffe, near Manchester. The whole of the electrical arrangements have been carried out by the Manchester and District Edison Electric Light Company, under the direction of their manager, Mr. Williamson, in a most complete and efficient manner. The conductors are everywhere efficiently connected, instantly accessible, neatly laid and arranged with a view to the least possible liability to damage or risk. The lamps in each room are capable of being independently lighted or extinguished by means of a switch close to the door, so that the whole of the lights are instantly turned "on" or "out" with the greatest facility. The lamps are of the well-known Edison type, nominally rated at 16 candle-power each, but giving fully 20 candle-power. As some check upon this we may state that throughout the works 200 of these lamps replace about 350 gas jets, and we are assured by Mr. Whittaker that he has now more light than he ever obtained from the gas. Certainly the amount of light is ample in every case, and some of the rooms are brilliantly lighted. Some of these lamps have been in constant use in the Theatre Royal for over two and a half years, which gives a life of over 5,000 hours, but taking the safe average first given, the cost at the Mount Sion Works for renewal of lamps will not exceed £42 10s. per annum, which amount may be borne in mind when we come to deal with the comparative cost of the existing and superseded systems. The machine employed in the generation of current for the lamps is of the Elwell-Parker type, and is remarkably compact, as is shown by the following dimensions :—Length, over all, 5ft.; width, 2ft. 3in.; height, 2ft. 4in.; whilst its weight is slightly over one ton. The horse-power required to drive it varies, of course, with the number of lamps in use, but when working to its full extent about 24 to 25 actual horse-power is required. That it is working very much within its limit is shown by the fact that in no part of the machine is any heating effect appreciable, the commutator bars are wearing uniformly and smoothly, and no tendency is apparent for the formation of grooves. The bearings are long and lined with special metal, and the armature is so well balanced that, although running at 1,100 revolutions per minute, no vibration is appreciable. In ordinary circumstances power is obtained from a water wheel making from 26 to 27 revolutions per minute, but the gearing is so arranged that the machine may be driven by the works engine. The fact that the necessary power can be obtained from the water wheel during nearly the whole year of course makes the installation a favourable example in working cost, but there is another feature which in ordinary circumstances would render it a drawback. A water wheel necessarily revolves slowly, so that a slight variation of speed is tremendously magnified in the dynamo. In this cases the driving arrangements, however, are so well balanced and controlled that not the least degree of fluctuation in the light has been observed. In the matter of attendance it has been found that in a works of such dimensions the item may be totally disregarded, since it is no more than would be required for gas—that is to say, a few minutes daily for oiling and cleaning. No additional labour or attendance has been required. With reference to the comparative costs of the two systems, based on the average consumption of the last three years, the cost of gas burnt in the superseded burners was £330 per annum. We have already mentioned that the annual cost for lamps will be £42. 10s., the amount allowed for interest and depreciation is £32; adding to these items the cost for oil and waste and attendance, it will be seen that Messrs. Whittaker and Co. have some justification for their estimate that they obtain a better light with cooler rooms and purer air at about one-fourth the cost they were previously paying. It goes without saying that, being in the possession of practically free power, Messrs. Whittaker and Co. are favourably placed for making such a comparison; but those who have to pay coal bills may readily calculate what the extra cost would be, and they may also make allowance for the difference in the price of gas.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.

BY OLIVER HEAVISIDE.

(Continued from page 272.)

Supposing now that we have, by the previous, satisfied ourselves that the distribution of current in the steady state is uniquely determinate by the subjection of the current to Ohm's law and continuity, and of the complementary force to being wholly polar, which last condition makes the activity of the impressed forces the greatest possible subject to conservation. The question then arises, how is this affected by the conductor being a dielectric as well, so that there must be elastic displacement in it? If we compare the dielectric conditions (87) with those for the conduction current (86), we see that they are of exactly similar form, except in the presence of ρ, the volume density of electrification. If, then, we start with $\rho = 0$, and proceed to find the displacement produced by the impressed force on the supposition that there is no conductivity anywhere (just as before, in the conduction problem, we assumed the specific capacity to be zero everywhere), we know that the displacement is uniquely determinate, as was the current before. Like the current, it is closed, and is so distributed as to make (not the heat) but the potential energy of displacement a maximum. The total work done by the impressed forces is twice this. The other half is not accounted for. In the transient state the energy is partly electric, partly magnetic; in the absolutely steady state it is wholly electric; practically there is always conductivity somewhere, so that half of the work is spent in the Joule heat of induced conduction currents, and is not radiated away, and, so to speak, lost. But that we have no concern with at present.

Now this distribution of displacement will not in general be consistent with that of electric current determined by the conductivity conditions. To be consistent, c the electric capacity, and k the electric conductivity, must be everywhere in the same ratio, or capacity × resistance (both specific) must be a constant. Hence, in general, either only one of the solutions is correct, or else neither. A little consideration will show that it is the conductivity solution that is correct, and that we must, after finding the distribution of electric force E from the conductivity conditions without any reference to those of capacity, determine the displacement and electrification to correspond to the thus found electric force by the first two conditions of (87), viz.,

$$D = cE/4\pi, \qquad \rho = \text{div. } D.$$

For we thus satisfy all the conditions, which we could not do by starting with the dielectric problem, finding E to suit, and from it, finally, the distribution of current. Why we are able to solve the problem by the conductivity conditions alone is mathematically accounted for by the presence of ρ in the continuity condition relating to the displacement. The distribution of displacement (or polarisation) D, and the distribution of electrification ρ are such as to have no polar force when existing together; or the polar force of the displacement alone and that of the electrification alone are equal and opposite. Thus the electric field is not in any way disturbed, and the current is therefore also undisturbed and independent of the existence of elastic displacement.

On this point it should be remembered that whereas in considering a magnet as a collection of very small magnets, or any very small portion of the magnet as being polarised, the positive end of a polarised particle is that end to which the vector polarisation points, and is the end upon which positive magnetic matter may be assumed to be collected; yet, on the other hand, if we do the same with electric polarisation, it is the negative electrification that is on the positive side of a particle, that to which the vector displacement points. We cannot, in the magnetic problem, imitate the above state of electric displacement and electrification having no polar force. For the magnetic analogue of D, which is $B/4\pi$, B being the magnetic induction, is always continuous.

Now, to go further. At the commencement we assumed that the conductivity nowhere quite vanished, so that we have been so far considering the current and displacement produced by given impressed force in an infinite conductor, in which k is finite everywhere, whilst c is quite arbitrary, and may vanish in certain portions if we please; it being the conductivity conditions alone that determine the field of force. But, practically, we must regard certain parts of space as being wholly non-conducting. This, though apparently included in the preceding, viz., by taking the special value $k = 0$ in certain spaces, really, to a great extent, necessitates a changed mode of treatment. It is not sufficient to find E from the conductivity conditions, putting $k = 0$ in non-conducting space. For this will not give the proper field in the non-conductors, but only in the conductors, unless at the same time $c = 0$ in the former, or, in special cases, c = constant.

Also, it may happen that when the conductivity is finite, though very small, in certain parts of space, it will be practically necessary to suppose it to be quite zero, on account of there being a first approximately steady state, and then, a long time after, a wholly different, quite steady state; which last, though it is not what is practically wanted, is what the conductivity conditions give. Consider, for example, a submarine cable whose ends are earthed through condensers. Put a battery in circuit at one end. The practical steady state is reached quickly, in a few seconds (of course not counting disturbances or absorption). But as the dielectric is slightly conducting, if we keep on the battery, the "charge of the cable" will in time —minutes or hours, according to the insulation—nearly disappear; theoretically, in an infinite time. This is the real final state, but the first approximately steady state is what is practically wanted, given, very closely, by assuming $k = 0$ exactly in the dielectric.

Now divide all space into two sets of regions, the conducting and the wholly non-conducting, including in the latter the dielectric in such a case as just mentioned. All conducting matter which is continuonsly connected must be regarded as a single conductor. Thus all the wires on a line of poles, if they are earthed, together with the earth, and all that is in conducting connection with it, forms strictly a single conductor. But if we loop two of the wires, removing earth, they form a separate conductor. (Leakage ignored.) There may thus be any number of distinct conductors, each self-continuous, but wholly separated from all the rest by non-conducting matter, or else unbounded partly, though the last is, as regards conductivity, practically unrealisable. Similarly the rest of space, the nonconducting space, forms a number of self-continuous regions, each either wholly bounded by conducting matter, or else partly unbounded, which last is practically realised.

Now, selecting any one of the conducting regions, let the impressed force e be given in it. It is readily shown, by the simplest modification of the conduction problem for all space, that C (and of course E) are definitely fixed by the distribution and e and of conductivity. The modification consists in applying the space integrals to the finite space occupied by the conductor, at the same time introducing the surface condition that the current is confined to the conductor or is tangential at its boundary, which condition is expressed by $CN = 0$, if C be the surface current density and N the unit vector normal to the surface. But this modification may be wholly avoided by integrating through all space as before, thus including surface terms, on the assumption $k = 0$ outside the conductor. The solution obtained applies to the conductor only, that part for the external space must be wholly rejected. There is an exception, namely, if $c = 0$ as well as $k = 0$ in the whole external space, when the external solution for the electric force will be the correct one, as will also be the case sometimes if c = constant.

Thus the internal electric state of any conductor depends solely on the conductivity and the impressed force in it, and is independent of all external conditions. (This is not true for the magnetic state of the conductor, which will be influenced by the external conditions not only as regards permeability, but as regards currents and magnetisation, but at present it is only the electric state that is in question.) We therefore settle the electric state of the whole of the conducting part of space, one conductor at a time. Not only that, but in the same manner as before done in the case of the infinite con-

Digitized by Google

ductor, we settle the displacement and electrification in every conductor, one at a time, from the known electric force in them, making no alteration whatever in the electric field.

There remain, finally, the non-conducting regions, and now the matter gets rather more complex. So far our knowledge ceases at the boundaries between the conducting and the non-conducting regions. But at every point on these boundaries, on the non-conducting side, the tangential component of the electric force is fixed. For the second equation of induction is

$$\text{curl}(e-\text{E}) = 4\pi\text{G} = \mu\dot{\text{H}}, \qquad (23)\ bis$$

where G is the magnetic current, H the magnetic force, μ the permeability. Here $\text{E}-e=\text{F}_1$ the electric force of the field by itself, not counting impressed force. Applying the Version Theorem to this, interpreting it for a mere surface, we see that the tangential component of F_1 must be the same on both sides of the surface. Otherwise the surface would be the location of a magnetic current sheet, of strength G per unit area. This continuity of the tangential component of the electric (similarly of the magnetic) force of the field is true whether the state be steady or not. When not steady F_1 is not polar. At present $\text{F}_1=\text{F}$ and is polar. We know then the tangential component of F (including its direction) at every part of all the boundaries. In terms of potential, we know its surface variation over every boundary, but not its absolute magnitude. The last is unknown, not merely as regards a constant, but as regards n constants, one for every conductor, which, if we choose to employ potentials, must be mutually reconciled, so as to leave only one of them arbitrary. Now we cannot do this without knowing the state of the dielectric non-conductors. The potential must be found last of all, even in the conductors, whose electric state is independent of one another. Obviously, even were there no other reason to give, this would be a powerful argument against potential representing any physical state, in the same manner as electric force, current, &c., do.

As before we took the conductors one at a time to completely find their electric state independently, so now we may take the non-conducting regions one at a time, and find the electric state of each independently of the others. Selecting, then, a single non-conducting region, the conditions to be satisfied within it are

$$\text{D}=c\text{E}/4\pi, \qquad \text{div.D}=\rho, \qquad \text{curl}(e-\text{E})=0, \quad . \quad (87)\ bis,$$

where now, of course, e is the impressed force at the point considered. Or, eliminating D, and putting $\text{E}=e+\text{F}$, F being the polar force,

$$\text{div.}c(e+\text{F})=\rho, \qquad \text{curl F}=0. \quad . \quad . \quad . \quad (90)$$

The electrification density ρ is now not to be *found*, as in the conductors previously, but must be *given*. Thus e, ρ, and c are given at each point, and D, E, F have to be found, or simply F, since that fixes the others.

There is also the before-stated boundary condition; FN being the normal component of F, (FN)N is the vector normal component, so that it is

$$\text{F}-(\text{FN})\text{N}=\text{V}\{(\text{VFN})\text{N}\} \quad . \quad . \quad . \quad (91)$$

that is given over the bounding surface or surfaces. Or, simply VFN, the tangential F turned through a right angle on the surface, may be regarded as given.

A preliminary examination, as regards energy, of the three conditions (90) and (91) shows that they are insufficient to determine F. We need to know, also, the boundary representatives of ρ the electrification. But it is not the electrification at every point of the boundaries, but only their totals, that is needed, *i.e.* the charges. Let q_1, q_2, &c., be the charges of the separate surfaces, then

$$q_1=\Sigma\text{DN}_1,\ q_2=\Sigma\text{DN}_2,\ \&\text{c.} \quad . \quad . \quad . \quad (92)$$

must be given, D being the displacement at a surface, and N_1, N_2, &c., unit normals from the conductors to the non-conductor.

For it is clear, by the continuity of the electric current, that if a conducting surface, wholly surrounded by dielectric, had a charge before the impressed force in the conductor began to act, such charge will not be altered in amount, though its distribution may be changed when the impressed force acts. Similarly, impressed force in the dielectric cannot alter its amount, but only its distribution, nor can the introduction of external electrification. The same applies partly when the conducting surface wholly surrounds a dielectric, neither e in the conductor nor the dielectric can charge it. But, on the other hand, the introduction of any interior electrification, by continuity of the current, requires the surface to have a total charge equal to the whole interior electrification taken negatively. In any case, then, Q_1, Q_2, &c., must be known, independently of external electrification, in the one case, or depending on interior electrification in the other.

We make no distinction between simply and multiply connected regions, *e.g.*, a rod and a ring, because there is no difference whatever required in the mathematical treatment, if we keep clear of the potential. But it will be convenient to break up the problem into two, thus:—

(*a*) Given e, ρ, and Q_1, Q_2, &c., and that VFN = 0. Find F.

(*b*) Given VFN, and that $e=0$, $\rho=0$, $q_1=0$, &c. Find F.

We take (*b*) first, as it is the simpler, and is also directly connected with the conduction current. That is to say, we suppose that before the impressed forces in the conductors began, the whole system was free from electrification or impressed force in the non-conductors. We have

$$\text{div.}c\text{F}=0, \quad \text{curl F}=0, \quad \Sigma\text{DN}=0, \quad \text{VFN}=4\pi g, \qquad (93)$$

F being the force in the region. The first two apply to every point in the region, the third to any conducting bounding surfaces as a whole, whilst in the last g is given over the whole boundary. We have

$$\Sigma\text{F}_1c\text{F}_1=\Sigma\text{F}c\text{F}+\Sigma fcf+2\Sigma\text{F}cf \quad . \quad . \quad . \quad (94)$$

if $\text{F}_1=\text{F}+f$, whatever they be. Suppose now F to be a solution of (93), and f to satisfy the second and fourth conditions, so that F_1 is a solution of the second and fourth, but is otherwise unrestricted. By the first D is continuous within the region, and, by the third, at its boundaries as much leaves as enters the region. We may therefore close D completely outside the region without disturbing D within it. D, thus extended, is a wholly closed flux, and therefore may be represented by $4\pi\text{D}=\text{curl}\text{Z}$, where Z is determinate in various ways. This makes

$$\Sigma\text{F}cf=\Sigma f\text{curlZ}/4\pi=\Sigma\text{conv.V}f\text{Z}/4\pi. \quad . \quad . \quad (95)$$

This summation extends through the region. By the Convergence Theorem, the last form is at once expressible as a surface integral over the boundary, viz.,

$$\Sigma\text{NV}f\text{Z}/4\pi=\Sigma\text{ZVN}f/4\pi=0$$

the vanishing taking place because $\text{V}f\text{N}=0$. Thus $\Sigma\text{F}cf=0$. Therefore, by inspection of (94), $\Sigma\text{F}_1c\text{F}_1$ is made a minimum by $f=0$, making $\text{F}_1=\text{F}$, and proving F to exist. That it is unique follows by the same reasoning as in the conductivity problem.

The physical interpretation of the above, as regards Z, which is best taken as the magnetic impulse, or time integral of the transient inductive magnetic force, is interesting, but must be left over. In the above, however, Z may be any vector whose curl is D in the non-conductor, its curl in the conductors being arbitrary. Thus, if we close D in any manner through the conductors, and call the complete system D_1, then

$$\text{Z}=\text{curl}\Sigma\text{D}_1/4\pi r+\text{any polar vector}$$

satisfies the requirement. Or, instead of the curl of the vector-potential of D_1, we may form the vector-potential of its curl.

As regards the transformation used in (95), if f and Z are *any* vectors, we have

$$\text{conv.V}f\text{Z}=f\text{curlZ}-\text{Zcurl}f;$$

and (95) follows because f has no curl.

Lastly, the assumption made in the above demonstration that F_1 is possible, to satisfy the second and fourth of (93), though nearly obvious, is made evident by constructing any scalar potential whose tangential variation at the boundaries is of the required amount, its value elsewhere being arbitrary, and letting F_1 be its slope.

(To be continued.)

ROYAL ENGINEERS AND THE POSTAL TELEGRAPHS.—Capt. Beresford, R.E., having returned from Egypt, resumes the command of the Royal Engineers and his position as Superintending Engineer of the Southern District.

THE PURCHASE OF SUBMARINE CABLES BY GOVERNMENT.

In the article from *The Times* which we reproduced in our last issue, the writer, after discussing the question of uniform tariffs, comes to the remarkable conclusion that "the Government would inevitably be landed, sooner or later, in the acquisition of the undertakings of all the cable companies, so far as regards European communications, and the taxpayer would in all probability pay a great deal more than the property of the Companies was worth, as he did on the purchase of the inland telegraphs, and perhaps be called upon to work a losing undertaking into the bargain." No doubt this is the conclusion to which we have all come after a more or less casual consideration of the subject. The matter, however, on a further examination, is not so simple, and ultimately the opposite conclusion is reached, viz., that it is impossible for any Government to purchase or own the system of cable connections even of Europe much less of the whole world. What are the facts of the case? How has the cable system been built up? At the end of the forties and beginning of the fifties English capitalists determined to connect the Continent electrically with England. They succeeded. Success put promoters and capitalists upon this new track, and gradually—and principally with English capital, energy, and pluck—the present network of cables has been laid. The cost of cable work is enormous, and in almost every case the promoters, in order to protect themselves, obtained concessions to guard against undue competition. The political signification and value of the work were altogether unrecognised, and hence the concessions were obtained with comparative ease. The commercial benefit was the sole object recognised. As years passed by the value of cable communication to the various Governments was more and more appreciated, till at this day it is admitted to be a political necessity. The value of the cable system commercially is at its highest when the system reaches every part of the civilised globe. A perfect political system to any one nation would be one entirely in the hands of that nation. Now, is it to be expected that any one of the great Powers, or, for the matter of that, any one of the minor Powers, would agree, singly or in combination, to a scheme putting such enormous controlling power into the hands of the holder of the system? To put the matter bluntly, Is England prepared to see Germany, or France, or Russia, purchase the whole of the cable system of Europe or of the globe? The answer to such a question is soon given, and is emphatically "No." Is it likely, then, that France, or Germany, or Russia, would permit the Government of England to become the owners of the cable system? The answer is similar, and is just as emphatic.

Under existing conditions each Government granting concessions is able to make its own terms with the Companies, and to compel those terms to be strictly carried out. Perhaps some one will be inclined to argue that international terms could be similarly arranged. So they could if mankind were angels, and the aim and objects of each Government were exactly similar. But it is well known that political clouds do arise between each and every Government, and it is not to be expected but that at such times the Government owning the cable system would be at a great advantage as regards all other Governments. The more the whole question is discussed the less probable is the idea of Government control. The loss of a million pounds to the English Government would be insignificant if a political object were to be gained; but no company could act in such a manner as to lose that sum, as well as in all the future to suffer from the after effects of the act. The various Governments can effectually control the action of the Companies, while such control would be obviously weak with the cables in the hands of a powerful nation.

The primary object of a cable company is to earn a dividend. Hence the development of the cable system in the hands of companies is of a commercial character, while in the hands of a Government it is difficult to see how such a character would be maintained. The moving idea with the Government would naturally be political. The cable system would be subservient to political exigencies, which it is now only to a minor extent. That any Government should protect itself is quite natural; but at present they can connect special points with the system by giving a subsidy, thus obtaining their object at a much less cost and with far less risk than by laying and maintaining the cables themselves. We commend these and similar considerations to the minds of those who may be able to influence the question one way or the other, and we shall be surprised if, after maturer thought, these conclusions are not accepted. We may imagine what would happen if at this moment no cables existed while we had the knowledge, scientific and practical, of the possibilities of such cables; and no doubt upon paper we could build up a magnificent system—supposing no opposition from any foreign country would be raised. But to any such scheme we know perfectly well that a most strenuous and effectual opposition

THE INTERNATIONAL INVENTIONS EXHIBITION.

Forbes' Non-Polar Dynamo.

Those visitors at the Inventories who are interested in technical matters will probably have noticed a peculiar model of a dynamo, with some explanatory diagrams, at the stand next to that of Mr. Swan. By-the-bye, a passing word may be said in praise of the artistic and excellent display by Mr. Swan. There is no doubt that this stand is by far the most attractive of those in the annexe. The lamps are arranged in various groups, and vary from the diminutive lamp—a number of which are used to scintillate in an ordinary sized brooch—to the largest and most brilliant of those used in practical lighting. An interesting object, too, is a handkerchief spun with the new material used for the filaments, showing that the celluloid material has a wider use than at first sight might seem probable. The attendants at this stand are to be complimented upon the taste displayed in producing such an attractive show.

We must, however, return to the discussion of the real object of this article, viz., Prof. G. Forbes's dynamo. Externally this machines gives few or no indications of its construction. The model looks like a simple hollow cylinder of iron, with a slot cut, through which a couple of wires are carried, rotating around its axis. The machine at work will be found close to Galloway's engine, and looks like an iron cheese with wires sticking out at the top. We give in Fig. 1 a perspective view of the machine to show its external appearance, while we are indebted for the following description of it to the *Engineer*:—At the west end of the North Court is exhibited a most remarkable machine intended for the electro-deposition of copper by means of a very large current flowing through a bath of copper sulphate. A smaller machine of a similar character is exhibited in the East Arcade, as also a number of drawings showing full size sections of Professor Forbes' machines. Before we can enter into a detailed description of these we must say a few words about the general principle of these unipolar, or, as Professor Forbes prefers to call them, non-polar machines. The latter term seems the more appropriate of the two, as no external magnetism can be detected when the machine is at work. No such thing as one isolated magnet pole can be found in nature; there must always be two poles of opposite sign, although only one of them may be directly utilised. In Professor Forbes' machine, however, both poles are utilised, and as both are well within the body of the machine, which consists almost entirely of wrought iron, none of their magnetic force is wasted externally, as is the case more or less with all other dynamos. The subject of unipolar dynamos is not new, about thirty patents having been taken out within the last few years; but the difficuties of rubbing contacts at high speeds have always stood in the way of their practical application. Not the least of the merits of the machine under consideration lies in the successful manner in which this difficulty has to all appearances been overcome. In the beginning of these articles it was pointed out that the electromotive force in all dynamo electric machines is due to the cutting of lines of magnetic force by a conductor, the direction in which the electromotive force is set up being at right angles to the direction of movement and also at right angles to the lines of force. If a metal disc be fixed, as per sketch (Fig. 2), between the poles of a horse-shoe magnet, and rotated in the direction of the arrow, an electromotive force would be created in direction downwards from the axis to the circumference, and by arranging rubbing contacts on the axis and at the lowest point of the disc a current could be taken off. Other things being equal, the current will be strongest if the poles are arranged to come very close to the disc, and in some cases it might be advantageous to make the disc of soft iron in order to reduce the resistance of the magnetic circuit, and to further intensify the magnetic action between the two poles. The arrangement shown in our sketch produces a current only along one vertical radius of the disc; but if we were to place a number of magnets all round the disc, and arrange a corresponding number of rubbing contacts, equal currents could be taken off along these radii; and if the magnet were made in the form of a ring-shaped shell, currents could be taken off along the whole circumference. This is in substance what Professor Forbes has done. In his machine the shell is an electro-magnet excited by a circular coil placed in the bend of the yoke, and the disc is made of iron of considerable thickness, partly to obtain a large surface of contact, and partly to reduce its internal resistance. In the first machine constructed on this principle the disc was made so wide that it became a cylindrical bar. Two coils were placed over it, leaving a space of about 1in. in the middle for the contact. The shell is in the form of a cylinder about 13in. long and 5in. in diameter. The bearings of the bar—which is the armature—formed one pole, whilst the other pole was the rubbing contact in the middle. This machine will be found on Stand 1,324 in the East Arcade. The next step taken by the inventor was to construct a double machine according to his patent No. 3,115, 1883. We give a longitudinal section of this dynamo in the sketch (Fig. 3), omitting, however, all constructive details. Two discs, D D, are mounted

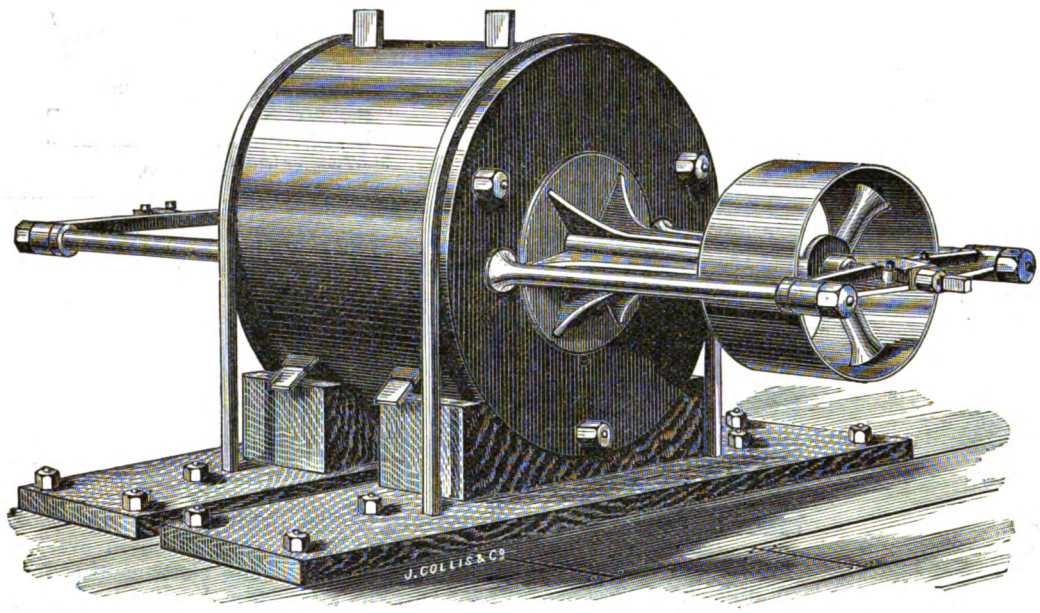

Fig. 1.—Forbes' Non-Polar Dynamo. Perspective View.

Digitized by Google

upon the same spindle, and revolve within a duplicate cylindrical shell of soft iron, S. Rings of trapezoidal cross section are turned out of the shell, into which are placed the insulated exciting coils *c c*. The lines of force created by the current in these coils surround them in closed curves as indicated by the dotted lines, and since the direction of the current is opposite in the two coils, the lines cut the first disc in opposite sense to the second, setting up in one disc an electromotive force inwards and in the other disc outwards. The current flows from the outer circumference of the first disc towards its centre, then along the axis to the centre of the second disc, and thence outwards to its circumference. The rubbing contact is at the periphery of each disc, and at first it was attempted to use mercury for this purpose, the mercury being retained between india rubber rings, as shown. It was expected that under the influence of centrifugal force the mercury would form a band of about equal thickness all round the circumference, and thus establish the best possible contact. Experiment proved, however, that mercury behaved more like a solid belt than a liquid band, adhering for a considerable distance closely to the disc but not touching the casing, and in other places leaving the disc and flying out to the casing. It was also found that the liquid friction of mercury was by far greater than is commonly assumed, and in consequence of this considerable heating took place. These difficulties fairly recognised, Professor Forbes cast about for a remedy, and discovered that iron and carbon form a splendid contact, which will work at high speed without heating and without appreciable wear. Engineers

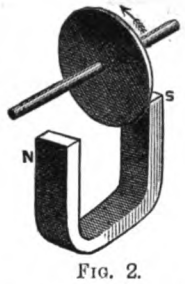

FIG. 2.

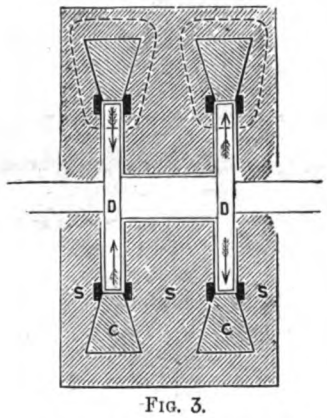

FIG. 3.

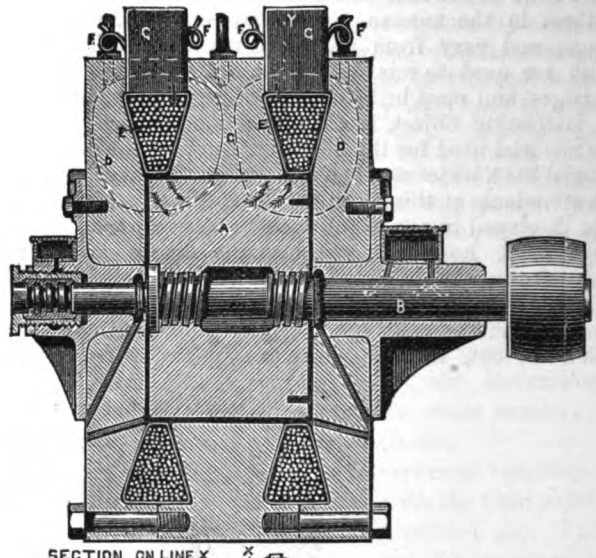
will, perhaps, be less surprised at this than electricians, for they have long known that, with polished shafts, bearings consisting mostly of carbon in one form or other can be made to wear for years without any lubrication whatever. Professor Forbes has therefore adopted carbon contacts, not only in all of his machines, but he also proposes to use them in all cases where rubbing metal contacts have hitherto been employed, especially for the brushes of dynamo machines. If he succeeds in this he will deserve the thanks of all makers and users of dynamos. At present the commutator is that part of a machine which wears most, and in many cases it is costly to replace; but if by the employment of carbon brushes the wear of the commutator can be reduced to a fraction of its present amount, the cost of keeping dynamos in running order will be reduced almost in the same proportion.

The diagrams exhibited on Stand 1,324 give, so to speak, the whole history of the invention. They show how the original idea was developed, assuming more and more a practical shape. Thus we find the next improvement represented in a drawing which we reproduce in Figs. 4 and 5. The machine shown in the above sketch has evidently more internal resistance than absolutely necessary; for by making the discs wider we could increase their conductivity without in any way lessening the number of lines of force which pass through them. It is not even necessary that the machine be any heavier, as we can widen the discs at the expense of the central mass of iron between them. Imagine, now, that we gradually widen the two discs by allowing their inner faces to approach more and more until they meet and form one continuous cylinder. We shall thus obtain not only a maximum of conductivity, but also the additional advantage of having transferred the two inner air spaces to the circumference of the cylinder, where, on account of the larger surface, their magnetic resistance is somewhat diminished. This arrangement is represented in Figs. 4 and 5. The dotted curves show again the

FIG. 4.



SECTION ON LINE X

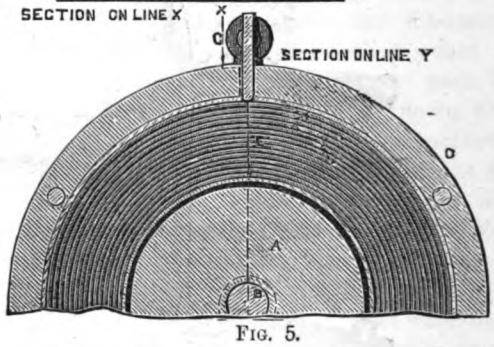


FIG. 5.

character of the lines of force, and the arrows indicate the direction of the currents, which in every point are vertical to the lines of force. The electromotive force is proportional to the speed of rotation, and to the total number of lines passing through the armature. If we assume the same degree of saturation for different size armatures, we find that the electro-

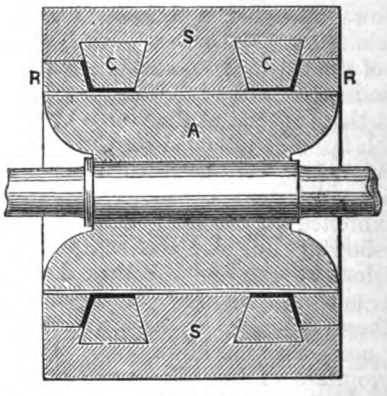

FIG. 6.

motive force is proportional to the square of their diameter. The machine just described, although being a great improvement upon the former type, has the defect of being liable to an enormous side-thrust consequent upon inequality of magnetic attraction on the two end faces of the armature. It is practically impossible to so place the armature that the clearance on either side should be mathematically equal, and hence a certain amount of side pressure must always

Digitized by Google

exist, which necessitates the employment of a thrust bearing as shown. To remedy this defect Prof. Forbes has designed a modified arrangement of the cylinder machine, which will be understood from Fig. 6. We again omit all constructive details. The armature A is 6in. diameter and 9in. long; the ends are turned out to the shape shown, so as to afford an equal area for the passage of lines of force at all points. What in an ordinary dynamo would be called the field magnet, is represented here by the shell S containing the two exciting coils C C. The cross section of these is trapezoidal as before, in order to leave as near as may be an equal area of soft iron round these coils for the passage of the lines of force. Part of the shell consists of two soft iron rings R R, which are insulated from the body of the shell and form the terminals of the machine. Two copper rings of angular section, shown in our diagram by thick lines, form the rubbing contacts. They are provided on the inner circumference with teeth, by means of which the ring of carbon, which is continuous all round and which forms the contact proper, is held in place. The air space or clearance between armature and shell is $\frac{1}{16}$in. This machine has not yet been finished, but from experiments made with other machines it is expected that it will give a current of 5,000 amperes at a difference of potential between terminals of two volts if driven at 2,000 revolutions per minute. For lighting purposes a similar machine could be made with a larger armature. If the cylinder be 4ft. in diameter and 4ft. long, it would give 60 volts at a speed of 1,000 revolutions. Such a machine would, however, be too cumbersome in comparison to the output that could possibly be required of it, although not too cumbersome as compared with the output it could give. It is also doubtful whether, at a speed of 12,500ft. a minute, even carbon contacts will stand. The inventor proposes, therefore, to obtain higher electromotive forces not by increasing the size of his machines to unwieldy proportions, but by making compound armatures, as shown in Fig. 7. The different cylinders are to be insulated from each other, and each is to be provided at the ends with rubbing contacts also insulated from each other. The contact 2 would be connected to 3, 4 to 5, and so on, the current entering the armature at 1 and finally leaving it at 10.

Another form of the non-polar dynamos is shown in Fig. 8. Only one exciting coil, C, is employed, consisting of a spiral of insulated flat sheet copper laid into a circular trough of cast iron, which is fastened to the armature and revolves with it. The sides of this trough carry the carbon contact plates, and contact is insured with the rings R R,

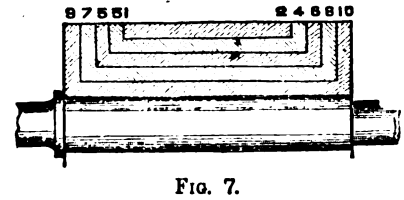

Fig. 7.

which form one terminal of the machine, by the magnetic attraction between the trough and these rings. The rings are insulated from the body of the machine, and have a little end play, so that they can be attracted towards the carbon discs. Suitable stops prevent them from turning. The other contact is formed by two carbon discs fastened to the ends of the armature, and the body of the machine forms the other terminal. The lines of force surround the exciting coil, as shown by the dotted curve, and the currents which cut these lines at right angles flow from the cast-iron trough outwards to the ends of the armature, as indicated by the arrows. The armature of this machine is 9in. in diameter and 8in. long, and is calculated to give a current of 10,000 amperes, at an electromotive force of one volt, if driven at 1,000 revolutions per minute.

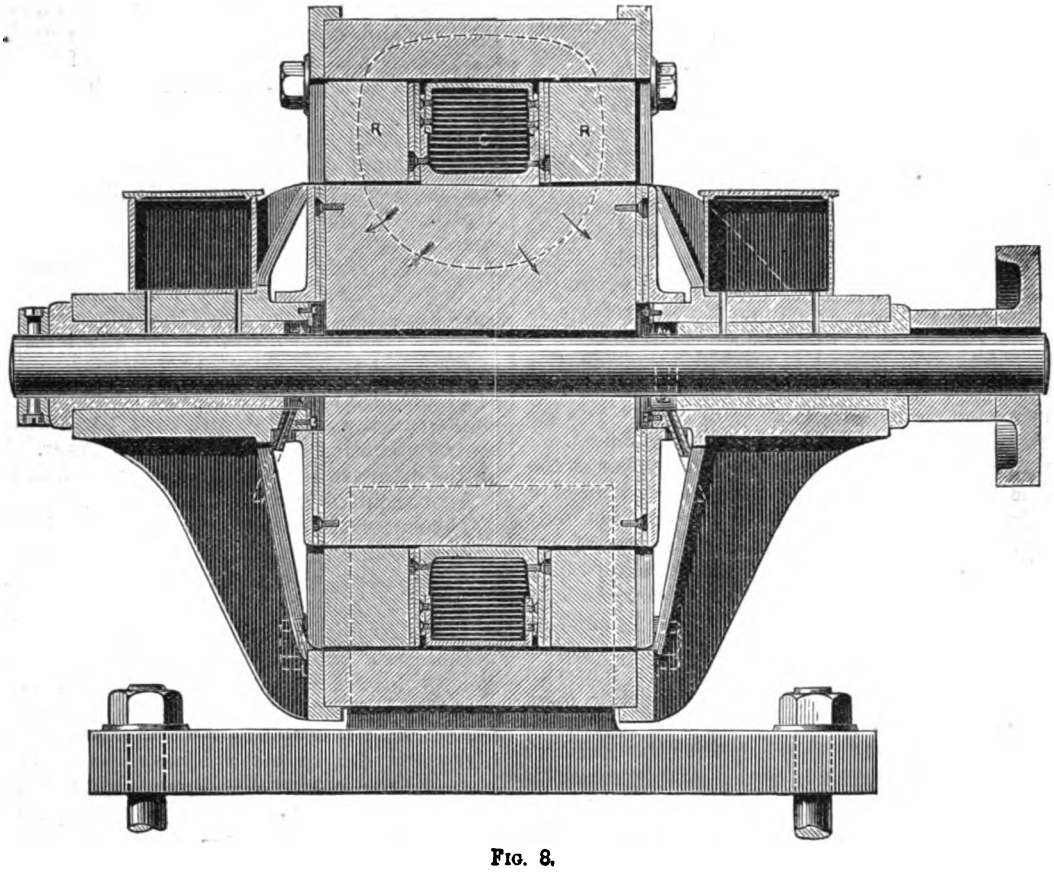

Fig. 8.

The machine shown in action is used to deposit copper, and is not intended for electric light work. We have always maintained that too little attention is usually paid to the construction of machines for special purposes; but there is gradually growing into vogue a better state of things, and few people now imagine that a dynamo will indifferently generate a current for arc or incandescent lighting or for electro-deposition. The field for the utilisation of electricity for lighting operations is extensive, the borders are scarcely explored; but this field is, we believe, small compared

Digitized by Google

with that of the use of electricity in electro-metallurgical and electro-chemical work. These latter are veritably fields of promise to the young investigator, and will amply repay all his attention to them. Whether Prof. Forbes has designed a machine that will prove the best for electro-deposition remains to be seen; but we understand that the experiments carried out under the auspices of the Franklin Institute last year in America showed that it gave results superior to those obtained from any other machine before the jurors.

THE FOUNTAINS.

In the second edition of the catalogue, which has been thoroughly revised and extended, is a description by Sir Francis Bolton of his arrangements to illuminate the fountains. It is not too much to say that the beautiful effects obtained by the illumination of the gardens, and especially of the fountains, have proved most attractive to the public, and have gone far to make these South Kensington Exhibitions so successful. We have seen illuminations in many Continental cities, but nothing to compare with the nightly exposition as developed under the genius of Sir Francis Bolton.

In the ornamental water, in the grounds, fountains of various designs have been arranged (invented and designed by Colonel Sir Francis Bolton, C.E.), which are illuminated after dark by means of powerful electric arc lamps. The following is a description of the means by which the effects shown by the fountains are produced:—The water for supplying the fountains is delivered direct from the West Middlesex Water Company's Hammersmith pumping station. The main enters the Exhibition grounds from the north-west, and is conducted to the four water meters, on the western side of the centre basin, which register the quantity of water consumed. From this point a large main leads to the central "island," where the principal jets rise. The water is supplied at a pressure of about 70lb. to the square inch, which is sufficient to carry it to a height of 120ft. The island is reached by means of a subway, and through this are laid the cables for the electric current and the signalling wires. The whole of the jets are worked by screw-valves and levers placed inside the island.

The fountain display is directed from the clock tower at the south side of the garden, the "operating room" being below the dial of the large clock. The operator controls not only the working of the jets, but also the colour and power of the lights, by a series of electric signals, arranged on a key-board with 48 keys, in three rows of 16 each, which communicate with bells and indicators inside the island. The illumination of the water-spray, which produces brilliant effects when falling, is effected from the seven small islands, and a powerful projected light from the clock tower. The machine room inside the island is an apartment 21ft. square. Its roof being only 5ft. from the floor, renders it impossible for the operators to stand upright in it. The floor is crossed and recrossed in all directions by iron pipes, conveying the water from the main to the various jets.

The fountains are set in action by screw-valves fixed vertically on the different branches attached to the water mains. The large jets, which send the water to the greatest heights, are worked by plug-valves and levers, so as to allow an instantaneous start and stop, which causes a shower of spray. There are altogether eleven wheels and three levers. The wheels are nearly equidistant round the room, the levers being in the centre. In some cases the valves are opened and closed by hydraulic rams controlled by an electric current from the operating room. In the roof are five circular skylights of very strong glass, one of them being exactly in the centre, the others forming a square about it. Under each of these sky lights is a wooden stand, on which is fixed a hand arc lamp of 8,000 candle-power. Over each arc is a lens, which concentrates the light on the jet. When the order "Lights on" is received, the five arcs are set going, the result being to powerfully illumine the jets of water internally, while the dropping water or spray is illuminated externally by the surrounding beams of light, thus producing a glistening effect. There is also a lamp opposite the cascade, the light being concentrated by a plano-convex lens. The current for these lamps and for the lamps in the seven small islands is supplied by a B 12 Siemens machine. These machines are placed in the electric light shed. The usual staff is seven—one man to work the valves, five to attend to the lights, and one to watch and reply to the bells. They cannot see what is going on outside, their only means of knowing that all is right being the signals from the clock tower. The quantity of water sent up averages 70,000 gallons an hour; but when all the jets are going at once 1,000 gallons are used in fifteen seconds. The lamp over the clock tower is placed in a projector kindly lent by the Chatham Military School of Engineering, the current for it being obtained from a Bürgin-Crompton dynamo.

THE GARDEN ILLUMINATIONS.

The grounds of the Exhibition are lit up by about 9,700 electric glow lamps of 5 and 10 candle-power, with a few 20-candle lamps on the band stands and on the verandah of the conservatory, the design of Colonel Sir Francis Bolton, C.E.

These lights, many of which are brilliantly coloured, have been placed partly on the permanent museum buildings and on the conservatory, so as to bring out the tracery of these buildings, and to give an appearance of vastness to the grounds, and partly on the balustrades, round the flower beds, and in the trees and ornamental water of the gardens, the general effect being a charming arrrangement of light and colour. The lights can be turned on or off either by sections or altogether instantaneously. Messrs. Siemens Brothers are the contractors for the installation and maintenance of the whole of these garden illuminations. The installation consists of 23 circuits, each of which is made up of eight parallels of lamps connected in series, the electromotive force of the 5 and 10 candle-power lamps being 25 volts, and that of the current at the machines 220 volts. Each of these circuits is connected to the main leads from the dynamos by an interruptor controlled by a solenoid, placed in the switch-house near the engines. There are also four interruptors on the main leads, similarly controlled, and by means of which resistances can be inserted, so as to diminish the power of the lamps. These solenoids are worked from a switch-board with 10 switches placed in the central operating room in the clock tower. The interruptors on the main are also worked from the clock tower. The total current required is about 750 amperes.

The current is obtained from three of Messrs. Siemens' B 13 self-regulating dynamos, each of which can supply a current of 450 amperes with an electromotive force of 250 volts when running at 300 revolutions.

The four series coils, which are coupled in parallel, are wound with copper wire 0·4in. in diameter, and the shunt coils, which are coupled in series, with No. 9 Sd. W. G. The armature is wound with flat strips instead of wire. Each of the dynamos is coupled direct to a Goodfellow and Matthews high-speed compound triplex engine, fixed on the same bed-plate. Each engine has three high and three low-pressure cylinders, placed tandem, and at an angle of 120 deg. The principal dimensions are:—

Height above bed-plate	6 ft. 6 in.
Length over all	7 „ 6 „
Width	7 „ 7 „
Diameter of high-pressure cylinder	9 „
Diameter of low-pressure cylinder	18 „
Length of stroke	10½ „
Approximate weight	5 tons.

They each indicate 180 horse-power when running at 300 revolutions, with steam at 120lbs. pressure. The steam is supplied by three of Babcock and Wilcox's water tube boilers, which are placed just outside the Quadrant, and between it and the Albert Hall.

As will be seen from the power of the dynamos, two of them would supply considerably more current than is required for the 9,700 lamps. One machine will therefore be spare; but will be kept running ready to be switched in should it be required. As a further security against accident, means have been provided by which the number of lamps can be reduced to what one machine can safely supply without materially affecting the illumination of the grounds.

Digitized by Google

would be raised; and similarily any attempt to adapt the actually existing system to the political needs of any one or two Governments would rouse the opposition of all the rest.

CITY AND GUILDS OF LONDON INSTITUTE.

The results of the May Examinations under the direction of the City and Guilds of London Institute for the Advancement of Technical Knowledge show an improvement which, though not very considerable, is steady, uniform, and on the whole satisfactory. The centres of instruction and examination appear to be multiplying, and the average of pupils attracted by these facilities and encouragements is increasing at the rate of about five hundred per annum. About half of the total number of students usually present themselves for the annual Examination, and, roughly speaking, half of these latter succeed in satisfying the Examiners. The proportion of failures is still far too large; but it may be confidently expected that, with the increase in the number of trained and competent technical teachers, the quality of the instruction will improve, and its results come out better under the test of independent Examiners. Of the total number of candidates examined nearly sixteen hundred presented themselves for the first time. The tables printed in the report before us, besides being wanting in descriptive headings, and puzzling in their arrangement, are defective in respect to candidates who having failed on previous examination have come up again, or have abandoned the attempt altogether; but of those who had passed in 1884 only three hundred and fifty-eight have advanced this year into a higher grade, a fact which seems to point either to stiffer papers or looser instruction. The report, however, expresses satisfaction on this and the general results, and we may be mistaken as to the significance of the figures. As regards the comparative number of passes, we also fail to see the point dwelt upon in the secretary's opening remarks. There were, it appears, 333 more candidates this year than last, whilst the increase of passes was 339. "Thus," says the Report, "the increase of passes is six more than the total increase in the number of candidates." As a statement of fact this is indisputable, but it is unimportant. If they related to new candidates only, the figures would be striking; but in reality nearly 600 examinees had gained passes, and many more, no doubt, had all but gained them at last year's Examination. Still, what would an annual report be good for if not inspiriting, or a secretary if not a dab at figures?

The point on which we are disposed to dwell with greatest satisfaction is the large estimated increase in the number of students who will this year gain their full Technological Certificates. Representing as it does a qualifying certificate in Science from the Science and Art Department, as well as that in Technology, the full certificate indicates a determination to pursue these studies with a serious aim; and the addition of 750 in the present year to the 566 of last year is a substantial gain which the promoters of technical education have reason to be proud of. From the list we published a fortnight ago it will be seen that the subjects most interesting to our readers have received a fair and increasing share of distinction. Outside London, Manchester carries off the palm in these, as in other items of technical training, having obtained the silver medals both for Electric Lighting and for Telegraphy. In the metropolis Electric Lighting attracts a greater number of students than follow it elsewhere; but this can hardly be said of Telegraphy, which appears to be much sought after and admirably taught in the provinces—notably, at Manchester and Dublin. At the last-named place a school, described as the Postal Telegraph Office, has obtained eleven passes, with four Honours and a bronze medal. A similar school connected with the Central Telegraph Office, London, however, has received the same number of Honours, with two bronze medals, and ten passes. All the results obtained at Manchester in respect to Electric Lighting and Telegraphy are credited to the Technical School at that place. In Electro-Metallurgy the few passes obtained go chiefly to Birmingham. Compared with the achievements of the provincial Institutes those of the Finsbury Technical College in London do not shine very brilliantly, numbering in all only twenty passes for Electric Lighting, five for Telegraphy, and two for Electro-Metallurgy. Considering the resources of the parent establishment, this may excite some surprise; but if the passes bear a due proportion to the number of pupils, as no doubt they do, the result only shows that the demand for technical instruction in London is, taking the size of the metropolis into account, far less than in most of the great manufacturing towns.

We should have been glad to have more information as to the avocations of the pupils who avail themselves of the educational privileges afforded by this great scheme of technical instruction, so that we might draw some conclusions as to its probable effect on the work of the future British artisan. That it will encourage and develope the taste for scientific pursuits, and promote the acquisition of accurate technical knowledge we have never doubted; and these things, being good of themselves, are well worth the cost. But we could not fully share the hopes with which the movement was inaugurated—hopes, namely, that British industry would beat its foreign rivals if the British workman were more highly skilled; which when put into plain English meant that if he could be made cleverer he would be better worth his high wages. No doubt of it; but in the workman's opinion he would be worth higher wages still; and he is not likely to make the sacrifices which hard learning entails unless he has a motive in the shape of higher reward. It is not in that way, or in any other way that we know of, that the inequalities of wages in different countries can be levelled. When workmen educate themselves it is to promote inequality in their own persons—in other words, to get on better than their fellows; never to compete with the foreign market. It is for their masters to do that, and chiefly in that direction may we look for the improvement we desire. Higher technical education for employers and their head-men is what is needed most, and this is what will pay best. We do not mean that the workman's technical education is a matter of no importance; what we do mean is that we need not despair or be greatly surprised if he is slack in acquiring it, supposing there is no spare wages fund from which he can be remunerated for his trouble.

CORRESPONDENCE.

METHOD OF EQUALISING THE CHARGE IN CELLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is a common practice to cut out any cell or cells in an accumulator which appears to be charged before the remainder, and to continue charging the others.

In fact, the E.P.S. Company advise this course in their instructions. I have always employed another method of equalizing the charge in the cells, which has proved very successful, so I think it right to place it before your readers, since I observe that it is not mentioned in the most recent instructions sent out by this company.

The process consists of "short-circuiting" any cell which appears to be overcharging through a resistance during a part

Digitized by Google

or the whole of the time of charging the cells. A very small resistance is sufficient, because the E.M.F. of the cell is only 2 volts approximately. To give an example:—Suppose an accumulator is charging at 30 amperes, and the E.M.F. of a cell at the time to be 2·3 volts. Then, if any cell is short-circuited through 0·077 ohm, it is clear that the cell is discharging as fast as it is being charged, and therefore its "contents," or rather "chemical state," remains stationary, whilst the others continue charging.

Any other resistance might have been used, according to the requirements of the case. This method is more convenient and scientific than the disconnecting process generally employed, which is troublesome and dangerous, unless spanners with wooden handles are used; and indeed no metal spanners should ever approach the cells, for fear of making accidental short-circuits when turning the "nuts."

Some curious points may be observed when a cell is short-circuited as described:—

1st. That the current which traverses the resistance is apparently the same, whether the cells are charging, discharging, or stationary.

2nd. That the usual laws relating to divided circuits apparently no longer apply.

3rd. That the current traverses the whole of the cells, and yet is apparently annihilated at the short-circuited cell. I say *apparently*, for these phenomena are not real when examined.

There is another point connected with cells which seems not to have been noticed. When the plates are fully charged the positive plates (E.P.S. Co.) begin to whiten, and they do not regain their dark colour till slightly discharged. At the moment of being fully charged the E.M.F. is very high; in a few minutes it falls, but rises slightly where the plates become darker.

I have observed this again and again, and now take this "whitening state" to indicate the time to stop charging, apart from the usual tests. All these tests seem to agree together when the plates and acid are new, but after a time the "boiling" and "specific gravity" tests do not appear to agree completely with the charge in the cells.

I have reasons for supposing that if the charging is habitually carried too far, this white coat gets too thick to disappear, and even if the plates are not injured, the E.M.F. of the battery falls permanently until the coating is rubbed off. I hope that others may make observations on this point and publish them. The question is, What is this white substance? Theoretically, it should be PbO_3; but I am not aware that such a substance can exist. Hence, since there is every probability that the process is one of oxidation, and as sulphur is present in the acid the white layer may consist of $PbSO_4$, which is not soluble, and therefore care should be taken to avoid more forming than possible. The process of charging removes small quantities, but I doubt if it is of any avail if the plates are *completely* and *thickly* coated.

Moral: Do not habitually overcharge.

I might be tempted to say more, but I feel to have trespassed too much upon your space already.—Yours, &c.,

DAVID SALOMONS.

Broomhill, Tunbridge Wells, August 24, 1885.

RESISTANCE OF VOLTAIC CELLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Dr. G. Gore's experiments (*see* p. 279) on the apparent variation of resistance of voltaic cells according to the current passing are very interesting to me as in a manner explaining the extraordinary results I used to obtain (some fifteen years ago) when measuring the resistance of Leclanché cells. When small resistances were in circuit a cell generally gave about 3 or 4 ohms, but if a large resistance x were inserted, the result was not $x+3$ or 4 ohms, but more likely $x+30$ or $x+300$, according to the resistance inserted, of course on the assumption that the E.M.F. remained constant. As two distinct observations with different strengths of current had to be made to get at the apparent resistance, the results were quantitatively almost useless, when they were used to find out the cause of the thing, especially as the E.M.F. of this kind of cell is very variable.

Would it not, however, be better to express the results in terms of volts than in ohms; for instance, to say that in the case of Cd and Zn (first example, Table I) the back E.M.F. at the negative plate is increased by ·0136 or by ·035 volt (assuming that at the positive plate to be constant), with given currents passing, or that the total E.M.F. of the cell is reduced by these amounts?—Yours, &c.,

OLIVER HEAVISIDE.

HISTORY OF THE INCANDESCENT LAMP.

For several years past the question has constantly presented itself whether the electric light was destined to supplant the artificial sources of light hitherto in use, especially that of gas light, and to be looked to as the only means of illumination for the future. For a long time it appeared in certain circles that the answer to this question must be unfavourable to the electric light. Among other objections, it was pointed out that electric illumination—the mass of the public understood this to indicate only those arc lights which were as yet alone in practical use—suffered from an *embarras de richesses*, for the powerful rays of the electric lamps, from their great intensity, were only suitable for large areas, while for general and domestic purposes gas still appeared the most suitable means of illumination. It is true that for the requirements of general practice a tolerably adequate subdivision of the light may be considered practicable, and the electric light produced by arc lamps can now be subdivided to intensities of from 10 to 20 gas jets. But in the first case the minimum of such a subdivision is still a great deal too high for many purposes, especially for domestic use, and again, so extended a subdivision requires a regulating mechanism which is proportionately so expensive that, as far as cost is concerned, electric light can under these circumstances make no competition with gas. Such being the case, it was of the highest importance to obtain a lamp by which electric lights of a much lesser brilliancy could be produced without any regulating mechanism, at least with a minimum intensity of a single gas jet.

But in this sphere there were many errors and delusions to be contended with before a practically satisfactory result could be obtained. The history of the incandescent lamp may well be called a history of errors in the sphere of electrical investigations, and, in spite of the scientific importance of such investigations, there is a comic side to the picture presented to the curious student of the story of the development of incandescent lamps.

The great problem to be solved was to discover a good conductor of electricity which could neither be consumed nor volatilised in a vacuum. Now came an eager quest after the treasures buried in the deep recesses of scientific knowledge, to obtain which each young enthusiast in natural science felt himself called. American capitalists were the first to provide the necessary funds for the development of an idea from the realisation of which a golden harvest was justly expected.

Starting on the principle that all roads lead to Rome, attempts were made to utilise the most manifold and various ways and means to attain the end in view, till the conviction established itself that practically there were only two substances in existence possessing to a satisfactory degree the properties absolutely essential to an incandescent lamp, and these were—first, platinum or an alloy of platinum and iridium, and, secondly, carbon. Platinum presents this advantage compared to carbon, that it can be brought to a white heat without being consumed in air, a property rendering this metal eminently suitable for the requirements of incandescent lamps; but in another not less important particular platinum stands far behind carbon, for it cannot stand, without melting, at anything approaching so high a temperature. But where incandescent lighting is concerned, the incandescent substance must be capable of enduring an excessively high temperature.

Digitized by Google

This circumstance has also an important bearing from an economical point of view, inasmuch as the light obtained from any glowing substance increases in a much more rapid ratio than the temperature of the material employed. For instance, if a piece of platinum wire or carbon thread is heated to redness, an almost inappreciable amount of light is produced, but if the temperature be doubled by allowing a corresponding increase of current to pass along the conductor, more than twice the very slight amount of light previously obtained is produced. It is consequently indisputable that the higher the temperature to which the incandescent substance is raised the less expensive is the energy absorbed to produce the light. Carbon or metal? Herein lay the great question which for ten years occupied the attention of every thoughtful electrician.

We shall here present a brief survey of the more important points of the above-mentioned movement, and dwell for a longer time only on the more prominent intellects, such as De Changy, King, Starr, Lane-Fox, Edison, and Swan, and submit their labours and successes to a closer inspection.

To Professor Jobard, of Brussels, is due the first impulse towards the most important of investigations on the subject of incandescent lamps. He suggested in the year 1838, in the *Courier Liberal*, the idea that a small piece of carbon, acting as conductor of a current in an exhausted receiver, would give an intense, steady, and continued light. Herr Jobard advised his future pupil, De Changy, to undertake the development of this idea. De Changy applied himself to these investigations all the more readily that, as a mining engineer, he hoped to be able to open out a wide field for incandescent lighting in mines. After some theoretical preliminaries De Changy began his work in 1844, an Englishman named Moleyns having previously, in 1841, made the first experiments with platinum incandescent lamps. For incandescent material he employed small splinters of gas carbon. These he enclosed in an exhausted glass receiver, and put these in connection with his conductors. To add to the consistency of the carbon, he attempted to fill its interstices by saturating the pieces with molten resin or sugar solutions, and then allowing them to solidify. The result obtained was, all things considered, a success, and De Changy proceeded to the construction of the first incandescent lamp. But thus was forged the first link in that chain of vanished illusions running through the history of the development of incandescent lamps. The experiment failed, first, because the piece of carbon was disintegrated by the current; and, secondly, because the electrical energy absorbed in the production of the light, and the amount of heat generated in the relatively massive carbon were very great. Besides, the imperfect sealing up of the lamp and exhaustion of the air allowed the carbon to be partially consumed in the oxygen of the air. A great part of the electrical energy was necessarily lost for production of light by conduction of heat and currents in the imperfectly exhausted air. Soon after this certainly encouraging result the appointment of De Changy as principal managing engineer of the Wedl-Ocean and Wedl-Ramoth mines caused a long interruption to his interesting investigations and experiments.

(To be continued.)

THE DEFORMATION OF THE LUMINOUS WAVE SURFACE IN THE MAGNETIC FIELD.—The results of this investigation are summed up by E. von Fleischl, as follows:—1. That the wave surface in the magnetic field has undoubtedly in general the form described by him of two surfaces of rotation which intersect one another. 2. That the form of these two surfaces differs to an extremely small extent from the spherical form; but that notwithstanding 3. The spherical form of both parts of the double surface which results from Verdet's law of the cosine, and which with this law is implicitly assumed in all previous inquiries, is only a faint approximation to the true form. And 4. That the form of the wave surface in the magnetic field is a double surface made up of two ellipsoids of rotation, which are so displaced in the direction of their greatest axes that they nearly coincide with each other.

CUNYNGHAME'S MEASURING INSTRUMENT.

We herewith illustrate an ammeter, consisting of a soft iron armature, mounted on an axis between the poles of an electro-magnet, and controlled by a spiral spring, the angle of torsion of which is measured on a dial by a pointer attached to a torsion head carrying one end of the spring.

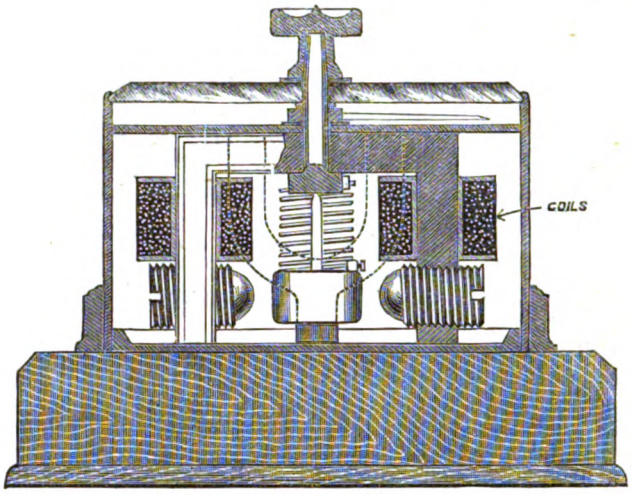

FIG. 1.—Patent Ammeter and Voltmeter. Sectional Elevation.

When no current is passing, and the torsion head pointer is at zero, the armature rests obliquely across the lines joining the poles of the magnet, and its pointer also rests at a zero mark. As soon as a current passes through the coils the armature is dragged by the magnetic force to a position length-

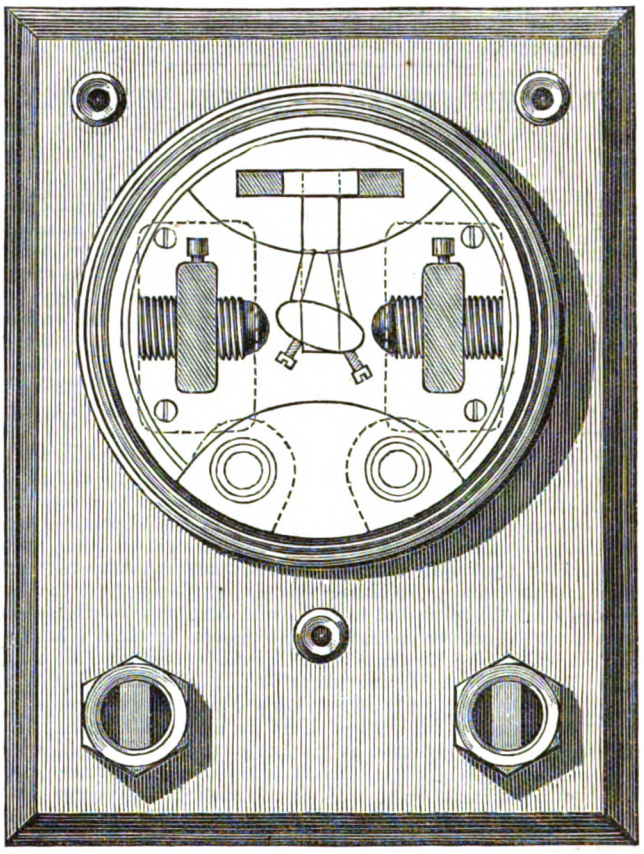

FIG. 2.—Sectional Plan.

wise between the poles of the magnet. The spring is now twisted by turning the torsion head by hand until the position of the armature is shown by its pointer to be the same as before. Then, since the magnetic force acting on it varies as the square of the current, and is balanced by the torsion of the spring, it follows that the tension of the spring is also equivalent to the square of the current. But the

Digitized by Google

tension of the spring depends on the angle through which it is turned, and therefore the square of this angle varies as the current. The dial is therefore marked with divisions representing successive amperes, which proceed as the squares of the numbers indicated on them; and by means of the movable pole pieces the magnetic force is easily adjusted to suit the dial. The form of the instrument is shown in Figs. 1 and 2. It measures about 8in. long by 6in. wide, and may be placed either in a horizontal or vertical position. The voltmeter must be used horizontally.

The advantages claimed for these instruments by Messrs. Woodhouse and Rawson, the makers, are :—

1. While possessing the accuracy of a Siemens dynamometer, they are readily portable, having no mercury cups, and may be fixed in any, although it is advisable to have them in a horizontal, position.

2. They do not depend on mercury contacts, so that the circuit is absolutely unbroken.

3. By reason of the strength of the spring they are almost dead beat.

4. The horse-shoe magnet and armature form together a closed circuit, so that they are not appreciably affected by outside magnetic influences.

5. They do not depend on permanent magnets, which are very variable.

6. They read amperes direct on a dial, instead of requiring a table of angles and current strengths.

7. They are adjustable by means of the movable pole-pieces, so that the same instrument may be readily set in order by one comparison with a standard instrument, and no calibration is required. Any instrument can by the like adjustment be made to register currents even double as great as those for which it was constructed.

By winding the magnets with very thin wire, voltmeters are constructed for which the same advantages are claimed as for the ammeters.

ARC LAMPS COUPLED PARALLEL WITH INCANDESCENT LAMPS.

Mr. Schuckert, the well-known dynamo engineer, has sent us for publication an article on the question of working arc lamps and incandescent lamps off the same circuit in parallel connection. Although the subject is not new, Siemens, Gülcher, Crompton, and others having already for some time adopted this method of working, Mr. Schuckert in his article explains the matter so very clearly that we think a short abstract of his remarks may be interesting to our readers.

In many cases, especially in mills and factories, it is necessary to employ both arc and incandescent lamps. If the installation is not sufficiently large to justify the employment of two separate dynamos, one for the arc lights, the other for the incandescent lamps, it is very desirable to find a method whereby both kinds of lamps can be fed from the same circuit independently of each other. It is also sometimes necessary to employ arc lamps of different power in the different parts of the same installation, a condition which can evidently not be fulfilled by the usual arrangement of putting lamps in series. One method of accomplishing this is by placing all the lamps in parallel connection, but in this case a comparatively large resistance must be inserted in each branch circuit, entailing a heavy loss of electrical energy. The reason for this will be obvious if we consider what would happen if arc lamps and incandescent lamps were coupled parallel without any resistances in the arc circuits. The pressure required for an arc lamp is about 43 volts. Let us assume that the dynamo is perfectly self-regulating, and able to maintain this pressure at its terminals, no matter how the total current may vary. If now, through impurities in the carbons, the resistance—or, to speak more correctly, the apparent resistance—in one of the arcs were to increase slightly, the current through that arc will slightly diminish. If the lamp does not regulate immediately—that is, if the length of arc remains unaltered for ever so short a time—this would still further increase the apparent resistance, and the arc would be broken. There is no lamp as yet in the market which can follow with sufficient rapidity the variation in current to save the light from temporary extinction when working under such circumstances. As soon as the arc is broken the carbons run together, and for an instant the main leads are thereby short circuited. This lowers the pressure on the other lamps, which in their turn lose their current and go out. Whilst the first lamp recovers, the carbons of one of the other lamps come in contact, thus extinguishing again all the rest. Under these circumstances it is impossible to obtain a steady light. To overcome the difficulty, it has hitherto been found necessary to fix the pressure at 65 volts, and to insert with each arc circuit sufficient resistance to bring the pressure at the lamps down to 43 volts. To avoid this comparatively heavy loss of 22 volts it is now customary to place two arc lamps in series, and each series in parallel with the others and with the incandescent lamps. This arrangement has in the first place the advantage of reducing the influence the disturbance in one lamp may have on the whole system. It also lessens the disturbances in each lamp, since the other lamp coupled in series with it acts to a certain extent as a steadying resistance. To make this system successful it is necessary that the regulating mechanism of each lamp should be exceedingly delicate, and that it should act quickly yet gradually. Mr. Schuckert recommends for this purpose the Piette-Krizik lamp, which, when so coupled, only requires 43 volts to give a steady light. The additional resistance required in each branch is therefore exceedingly small, and a loss of only 10 volts out of 100 is incurred.

We may add to Mr. Schuckert's remark that results nearly as satisfactory as these are commonly obtained in England with a number of differential lamps. The pressure between the mains is generally fixed at 110 volts, and each arc lamp is regulated so as to require from 45 to 47 volts. The pressure utilised in the lamps is therefore about 92 volts, out of 110 volts generated.

THE INTERNATIONAL TELEGRAPH CONFERENCE.

Mr. M. Smith, the Victorian Agent-General, has arrived at Berlin, and will represent Victoria during the further deliberations of the Conference.

At a plenary meeting of the Conference, on the 22nd inst., the resolutions of the Tariff Committee were discussed and approved in such a form as entitles one to say that the proposals of the German Postmaster-General for the introduction of a reduced and uniform European tariff were adopted to about half their original scope and extent, but that is all. Of twenty-five delegates representing States, twenty-one voted in the affirmative, while four refrained from voting on the ground of want of instructions. England, Russia, France, and Austria were among the ayes. Stated in brief and general terms, the result of the decision is simply this, that what is called the "grundtaxe," or fixed primary charge on all telegrams, irrespective of the price per word, will be abolished, and that henceforth, therefore, the tabulated word tariff under the European Telegraph Convention will represent the real, as well as the apparent, price of messages. Some States, however, Germany for example, reserve to themselves the option of imposing this grundtaxe (so as not to lose on small messages), but yet in such a manner as shall not raise the cost of a telegram above the total amount of the simple word charge.

Another important result of the resolution is that what is called the terminal tax, or share of charge on telegrams falling to the country of receipt, will be reduced and regulated—the large States receiving 10c. per word, smaller ditto 6½c., and Russia, which insisted on a special arrangement in her favour, 30c. Germany had proposed 8c. and 4½c. for the larger and smaller States respectively. In like manner, transit dues, or share of cost falling to countries through which a message merely passes, are to be fixed at 8c. for the large States, 4c. for the smaller ones, and 24c. for Russia. Russia and Turkey to be allowed to impose an additional rate in consideration of the difficulty of maintaining long telegraph lines through extensive and partly uncultivated districts. Where there is more than one telegraph line between two points, the rate for the cheapest to be invariably made irrespective of the route by which the telegrams may have been actually forwarded.

Our contemporary, the *Colonies and India*, says :—The Australian delegates have had no difficulty in presenting a strong case. According to Mr. Heaton's figures the 10s. 8d. now received for every word in cable messages is distributed as follows :—

	For conveying the message.	Miles.	
The Eastern Company get ...	3s. 1d.	6,479	London to Bombay.
The Indian Govnmnt. get ...	0s. 8d.	650	Bombay to Madras.
The Eastern Exten. Co. get..	5s. 8d.	3,862	Madras to Port Darwin.
The South Aust. Gov. get ...	1s. 3d.	2,100	Port Darwin to Adelaide.
	10s. 8d.	13,091	

The Indian Government charge is a monstrous one, particularly as they only charge about 1d. per word over the same wire for a local message. The income from Australasian business is nearly £300,000 per annum (including a subsidy of £30,000 per annum), and the Australasian business has doubled itself in ten years. A private meeting of those interested has taken place, with the result

Digitized by Google

that the cable companies have offered to reduce the charges by 2s. 6d. per word, or a total of 8s. 2d. per word to the public, and convey cable messages for quarter rates, or a total of 2s. 8d. per word from England to Australia. This is a most substantial reduction, and is likely to give great satisfaction to the colonies. But it is not quite settled yet. The consent of India and of South Australia has to be obtained.

LIGHTHOUSE ILLUMINANTS.

The Select Committee appointed by the Trinity House to inquire into the relative value of oil, gas, and electricity as illuminants for lighthouses have drawn up their Report, from which we print the following particulars, published in *The Times* of Thursday, the full Report not being issued to the public for some days to come :—

The gas system had been developed chiefly in Ireland, while the lighthouses on the English and Scotch coasts were illuminated mainly by oil. To make a general change from oil to gas would have involved a very heavy cost, which the Elder Brethen and the Board of Trade evidently demurred to, they being of opinion that the oil light was sufficient for the purpose of the mariner.

The question, therefore, had to be submitted to the practical test of experiment, whether it was worth while to incur the great expense of altering existing oil lights for the sake of replacing them with either electric or gas lights. In this question mariners and shipowners are deeply interested ; in the one case safety and speedy navigation are largely dependent upon the efficiency of the coast lights ; on the other hand, the shipowner, though desirous of having the best lights for the protection of his ships and their cargoes, is not willing to pay more than is absolutely essential for the maintenance of good lights.

In arranging for carrying out the experiments, the Trinity House Committee had under their consideration two broad divisions of the whole subject—viz. (1) the lights to be exhibited, and (2) the observations to be made upon those lights. In selecting the South Foreland as the site for the trials the committee were influenced by both these considerations. The establishment already there for exhibiting electric lights in two permanent towers afforded the requisite motive power (steam) for working experimental electric machines. The position afforded a wide range for observations from seaward, and the general face of the country, without trees and hedges, gave facilities for setting off tracks along which the lights could be kept continously in view for distances under three miles, if the state of the atmosphere permitted, and provided the means for making measurements and observations requiring a shorter range and steadier base than are attainable at sea.

Three experimental towers were put up, lettered respectively A, B, and C ; the first (A) appropriated to electricity, the second (B) to Mr. Wigham's gas system, and the third (C) to oil and occasional gas lights. The towers were separated from each other by a distance of 180ft., which was found sufficient to prevent the blending of the light at long ranges.

The lantern surmounting each tower was 16-sided, having five sides glazed towards the north and four towards the south. Those for A and C were identical in shape and size, and were constructed at the Trinity House workshops at Blackwall. That for B tower had the same diameter as the others, but not the same height, being shorter by a few feet. It was supplied and fitted by Mr. Wigham to suit his quadriform gas system.

Each lighting system was adapted to be shown in multiform arrangement, *i.e.*, with lights placed vertically, one above the other, it being believed that the great body of light so produced is effective in thick weather. For gas, provision was made for showing, simultaneously, four such lights—quadriform, as the arrangement has been termed ; while for the electric and oil systems provision was made for the exhibition of only three superposed lights—triform. There appears to have been some apprehension that it might not be possible to exhibit with safety more than three mineral oil lights in the vertical space available in the lantern, the superposing principle being to some extent a novelty in lighthouse illumination with mineral oil. To Mr. Wigham is due the chief credit for the development of this principle in respect of his gas lights, and the splendid column of light produced by his quadriform arrangement may have suggested the desirability of applying the system to oil-burners. The question of patent right in respect of the superposing principle was in an unsettled condition at the commencement of the trials, but it has since been finally set at rest, and any cause of dispute on this point has thus been eliminated from the inquiry. It is stated as one of the results of the experiments that there is now no doubt "it is possible to exhibit either of the two systems (gas and oil) in a lighthouse under precisely similar conditions as to vertical distance between the lights."

It will now be understood that in the A and C lanterns of 19ft. in height, the three lights were separated by much greater vertical spaces than the four lights in B's lantern of 17ft. ; while, on the other hand, an endeavour was made to compensate to some extent for this defect by the use in the C lantern of larger lenses for the production of the revolving beams than those employed in B tower.

Inside the lanterns, at the proper focal distance from the lights, and mounted on circular rotating tables, were portions of lenticular apparatus such as are employed in lighthouses. These optical aids were of two kinds—one adapted for showing a periodic revolving beam, the other for showing a continuous fixed light—and were at the outset of the experiments special in relation to the illuminant with which they were to be used. The small but intense electric arc was provided with the optical apparatus considered to be best suited to it. It consisted of a panel of the apparatus for a second order fixed light with the external addition of vertical prisms, so that the rays, being parallelized in both the horizontal and vertical planes, issue as a condensed beam. With a 12-sided apparatus, twelve beams would issue forth ; and if the apparatus were rotated, successive beams would pass by at regulated intervals. But one panel only was sufficient at South Foreland to illustrate the effect of the revolving beam of an electric light. Gas, with its far larger flame, had large annular lenses forming part of the revolving triform apparatus intended for the new lighthouse on Mew Island, on the Irish coast ; and oil had still larger annular lenses of the type adopted at the Eddystone lighthouse, which, it was apparently anticipated, would compensate for the absence of the fourth superposed light. These annular lenses condense the incident light into a beam of parallel rays, and when set in motion by rotating the framework on which they are mounted, present to the observer the appearance of a revolving light. The lenses provided for exhibiting fixed lights were the same in all—*i.e.*, panels of an all-round lenticular apparatus—except that the electric light was furnished with lenses of the second order, while those for gas and oil were of the first order. The upper and lower prisms usual in apparatus for fixed lights were not provided.

For each light in superposed arrangement a pair of lenses was appropriated to show as either a revolving or fixed light ; thus the electric had three panels of revolving and three of fixed apparatus ; the gas had four panels (annular lenses) of revolving and four of fixed apparatus, and the oil had three panels (annular lenses larger than those in the gas lantern) of revolving and three of fixed apparatus.

We now come to the lights exhibited. In the electric tower three regulators or lamps of the Berjot type were used, one on each tier. The carbons in use have been varied several times. The "fascine" or bundle carbons, supplied by Baron de Meritens, were tried, but they did not give satisfactory results. Siemens's carbons of 20, 30, and 40mm. were much used, some having a core of graphite in the centre. All were circular in section except the "fascine" pattern, which were square. The three magneto-electric machines which furnished the illuminant for this tower were fixed in the engine room of the establishment 800ft. distant from the tower, in convenient positions for the application of steam power. The machines were supplied by Baron de Meritens, of Paris. Each contains 60 permanent magnets, of horseshoe form, eight laminated pieces to every magnet, the whole disposed in five rings of 12 magnets each and associated with five discs revolving within them, each having 24 coils on its outer ring. The machines are worked at a speed of about 600 revolutions per minute. Such powerful arc lights as those produced by these machines have never before been exhibited in this country.

The exhibition of the experimental lights was commenced in the spring of last year. It now becomes necessary to refer to the means adopted for observing the effects of these various lights.

It has been stated as one of the reasons why the South Foreland was selected for these trials that the nature of the adjacent country afforded facilities for observing the light at distances under three miles. This was naturally of advantage in thick weather, and from the towers a line was marked off with posts, 100ft. apart, to observation hut No. 1, distant 2,144ft., or nearly half a mile. The undulating character of the ground made it necessary to take up the line at another point, but at the same distance from the towers as hut No. 1. From this point the line was carried with one divergent break to hut No. 2, distant from the lights 6,200ft., or nearly a mile and a quarter. From this hut another divergence had to be made, the line being picked up at the same distance from the lights as hut No. 2, and carried without break to hut No. 3, distant two and a half miles. Along all these lines the lights were fully visible in ordinary conditions of weather, and observers were stationed at the huts in order that nightly observations of the lights should be recorded. The members of the committee and officers of the Trinity House, together with numerous distinguished visitors, made frequent use of these lines of posts and the huts. For observations at greater distances, the services of the Coastguard between the North Foreland and Dover ; the lightsmen on board the "Gull," the "Goodwin," and the "Varne" light vessels ; the lighthouse keepers at the North Foreland ; pilots and masters of vessels navigating in the vicinity ; and the Elder Brethren of Trinity House and their officers, at various times and distances at sea and on land, were called into requisition. The observations so recorded have been classified as eye-measurements—that is, those made by the naked eye unassisted by instruments ; another classification, of which we shall speak presently, is that of observations made by photometry. According to a tabulation given in the report it appears that upwards of 6,000 observations have been recorded, of which for various reasons it has been found necessary to reject 1,946, leaving more than 4,000 available for analysis. Four tables are given indicating the results obtained by analysis of the recorded observations. Table I. shows the result of comparing the electric light with the highest powers of gas and oil, both as revolving and fixed lights. Seven hundred and fifty-four observations made at various distances and in all kinds of weather are taken, the analysis of which shows that the electric light, under all conditions of weather, has a superiority of about 35 per cent. over the quadriform gas with 108 jets, and about 40 per cent. over triform oil, six wicks. Probably the percentages are in reality much higher than these, but it is difficult to assign even an approximate numerical value to lights by eye measurement. A note to this table states that, although there are upwards of 3,000 other observations in which the lower powers of gas and oil are compared with different powers of the electric light, it is thought sufficient to show the result of comparing only the highest powers of gas and oil with the electric light. This table is apparently regarded as definitely establishing the superiority of the electric light, and accordingly the following tables are devoted to direct comparisons of the gas and oil lights. Table II. gives an abstract and summary of observations at various distances upon comparison of the

Digitized by Google

different powers of Wigham's gas burners with the Trinity House 6-wick oil burners—(1) in clear weather, (2) in weather not clear. The summary of this table indicates that in all kinds of weather quadriform gas revolving lights with 68, 88, or 108 jets are rather better than triform oil revolving lights (six wicks); but that when the lights compared are equal in number. the difference is hardly perceptible. For fixed lights in all kinds of weather the gas lights are superior. Table III. gives some results of comparing single lights when shown through lenses of equal size, and also a comparison of the large Eddystone lenses used in C tower with the smaller Mew Island lenses used in B tower. A very small percentage of superiority is recorded for the 108 jet and 88 jet gas burners over the 6-wick oil burner, and a slight superiority of the large Eddystone lens over the Mew Island lens.

Table IV. gives the average recorded values of the Wigham gas-burners as compared with the six-wick oil burners at distances varying from half a mile to 15 miles in weather not clear but without absolute fog. In an aggregate of the whole of the observations in this table the result is generally in favour of quadriform gas; but it is noticeable that, as the distance increases, the difference between quadriform gas and triform oil is less and less apparent. The Committee state that it would require a much more decided and constant superiority to justify them in giving either an unqualified preference, except as regards lights in the fixed phase, when the superiority of the gas is definitely established.

In continuation of the eye measurements one section of the report is devoted to the important subject of the fog and mist. Each experience of fog or thick mist is described in detail. The records are at times of a highly interesting character, and a summary of the results of the observations is given after each fog report. If these are followed through it will be found that electricity is, with one or two exceptions, the reason of which is explained, more effective in fog than either the gas or oil lights. There is an interesting variety in the observers as well as the mode of recording; but the summary in each case is matter-of-fact and judicial. The most noticeable feature about these fog reports is the exceedingly short distances at which these most powerful lights are visible in thick fog. The bulk of the observations are made within a distance of 2,000 feet, and the superiority of the electric light is determined by possibly two or three hundred feet, or less, while the gas and oil lights at full power are practically equal. For purposes of navigation in foggy weather a difference in the visibility of lights of two or three hundred feet is of no value whatever, and the conclusion is inevitable that the most powerful light exhibited is useless in a fog. Glare and flare alike seem to be unavailing, bonfires or electric arcs, diffused or condensed lights, are all obscured by fog within a very short distance from one another. But in weather not absolutely foggy, when the normal range of the lights is lessened by haze, the evidence given by these observers indicates that the electric light is seen further than the gas and oil lights, and that its superiority at such times is of real practical advantage to the mariner. It was a little unfortunate that, to quote the Committee's words, "the year in which these experiments have been carried out was marked by a singular prevalence of clear weather;" but, nevertheless, the experiences obtained are valuable, and form an important contribution towards the settlement of a vexed question.

TABLE A.

Burner.	Illuminating Power of Naked Light.	Illuminating Power through Lens in Clear Atmosphere.		
		Cylindrical Belt and Vertical Prisms.	Eddystone Lens.	Mew Island Lens.
Electric, 1 machine.....	10,000	1,250,000	—	—
Electric, 2 machine.....	15,000	1,500,000	—	—
Douglass, 10-ring, gas...	2,500	—	105,000	94,000
Douglass, 6-ring, gas ...	825	—	92,000	70,000
Wigham, 108 jet, gas...	2,300	—	—	59,000
Wigham, 88-jet, gas ...	1,400	—	—	54,000
Wigham, 68-jet, gas ...	990	—	—	48,000
Wigham, 48-jet, gas ...	680	—	—	42,000
Wigham, 28-jet, gas ...	250	—	—	33,000
Sugg, 6-ring, gas.....	820	—	55,000	—
Siemens, gas.....	600	—	10,000	—
Douglass, 7-wick, oil ...	950	—	60,000	49,000
Douglass, 6-wick, oil ...	730	—	64,000	48,000
Service, 4-wick, oil.....	415	—	55,000	44,000

We have now to consider the means adopted for measuring the lights with more exactness than could be accomplished with the unassisted eye. In this branch of their inquiry the Committee, besides having the advantage of the advice and assistance of Mr. A. G. Vernon-Harcourt, F.R.S., who watched the experiments on behalf of the Board of Trade, had retained the services of Mr. Harold Dixon, M.A., of Balliol College, Oxford, whose experience in matters relating to photometry is considerable. To this gentleman was intrusted the duty of making photometric observations on all the lights submitted for trial. These operations were carried on at the observing huts Nos. 1 and 2, and at the photometry gallery, a building 280ft. long by 8ft. wide, with all appliances for exhibiting any of the lights under trial, with or without lenses, under conditions convenient for direct measurement. Sir James Douglass, besides assisting in the preliminary consideration of these arrangements, adapted some of the instruments ordinarily used in lighthouse work for the special service in view. A detailed description of the various apparatus employed is given in Mr. Dixon's report, and partly in the text of the Committee's report. It will be sufficient here to state that the Harcourt pentane standard flame was chiefly employed in these measurements, though occasionally the flame of a mineral oil Douglass burner, enclosed in a lantern fitted with slides on the Methven principle, so as to enable the visible area of the emerging light to be adjusted to the value of two, four, eight, or any convenient candle-power in accordance with the pentane standard, was employed, and was found to be very serviceable on windy nights when the pentane flame was rendered unsteady.

Mr. Dixon, at the outset, classes the questions submitted to him for determination by photometry under four heads:—(1) What is the total unaided light given by each of the illuminants submitted to trial, and what is the "efficiency" of each? (2) What is the light given by each illuminant through the optical apparatus designed to show it—first, as a revolving light, second, as a fixed light? (3) What is the relative value of superposed lights in each system? (4) What is the relative illuminating power of each source of light under different conditions of weather?

The first two questions are answered chiefly by tables of measurements in which the order of merit of the various burners is stated with exactness. The preceding Table A gives the candle-power of each illuminant not superposed, with and without the optical apparatus designed to show it as a revolving light.

As regards Question 3 Mr. Dixon's conclusion is that "multiplied lights are superior to single lights in penetrative power at all distances beyond the point where the separate lights begin to blend together in the eye. This point is about half a mile from the lights in A and C towers, and less from the lights in B." He further states that "actual experience in fog and hazy weather leaves no doubt of the utility of the multiform arrangement with gas and oil lights at all distances beyond half a mile. In the case of the electric light the greatest visibility is secured at short distances by sending the current from one or more machines through a single arc."

To Question 4 Mr. Dixon replies that oil and gas lights when shown through similar lenses are equally affected by atmospheric variations, and that the electric light is absorbed more largely by haze and fog than either the oil or gaslight. The Wigham 108-jet gas burner has an advantage of 16 per cent. over the 6-wick oil-burner in all weathers where both are shown through equal lenses, but this means but slight difference in penetrative power. "In many observations, both on sea and land, in haze and in thick fog, the quadriform 108-jet gas light was picked up just before, but only just before, the triform 6-wick oil light; in other observations the two lights were picked up simultaneously." Mr. Dixon also concludes that in all weathers and at all distances the electric light, whether shown as a revolving or fixed light, has proved superior to the highest powers of gas and oil.

The next division of the report has reference to the cost of installation and maintenance of the respective illuminants in a lighthouse. Collating the figures given, which at first sight are somewhat confusing, we may deduce the following comparison:—

——	First Cost.		Annual Maintenance.	
Electric station, without superposed lights.....		£17,749		£1,927
Gas station, quadriform as at Galley Head		20,516		1,687
Oil Station—				
Single light as at Anvil Point	£8,064		£724	
Add for change to triform	3,500		400	
	——	11,564	——	1,124

According to these figures oil is much the cheapest illuminant both as respects first cost and annual maintenance. A single electric light costs less for installation than a quadriform gas light, but is more expensive to maintain. It should be mentioned that in the totals for annual maintenance are included items for interest on original outlay at 4 per cent., and percentages for repairs and renewals of buildings, apparatus, and machinery. The actual expenditure for annual maintenance of each system is therefore considerably less than the totals given above.

Following the section dealing with the subject of cost, the Committee make some general references to a few points of collateral importance in connection with the general question of the relative merits of the respective lighting systems—the adaptability of the respective illuminants for showing coloured sectors of light to mark special dangers; the advantage of the lengthened flash of a broad flame in the revolving beam; the possible value of "atmospheric thrills," sky flashing, occultations, &c.; and the suitability of the lights for producing such effects.

Before stating their general conclusions upon the whole question, the Committee distribute a shower of acknowledgments to the various gentlemen by whose advice and assistance the experiments have been carried on, and make the following somewhat significant references:—

"Your committee have not considered it within their province to take any note of those questions of patent right or of the claims of inventors which have been raised in the earlier stages of the discussion which preceded their inquiry. They have endeavoured to give every facility to Mr. Wigham towards exhibiting his best effects in gas lighting within such limits as they deem compatible with safety and certainty in lighthouse service. Likewise, as respects the claims of oil, they have allowed full liberty to Sir James Douglass and their own staff. But throughout they have endeavoured to put aside all consideration of personal merit or credit, and to keep in view only the efficiency of lighthouse apparatus and its practical utility to the mariner."

Digitized by Google

The Committee also think it a matter of congratulation that, although from antecedent circumstances some occasion of dispute might have arisen, the desire to act with thorough impartiality has, they believe, been recognised on all sides, and the whole investigation has been carried out without any breach of harmony among the parties concerned.

After weighing carefully the evidence given by photometrists and eye observers, and taking into account the questions of effectiveness, economy, and convenience as affecting each lighting system, the Committee thus sum up their opinion with regard to the relative merits of electricity, gas, and oil as lighthouse illuminants:—

"1. That the electric light as exhibited in the A experimental tower at South Forcland has proved to be the most powerful light under all conditions of weather, and to have the greatest penetrative power in fog.

"2. That for all practical purposes the gas light as exemplified by Mr. Wigham's multiform system in B experimental tower, and the oil light as exemplified by the Trinity House Douglass six-wick burners in multiform arrangement up to triform in C experimental tower, when shown through revolving lenses are equal light for light in all conditions of weather; but that quadriform gas is a little better than triform oil.

"3. That when shown through fixed lenses as arranged in the experimental towers, the superiority of the superposed gas light is unquestionable. The larger diameter of the gas flames, and the lights being much nearer to each other in the gas lantern, give the beam a more compact and intense appearance than that issuing from the more widely separated oil burners.

"4. That for lighthouse illumination with gas the Douglass patent gas-burners are much more efficient and economical than the Wigham gas-burners.

"5. That for the ordinary necessities of lighthouse illumination mineral oil is the most suitable and economical illuminant, and that for salient headlands, important landfalls, and places where a very powerful light is required, electricity offers the greatest advantages."

Part II. of the report, which will consist chiefly of diagrams, drawings, detailed reports on the electric lights and photometry, tabular matter, &c., it is expected will be published in a few weeks' time.

THE INDIAN TELEGRAPH SERVICE.

The following letter appeared in a recent issue of *The Times*:—

The grievances of the officers of the Indian Telegraph Service form a subject which may interest few of your readers, and it is not a time to ask for further outlay, however small, when we suddenly awake to the fact that the proximity of the Cossacks to the north-west frontier of our Indian Empire necessitates an additional annual expenditure of two millions for the increase to our Indian army alone. However, the grievances are real, and, as the numerous memorials submitted by these officers to the Viceroy and to the Secretary of State for India, at first collectively, and since the prohibition of joint memorials individually, have produced no substantial redress, I make no further apology for asking you to use the influence of your journal in bringing the matter before the public and the authorities of the India Office.

It does not follow because a memorial is addressed to a Viceroy or to a Cabinet Minister that it should ever reach the fountain head. A too obsequious henchman stands over on the alert to intercept the cry of him that hath no helper, and, as is popularly believed, burns the offending memorial before it has progressed its own length down the official labyrinth. Such, at any rate, appears to have been the fate of many memorials of the telegraph engineers, for although several were submitted to the Secretary of State upwards of eight months ago no reply has been received by any of the memorialists. In fact, I am informed on good authority that neither the Viceroy nor his Council has so much as seen these appeals for help. The memorials were strongly supported by the Director-General of Telegraphs, and an admirable scheme of reorganisation was submitted by that officer. This scheme, with the several memorials, was pigeon-holed by the Government of India, pending a reply from the Secretary of State regarding certain proposals submitted last year for the amelioration of the grievances of the Public Works Department. Finding that these proposals were to be rejected, the Government ordered the Director-General to withdraw his scheme, and to send in its stead one drafted by themselves, which is totally inadequate and calculated to satisfy no one. This scheme has now been forwarded to the India Office for sanction, so that, unless some steps are taken at once to prevent its being accepted, a cruel injustice will be done to one of the most deserving bodies of officers that have ever served the Government. It is for this reason that we ask you to bring their case before the public with a view to having it mentioned in the House. I am sending with this a carefully compiled statement showing the position and prospects (if such they can be called) of these telegraph engineers, with a summary of their grievances; but as this statement would occupy too much of your space, it will be as well to mention briefly the state of the Telegraph Department when these officers were appointed and the prospects that were held out to them.

In 1857 the Telegraph Department was in its infancy, and, with a view to introduce the Morse system of signalling, Sir William O'Shaughnessy, then at the head of the department, was deputed to England to train and send to India a certain number of officers qualified to teach Morse signalling. In 1857-58 no less than 71 officers, whose ages varied from 15 to 21 years, were drafted into the service, the department was reorganised, and the new appointments were apportioned between the Morse assistants and the officers previously appointed, "without injustice to the latter." The department worked satisfactorily for a time, but in 1865 complaints became so numerous that the attention of the Government was seriously drawn to the necessity for a wholesale reorganisation, and Colonel Robinson, R.E., the director-general, was addressed accordingly.

In his reply Colonel Robinson stated that he must have in the superior branch "none but gentlemen by education and feeling," and he desired that appointments might be given after competition and a technical course of study to "the sons of officers who had done good service to their country." He likewise asked sanction for 107 new appointments, to consist of nineteen superintendentships and eighty-eight assistant superintendentships. The proportion of higher appointments among a number of young men of nearly the same age was fixed far too low. The scheme was generally approved by the Secretary of State, and the India Office issued a memorandum detailing the tests to be passed, and pointing out the advantages of the "reorganised" service with its attractive appointments rising to £3,600 per annum. In this memorandum it was expressly stated that promotion to the higher grades would be "not by seniority but by merit." The salaries of assistant superintendents were to increase by annual increments of £25 from £240 to £500, but in a footnote it was added "these periods may be prolonged or shortened in special cases."

In the interval which elapsed between sanction and execution of the project, the first 92 of the 107 new appointments, which the India Office was holding out in London as inducements to the nomination assistants to enter the service, were filled up in India by the Indian Government from the Morse sssistants and inspectors appointed under the old system. The average age of the Morse assistants at the time of appointment was 19. The appointments by nomination were offered to men whose ages were above 18 and under 24 years. The selected candidates, many of whom had been within a few marks of passing for the Indian Civil Service, were required to pass a stiff examination in technical subjects, including physical sciences and mathematics, after a training of nine months, after which they had to obtain certificates from a qualified telegraph engineer after a course of four months' training in practical telegraphy. No less than 72 selected candidates were thus sent out to India to find themselves placed at the bottom of a fully officered department in which the first 92 appointments had already been filled by men of almost their own age, and in which most of them have now served for many years as supernumeraries. In 1872 the Government of India awoke to the true state of things, and no further appointments (excepting the appointment of two officers from the Indo-European Telegraph service) were made until 1878, when the first batch of officers joined the department through Cooper's-hill College. Of the working of the new scheme the Director-General, Colonel Robinson, wrote to Government:—

"This scheme, which met with the hearty approval of the Right Hon. the Secretary of State and the Government of India, has now been in operation four years, and its results have amply fulfilled the expectations formed of it. It has worked admirably; we have now as fine a set of young officers as are to be found in any service in the world; and in proof of its success I may mention that the higher officers of the English Postal Telegraphs think so well of it that they purpose to adopt the same system for filling their own ranks."

This is, indeed, high praise, and it will scarcely be believed that the officer who spoke so highly of the success of his scheme would, when he realised the hopeless position of his own "children," as pointed out in a joint memorial submitted in 1874, have refused to raise a finger to help them. Such, however, was the case. The present position of these fine young officers has been correctly summarised thus:—

(*a*) For 14 years after the organisation of 1865 no nomination assistant obtained any permanent promotion whatsoever.

(*b*) Now, after 19 years from the same date, only 14 out of the 72 are holding appointments in the two lowest grades of superintendents.

(*c*) The advancement of these 14 is the result of five years' working of a partial third reorganisation (1880) creating 16 new appointments with slightly increased salaries from the 1st of April, 1880.

(*d*) Lastly, 32 out of the 72 are still unpromoted, while the names of 26 have disappeared from the return to swell the list of casualties.

These 72 officers were the Secretary of State's "special nominees," who received nominations as possessing "decided claims upon the State for consideration." The special consideration that after all these years has been accorded to them is their present position of poverty and neglect, accentuated by a knowledge of the significant fact that the names of two have been added to the list of casualties for every one that has received a step in promotion. Such treatment compares most unfavourably with that meted out to "Morse assistants" appointed in 1857. A careful consideration of the average yearly casualties, compared with the numbers of the men who are still assistants, shows that the survivors of the last two batches of nomination assistants (1870-71) cannot hope to reach the lowest grade of superintendents until they have completed, at the very least, from 21 to 25 years' service. Such an outlook, in a service of such exposure as the telegraph, is nothing less than heart-breaking, and is without a parallel in any Home or Indian Department. The risks of the service and the exposure it entails are considered so great that the leading insurance companies will accept insurances on the lives of telegraph officers only at military rates. The work of the department has increased enormously of late years. All the important sub-divisions now are from 700 miles to 800 miles in length, and include, besides the up-keep of thousands of miles of wires, a technical charge of from 20 to 80 officers. The responsibilities of an officer in charge of a large sub-division are second to those of no executive officer in the country. Large sums of money pass through his hands. He has generally two or three construction works going on at once, besides technical supervision of innumerable offices, training classes, telephone systems, &c., and he has to make electrical tests of all systems of lightning conductors attached to Government buildings within his district. He must be ubiquitous, and turn up dressed like a gentleman at a moment's notice in any part of a district as large as Scotland. His clerical staff, if he is fortunate enough to have one, is

Digitized by Google

totally inadequate for the preparation of his innumerable returns and for his ordinary office work.

The telegraph officer is liable to service in any part of India, Assam, or Burmah, and in time of war he has the entire charge of all field telegraph operations. He has to travel at all seasons of the year and in all climates. Many officers have spent the hottest months under canvas. Is it to be wondered at, then, that the casualities have been so numerous? What has been the average pay of this officer, from whom so much is required, for the first ten years of his service? Three hundred and twenty-one rupees a month. Scarcely a subsistence allowance in many parts of India. Five hundred rupees is the most that many of these gentlemen can ever hope to draw. Pensions are calculated upon the average emoluments, so that an officer not only finds it impossible to save money during his service, but on retirement he is obliged to eke out his miserable pittance with any work he can obtain. I know the case of one of these officers who is at the present time serving as a shop assistant in one of our large towns. Contrast his case with that of his more fortunate schoolfellow in the Civil Service, who on completing 21 years' service can retire on £1,000 per annum, and no further argument will be needed to show that there is at least one body of officers in the service of the Indian Government that has served its country loyally, but which in return has met with the most cruel injustice. These officers have memorialised till they are sick of the very name of a memorial; their cause has been warmly taken up by the press in India; they now appeal to the press in England to insist that at this the eleventh hour justice should be done to such of them as have survived the burden and heat of the day.

The actual profits of the telegraph department as recorded in the administration reports for the last seven years, exclusive of compound interest, have amounted to 52½ lakhs of rupees. The combined office scheme (postal and telegraph) lately introduced is already paying 16 per cent. It is, therefore, not too much to expect that the Government of India should expend a portion of these profits in affording relief to those officers who have done so much to bring the service to its present state of efficiency. Of the universal excellence of the work of the department, the Indian Press has but one opinion. The *Civil and Military Gazette*, March 16, 1885, writes:

"Of the importance of the work of the department and of the excellent work done by it there can be no two opinions. Whether in ordinary times, or in times of war or famine, it has always been found that the officers of the telegraph department have done speedily and thoroughly everything that was required of them. It is only fair that something should be given to a service of which so much is required; and we would, therefore, earnestly invite the attention of the Government of India to the present unsatisfactory state of things in the telegraph department." And, again, "No one can doubt that if the department possessed one tithe of the influence or power of organisation which is inherent in a body like the Civil Service, for instance, it would secure a hearing for its case and a remedy for its wrongs. The very fact that it is, so to say, nobody's child, should induce the Government of India and the Secretary of State to look closely to its interests. So far, however, is this from being the case, that telegraph officers cannot even get replies to the memorials which they have submitted regarding their position and prospects."

LEGAL.

Liardet and another v. The Hammond Electric Light and Power Supply Company (Limited).

The plaintiffs in this action were Messrs. John Evelyn Liardet and Thomas Donnithorne, and they sued the defendants for £45,000 damages for breach of certain covenants in an agreement under seal of June 17, 1882, and specific performance of the remainder of the agreement. By that agreement the plaintiffs contracted to sell to the company three patents—namely, (1) a patent of November 29, 1884, for hydraulic motors applicable for the production of electric light; (2) a patent of December 10, 1884, for an arrangement of electric lighting apparatus in railway trains; and (3) a patent of January 9, 1884, for an apparatus for storage of electricity. The price was to be £30,000 in cash and £15,000 in fully paid shares, £6,000 being paid in cash as a deposit on the signing of the agreement, and the completion of the contract was expressly made subject to the following conditions: 1. "The vendors shall prove that the accumulators made under the accumulator patent are, as against the Faure accumulator, practically half the weight and half the cost for equal power, and further, that they are equal for commercial and practical purposes to the Sellon and Volckmar system. 2. The said proofs shall be given on or before the 1st of December next. Immediately on failure of such proof the said deposit shall be immediately repaid to the Hammond Company." The plaintiffs alleged that they had performed their part of the contract, but charged the defendants with a refusal to complete. The defendants' case was that the plaintiffs had failed to give the proofs required by the contract, and that the experiments which had been made had fulfilled none of the conditions of the contract, and they claimed a return of the deposit without any deduction for the expenses of the experiments which had been made and the scientific opinions which had been taken.

His Lordship, after hearing the evidence of Mr. Donnithorne, the only witness called on behalf of the plaintiffs, held that the proofs which were stipulated for had never, in fact, been given, and that it, indeed, appeared that without the use of another patent, the Sellon-Volckmar, which had been denied by the patentees to the plaintiffs, it was not possible to give them. That being so, the action must be dismissed with costs, the plaintiffs must procure the return to the company of the whole of the deposit, and the company must take all necessary steps to enable the registration of the agreement to be cancelled at the Patent Office.

Charge of Perjury.

On the 26th inst., at the Marlborough-street Police-court, Chas. Dickson Aria, of 139, New Bond-street, appeared to an adjourned summons, taken out by Sir Coutts Lindsay, charging him with having committed wilful and corrupt perjury in an affidavit made by him on oath in a suit in the Chancery Division between Sir Coutts Lindsay and Co. and Smethurst and Co. Mr. George Lewis, solicitor, appeared for the complainant; and Mr. Gill, barrister, defended. From the evidence previously taken it appeared that the complainant, who is the proprietor of the Grosvenor Gallery, New Bond-street, some time since formed a company, under the title of Sir Coutts Lindsay and Co., for the purpose of lighting up that establishment by electricity, and in February last the company commenced to run an engine in connection with the works, and also erected a chimney at some distance from the premises occupied by the defendant, who is a lamp and oil merchant, carrying on business in the neighbourhood. In the month of June the defendant commenced an action against Sir Coutts Lindsay, to restrain him from having the chimney in the position it then occupied, and also from making a noise with the engine. Affidavits were filed on both sides, Sir Coutts Lindsay stating in his that the engine complained of was only a temporary one, and that the permanent machinery would be situated in a cellar 23ft. below the level of the street. The defendant thereupon filed a further affidavit, in which he swore that his premises extended to a depth of 25ft., and that the permanent machinery would probably cause more damage to his premises than that already erected. It was subsequently discovered that the defendant's premises were not of the depth stated by him, and Mr. Aria himself then filed an affidavit giving their correct dimension. On the case coming on for hearing, Mr. Lewis, after some discussion, said that his clients would be content that the summons should stand adjourned until the decision of the superior court had been given.—Mr. Gill urged that it would be unfair to the defendant to keep such a charge hanging over his head, and asked that the summons should be dismissed.—Mr. Newton said he considered the suggestion a fair and proper one, and should therefore adjourn the case until 26th January, 1886.

Change of Address.—Mr. Armand Levy (late of 252, Goswell-road), has removed to more central premises, 20, Chiswell-street, London, E.C.

Personal.—We learn that Mr. H. E. Harrison, B.Sc., A.M.I.C.E., has severed his connection with the Electrical Engineering College, Red Lion-square, of which he has been Principal since its foundation, and has entered into partnership with Mr. F. C. Phillips, electrical engineer, of 2, Victoria-mansions, Westminster.

NOTES.

NOTICE OF REPAIR.—The cable between Fao and Bushire is now repaired.

ELECTRIC RAILWAY WANTED.—The Board of Management of the new American Exhibition to be opened this winter at New Orleans has invited tenders for an electric railroad in the grounds.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of August, 1885, were £1,276, against £1,190 in the corresponding period of last year.

IN AN OVEN.—An Edison incandescent light is used with great success in a baker's oven at a restaurant in Chicago. Why not? The incandescent light burns merrily enough inside our English Law Courts.

NEW COMPANY.—Articles of incorporation have been filed for the Buel Electric and Pneumatic Company, of New York, which is organised to push inventions relating to the application of electricity and compressed air to heating and propulsion.

STRUCK BY LIGHTNING.—At Harmarsville, Pa., recently, a boy, twelve years old, who was learning to telegraph, and who had his hand on the key, was struck by lightning and instantly killed. The operator in charge of the office was also stunned by the electric discharge.

ARC LIGHTING.—We give it upon the authority of Mr. Leggett, of Detroit, that at a distance of 1,000 feet the light from two groups of four 2,000 candle-power arc lights placed 150 feet from the ground was equal to that of a 16 candle-power gaslight at a distance of 45 feet.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ending Aug. 7 and 14 amounted to £2,648 and £3,397 respectively; and for the weeks ending August 21st and 28th they amounted to £2,778 and £3,073 respectively.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st August are £2,293, as compared with £2,527 in the corresponding period of 1884. The May receipts, estimated at £7,624, realised £7,641.

UNDERGROUND WIRES IN BROOKLYN, U.S.A.—The Commission on putting electric wires underground in Brooklyn met August 11th to consider plans. The Fire Commissioner asks the wire Commission to grant a permit to the Fire Department to extend its overhead telegraph system.

CONSOLIDATION OF AMERICAN COMPANIES.—The consolidation of the Brush, Weston, and the Merchants' electric light companies, of Boston, Mass., has been completed. The new company has 700,000 shares, of which the Brush interest obtains 250,000 and the Weston and Merchants 225,000 each.

LEGAL.—In the Chancery Court on Tuesday last, before Mr. Justice A. L. Smith, a petition was presented by F. Horner Lyell, a creditor and shareholder in the Electro-Amalgamator Company, for a winding-up order. No counsel appeared when the case was called, and the judge directed that it should be struck out.

CHEAP TELEGRAMS IN AUSTRALIA.—The reduction of the fee from 2s. to 1s. for the transmission of ten-word telegrams from Victoria to New South Wales has resulted in an increase of 17,617 in the number of messages, or 30 per cent., but a falling off in the revenue of nearly 11 per cent. This result is considered satisfactory.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of August was 2,832, estimated to produce £2,200, against 2,916 messages, producing £2,515 in the corresponding month of last year. The traffic receipts for the month of May, estimated at £3,700, realised £3,736.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ended Aug. 7 and 14 were £1,913 and £1,919, and for the weeks ended 21st and 28th August £1,562 and £1,759, respectively, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company in each case.

THE CHAIR OF ENGINEERING IN EDINBURGH UNIVERSITY.—Professor George Frederick Armstrong, M.A., F.G.S., C.E., who filled the Chair of Engineering in M'Gill University, Montreal, and the Yorkshire College, Leeds, has been appointed to the Chair of Engineering in the University of Edinburgh, in room of the late Professor Fleeming Jenkin. The appointment was in the gift of the Crown.

INCREASED BUSINESS.—The business of the Consolidated Telephone Construction and Maintenance Company in magneto-bells and other instruments has increased so much of late that the directors of this company have deemed it advisable to order from America some further machinery adapted to their manufacture. The machinery having now arrived, a considerably increased output is expected.

ELECTRIC LIGHT AT LIEGE.—It is reported, on good authority, that a company, promoted by Mr. A. Mullender, U.S.A. Consul at Liége, has been formed in that city, with a capital of 275,000f. (£11,000), divided into 1,100 shares of 250f., or £10 each, nearly all subscribed, for working the patents of the Thomson-Houston International Electric Company. It is also said that the new company has sufficient orders for lighting to begin active operations in November.

THE COMING ELECTION AND THE POST OFFICE.—In view of the forthcoming General Election, the Postmaster-General has issued a warning to officers of the Post Office against taking any prominent part on one side or the other in the political contest. This intimation is addressed especially to the case of postmasters; but as the officers of the Post Office are specified in general terms as Public Servants, we imagine that those belonging to the Postal Telegraph Service are included in the prohibition.

THE SCOTTISH TELEGRAPH CLERKS.—The Edinburgh telegraph clerks have received a reply to their memorial of 10th July, in which payment for Sunday labour was asked. Lord John Manners, in stating his inability to concede payment for the work performed, says similar applications have been very carefully considered by his predecessors, and that a decision was arrived at which was communicated to the memorialists within the last few months. He regrets that, on a review of the circumstances, he can see no sufficient reason to depart from that decision.

THE BECHUANALAND TELEGRAPHS.—According to Sir Charles Warren's report, the telegraph service from Shoshong to Taungs can be maintained for £3,000 per annum. This sum would pay for about ten policemen, and there can be no doubt that a telegraph line over 400 miles in length would be of more advantage than these men, especially as the linesmen themselves are in the nature of police. When the expedition

Digitized by Google

arrived in Bechuanaland there were employed about twenty policemen on the road from Vryburg to Barkly carrying despatches, at a cost of £6,000 per annum.

A DEFECTIVE FIRE ALARM.—As we are going to press we notice that, in connection with a fire which occurred yesterday at the Industrial Home for Boys in Islington, a fire alarm in the vicinity proved to be out of order. It would be interesting to know if the fire alarm circuits are regularly tested and their condition ascertained. It is absurd to suppose that they can keep themselves in good working order. Someone ought to be held responsible if, as is stated, the failure of the alarm led to excessive delay in procuring aid, and not improbably the total destruction of the building.

THE ACOUSTICS OF THUNDER.—Among the papers read at the 120th corporate meeting of the Boston Scientific Society was one by Mr. H. P. Curtis on "Acoustics of Thunder." He said that "contrary to the assertions of physical treatises, which hold that thunder is audible only 10 to 15 miles or possibly 18 miles from the generating flash, as the result of 10 years' observation in Europe and here, he had heard thunder at a distance of 100 miles from the flash. Other observers had noticed flashes, and by timing the interval between flash and thunder, a distance of 150 miles was obtained."

COST OF TELEPHONE SUBSCRIPTIONS.—London, £20; Paris, £24; Riga and Odessa, £25; Austria, £9 to £15; Germany, from £10, with an increase of £2. 2s. for every 1·24 mile over two; Italy, varying from £4. 12s. to £7 with the towns; Norway, £4 to £8, according to distance; Sweden, £6. 8s. to £10. 16s.; Holland, £10; Portugal, £15 for traders and £7 for private individuals; Switzerland, £4 to £10; New York, £40 a year; Boston, Chicago, Philadelphia, Baltimore, St. Louis, £30. Cities of an average of 60,000 to 100,000 population £30 a year. Little towns with 50 or 60 subscribers £10 a year.

THE LIGHTING OF DUNDALK.—There seems to have been some division of opinion in Dundalk as to the lighting of the town. Some time ago tenders or proposals were invited with a view to selecting electricity as the illuminant, and finally a contract was, we are informed, entered into with a Belfast firm to put down an installation. Delays, however, arose, and it transpired that an application for a licence would have to be made to the Board of trade, and ultimately, O, degenerate Dundalk! oil lighting was adopted. The inhabitants of that town are we believe very justly incensed at the turn matters have taken.

IRON TELEGRAPH POLES.—Iron telegraph posts have been introduced with great success in Switzerland, and are now being extended daily. They have been already put up on Swiss railways a distance of 350 miles. In Prussia they are being placed experimentally on the railway from Weissenfels to Gera, and on the line between Berlin and Potsdam. As iron is now so cheap, it is considered that in a short time they will altogether replace the old wooden poles in Germany, which cause frequent interruptions to telegraphic communication from rotting or being blown down by every high wind, especially in exposed situations.

THE POST OFFICE VOLUNTEERS IN EGYPT AND THE SOUDAN.—The Postmaster-General notifies that he has seen with great pleasure that in his report to the Secretary of State for War upon the recent operations on the Upper Nile and near Suakin, dated Cairo, 15th June, 1885, General Lord Wolseley, G.C.B., commanding Her Majesty's Forces in Egypt, makes the following remarks, which he publishes for general information:—"The volunteers were represented by men of the Volunteer Engineers and of the Post Office Corps, who, both by their zeal and their soldier-like bearing, sustained the reputation of the service to which they belong."

TRANSMISSION OF POWER IN NEW ZEALAND.—It is reported from New Zealand that a Dunedin electrical engineering firm is carrying out a contract for the transmission of power to run a stamping battery of twenty heads. The scene of operations is a gold mine in the mountainous country some thirty miles behind Lake Wakatipu, and the power to run the battery is transmitted from a waterfall in the neighbouring valley, straight over a mountain of about 2,000ft. in height, and for a distance of about two miles. The conducting wire is of the same size as an ordinary telegraph wire, but of copper, and is suspended from telegraph insulators in the usual manner.

LAUNCH.—Messrs. Wigham, Richardson and Co., of Newcastle-on-Tyne, launched on Saturday last the screw s.s. "Buccaneer." She will be fitted up for cable work, and will be used in company with the India Rubber, Gutta Percha, and Telegraph Works Company's s.s. "Silvertown" in the laying of the West Coast of Africa cables. She will be off the works of that company about the end of this month. Her speed is expected to be from 13 to 14 knots. The same company are at present shipping 530 knots of heavy cable on board the s.s. "International" and s.s. "Dacia," which is to be laid in the Peruvian Gulf, under the superintendence, we understand, of Colonel Bateman-Champain.

THE TELEGRAPH IN SOUTH AMERICA.—Later reports from America announce that the American Telegraph Company has opened telegraphic communication between Chillan, Talcahuano, Concepcion, Coronel and Lota, and it is expected that the line in course of construction between Chillan and Talca will be completed by the end of the present month, which will place the port of Valparaiso in direct communication with the southern part of the republic. A telegraph line is to be erected between Arica, in Peru, and Lapaz, the capital of Bolivia, the tariff to be two Bolivian pesos per word. The line is to be completed within six months. The Peruvian telegraph line is now in operation to Casma.

THE EARTHQUAKES.—A telegram from Vienna reports that on Wednesday afternoon there were repeated and severe shocks of earthquake, lasting for three seconds, at Kindberg, in the Styrian Alps. The inhabitants fled from their houses, which have in many instances been damaged, though not very seriously. In this part of Austria earthquakes have been of frequent occurrence in recent times. A telegram from the Canary Islands also states that a shock of earthquake has been felt there. No damage is reported. A shock of earthquake has been felt in Melbourne. In some places it was very severe. It was accompanied by a rumbling noise like that made by a train. No shock so severe had been felt for many years.

A CONDITION OF ELECTRICAL CONDUCTIVITY.—A paper was recently read before the Paris Academy of Sciences on the electric conductibility of solid mercury and of pure metals at low temperatures, by MM. Cailletet and Bouty. From numerous experiments made with mercury, silver, tin, aluminum, magnesium, copper, iron, and platina, the authors conclude that the electric resistance of most pure metals decreases regularly when the temperature is lowered from 0 deg. to 123 deg., and that the coefficient of variation is apparently much the same for all. It seems probable that the resistance would become extremely slight at temperatures lower than 200 deg., although this point has not yet been practically tested.

THE MINING EXHIBITION IN GLASGOW.—The arrangements in connection with the forthcoming mining exhibition,

Digitized by Google

to be held in Burnbank Drill Hall, Glasgow, this month, under the auspices of the Mining Institute of Scotland, are now in a forward state of completion. The whole place, grounds, and halls will be illuminated by electric lights, and visitors will have an opportunity of studying how the light is produced and maintained, and they must not forget, says a Scottish contemporary, that they are looking at what is almost sure to be the mine-light of the future. The example set by Mr. Watson, of Earnock, is not likely to be long without a following, and every further effort will be a step nearer perfection in mine lighting.

UNFORTUNATE.—At the Sunderland Bankruptcy Court on the 27th ult., Wm. Edwin Irish, electrical engineer, and the inventor of several electrical appliances of great merit, came up for first examination. He had acted as manager of the United Telephone Company for the North of England, and of the Northern District Telephone Company. He commenced business in 1881 with a capital of £500. His liabilities were £3,300, which included a liability of £2,300 to the Northern District Telephone Company, who had obtained a judgment against him for £1,700. His assets, he thought, would be about £6,000, including seven patents for electrical inventions, which he valued at £5,000. The cause of his insolvency was litigation with the Northern Telephone Company. The further examination was adjourned until 8th October.

LIGHTING A TUNNEL.—According to an American contemporary, Manager Locke continues to work on the problem of lighting the Hoosac Tunnel. He is of the opinion that some sort of an engine will ultimately be used in the tunnel which will not make any smoke, and that when this is done the tunnel can be lighted with electric lights. When this is accomplished it will become popular for excursionists, who will pass through, stopping at the central shaft, where they can climb up the stairway through the galleries to the base of the shaft and take a look to the top of the mountain, over 1,000ft. above. It is proposed to build a platform out into the shaft and have it so arranged that the people who visit this unpoetic spot can take in the stupendous height without being drenched by the constantly falling water.

A DEGENERATING DYNAMO.—All our efforts on behalf of electricity, if we are to credit the *Glasgow Herald's* rendering of a par from *Engineering*, are unfortunately not on the side of progress. Our contemporary says :—"We may also mention that four large punkahs are now driven at the well-known Restaurant Marguery, Boulevard Bonne-Nouvelle, Paris. They are placed upon the terrace of the Gymnase Theatre, which M. Marguery has rented for the summer season, and actuated by the Gramme motor fed by the current from a *degenerating dynamo* already used on the premises for domestic purposes." We may inform our readers that in substance this is an old note of ours, which appears to have been reproduced by *Engineering* and then degenerated by our Scottish contemporary, whose joke was of course unconscious.

GALLANT ACT OF A TELEGRAPHIST.—A brave act was performed at Dover on Saturday evening by a telegraph clerk, named James M'Cadden, engaged at the Dover General Post Office. M'Cadden, who is only 18 years old, was engaged at the telegraph room which overlooks the docks, when he noticed a man belonging to the Royal Irish Militia, who was the worse for liquor, and in the company of two comrades, stagger and fall in the dock. M'Cadden at once left his bench, and running out on the quay, dived into the water and succeeded in bringing the drowning man to the surface. The occurrence was witnessed by a large number of people, who expressed their admiration for the young man's bravery. M'Cadden had great difficulty in supporting the man, as he was intoxicated; but notwithstanding this he afterwards swam to and assisted in saving another soldier, who had jumped in after his comrade, but could not swim.

THE "HELIOGRAPH."—*Apropos* of Sir Henry Mance's recent honours, the following may be of interest :—The "heliograph," called also heliotrope, an instrument much used of late for signalling messages by sun flashes reflected from mirrors, between the sections of an army in the field, was invented by Karl Freidrich Gauss, one of the best mathematicians of modern times. He was born at Brunswick on the 30th April, 1777, and early displayed such remarkable capacity for mathematical calculation that (his parents being poor) the Duke of Brunswick took charge of his education. From the age of eighteen he gave many proofs of his extraordinary mental power, and in 1821 he was charged by the Hanoverian Government with the triangulation of the kingdom of Hanover. In executing this work Gauss found that the appliances then in use did not allow the vertices of the triangles to be seen distinctly from a distance, and to remedy this defect he invented the heliograph, which under recent improvements has been made serviceable for distances of nearly 200 miles.

SOLID ELECTROLYTES.—The following letter has been written to *Nature* by Prof. Silvanus P. Thompson :—"Having been for some months occupied with the electrical behaviour of the compounds of copper, silver, and lead with tellurium, selenium, and sulphur, I can confirm the observation communicated to your pages by Mr. Bidwell as to the behaviour of sulphide of copper. He has constructed a primary cell with solid sulphides for the electrolytes. The smallness of the electromotive force which he has obtained is entirely due to the close proximity of copper and silver in the thermo-chemical series in respect to their heats of combination with sulphur. The theoretical electromotive force should be only ·05 volt. Let me add to Mr. Bidwell's observation one of my own. If a piece of sulphide of copper is placed between platinum electrodes, a current of electricity from a battery can be passed freely through it, as it is a good conductor. But if after a time the battery is removed and the platinum electrodes are connected with a galvanometer, a current is observed. The solid sulphide between two platinum plates constitutes, therefore, a secondary cell or accumulator capable of being charged and discharged."

THE NOTTINGHAM CENTRAL POST OFFICE.—The business of Nottingham has increased enormously of late years, so far as the post office is concerned, and the addition of other departments has greatly added to the congestion. The changes at present being made are of a most extensive character, and are necessitated by the adoption of a "dead letter" department and the introduction of sixpenny telegrams. Recently a story was added to the building, now a doorway is being opened out at the corner of Victoria and Queen-streets, giving a fresh entrance to the structure. The postmaster's (Mr. Pratt) and the chief clerk's (Mr. Richard) offices have been removed from the first to the second story, to make room for an extension of the accommodation of the Parcels Post department. The telegraph department, except for the mere receipt of messages, which will be as usual on the ground floor, has been removed bodily from the second to the third or recently added story. The entrance is still in Victoria-street. On the left are the rooms of the chiefs, and beyond are the instruments. The alterations are being carried out under the direction of Mr. Revel, of the Board of Works, by Messrs. Fish and Son, contractors, Nottingham.

A DISPUTED POINT.—Mr. Calladon recently, addressing the French Academy of Sciences, said that there was no truth in the popular supposition that a building with a metal roof, or with metal in its construction, is more likely to be struck by lightning than a building composed wholly of non-conducting materials, providing there is no means of electric communication between the metal and the earth. A house in Neufchatel, Switzerland, had been struck by lightning and burned, and somebody suggested that a lot of old iron stored in the attic had attracted the electric fluid. It was this suggestion that brought Mr. Calladon to his feet. He said that the iron had had nothing to do with attracting the lightning, but had probably been a cause of the burning of the building after it had been struck. The explanation of that is that a combustible substance placed between two conducting surfaces (in this case the humid atmosphere and the pile of iron) is generally sure to take fire when an electric current is passed through it from one conducting surface to the other. The lightning having struck the house, concludes the scientist, found its way to the metal within and ignited whatever combustible material it passed.

THE TELEPHONE AND FIRES.—In connection with the fire which broke out in the extensive timber yard of Mr. T. Forman, 148, Kennington-road, on Saturday morning last, we learn that upon the news being communicated to Superintendent Hamlyn he immediately ordered out all the nearest engines, and sent by telephone a message to the authorities at Southwark stating that engines and men were turning out for Forman's timber yard in the Kennington-road, well alight, and asking that extra steamers and men from the three other districts on the north of the river should be immediately ordered to the scene. This serious message, when it was communicated to Mr. Simonds, the second officer of the brigade, at once produced the order for help to be sent on, and engines from Brompton, Chelsea, and Kensington in the "A" district, from Watling-street and Scotland-yard in the "B" district, and from Mile End and Shoreditch in the "C" district, were soon on their way to the fire. In the meantime the engines from Kennington, Tooley-street, Rotherhithe, Deptford, Old Kent-road, Camberwell, Brixton, Clapham, and Waterloo-road had begun to arrive in rapid succession; and as promptly as they appeared their powerful machinery was got to work, and water was pouring on the flames from half a dozen different directions within ten minutes of the first raising of the alarm.

TOWN LIGHTING BY ELECTRICITY.—The experience gained at Detroit is interesting, inasmuch as there was a keen competition between electricity, gas, and oil for the lighting of the city. For the current year the tender of the Electric Light Company is 89,300 dols., against 40,000 dols. of the gas and naphtha companies, a difference of 49,300 dols. in favour of the latter when cost alone is considered, though it is suggested that this tender assumes a loss of at least 40,000 dols., a loss which the gas companies agreed to in hopes of ousting their more successful rival. The main cost, however, came to be, as we always said it should, a secondary consideration. The citizens would not have gas or naphtha at any price, they cut down the lamp-posts, and finally the cry of "more and better light" prevailed. A year ago the electric tender was 95,000 dols. for lighting an area of 10·5 square miles. This area, as in almost all large towns, consists of a thickly populated centre, with a suburban and semi-suburban district. In order to light the area 90 skeleton iron towers were erected, three being 175ft. high, the remainder 150ft. high, placed in triangles 1,000 to 1,200ft. apart in the centre and 2,500 to 3,000ft. apart in the suburban districts. On these towers 358 (2,000 nominal candle-power) arc lights were placed, but these were supplemented by 23 pole lights in special positions. It is said that the lighting of the city was extremely good, streets, lanes, and alleys being lighted as by moonlight, to the great benefit of the inhabitants. Meanwhile we in the old world are content with the old order of things, because if we want more light we are unwilling to pay for it.

A MEAN THIEF.—At the Mansion House recently Edward Ratcliff was brought before Alderman Sir Andrew Lusk, M.P., charged with stealing a purse and money, the property of Her Majesty's Postmaster-General. The evidence showed that the prisoner was in the employment of an electric light company, and it was his duty to attend to the electric lights in the premises of the Post Office Savings Bank Department in Queen Victoria-street. Recently there had been several complaints made of the loss of purses belonging to young ladies employed in the department, and accordingly the Post Office authorities took steps with a view of finding out who the thief was. On Friday a purse containing marked money was placed in one of lockers in the young ladies' dressing room, and a Post Office constable took up a position in a cupboard where he could see anything that took place. He saw the prisoner come into the room and look into four lockers, but took nothing out. Afterwards, however, the prisoner looked into the fifth locker, which contained the purse and marked money. The prisoner took the purse out, and was walking away when the police officer stopped him and took him in charge for stealing the purse. It was said that the prisoner had no business in the room at all; but he asserted that he had to go there to look after the lights. The prisoner, in defence, denied that he had stolen the purse, and urged that he had gone into the room with the *bonâ fide* object of attending to the lights, as was his duty. He said he bore an excellent character, and was placing the purse back in the locker when the constable suddenly came out of the cupboard and accused him of stealing it. He emphatically denied the charge. Sir Andrew Lusk said it was a very ungallant thing for the prisoner to try to take away a poor girl's purse. He sentenced the prisoner to three months' imprisonment with hard labour.

AN INDESTRUCTIBLE EARTH CONNECTION.—Mr. Justin Malisz, after drawing attention to the defects of ordinary earth plates, describes his method of preparing an earth connection which conducts well, is self-depolarising, and has its junction with the line easily accessible. A hole about 6½ft. deep, and about 3ft. square, is dug in the ground, and a layer of coke laid on the bottom, and firmly stamped down. A tube with its lower end resting on the coke is placed against one face of the hole, and filled tightly with coke almost to the top. The hole is then filled up, and the earth rammed well round the tube, the upper part of which projects above the surface of the ground. A lump of coke or retort carbon, to which a copper band is rigidly attached by soldering or pouring molten lead over it, is put in the tube, and a final layer of coke pressed firmly around it. The copper band projects from the top of the tube, and to this band the line or the lightning conductor is soldered. By this arrangement a constant earth connection is obtained, as coke has a uniform conducting power under all circumstances, and its large surface ensures for the current an easy path to earth. The column of coke in the tube not only enables the junction between earth and line to be permanently above the ground and easy of access, but it has a depolarising action on the bottom layer of coke, thereby preventing the prejudicial effect of a counter electromotive force, which in so many cases renders an ordinary earth-plate useless. Mr. Malzis

Digitized by Google

considers that the coke, which in the upper part of the tube is in contact with the air, condenses oxygen, and can likewise absorb and oxidise the hydrogen formed by the current. The gases resulting from polarisation rise through the column of coke in the tube, and are dissipated in the air, and this column in virtue of its power of condensation plays an important part in the deplorisation of this form of earth connection.

LARGE DYNAMOS.—There is rapidly approaching completion at Messrs. R. E. Crompton's works the construction of three huge dynamo machines, driven direct by high-speed engines. They are intended to form part of an electric light installation to be carried out by this firm for the Imperial Continental Gas Association at Vienna, the Emperor having, since the great fires that took place in that city some years ago, adopted electric lighting on a large scale. In order to facilitate the erection of these machines and engines, a shop has been specially built for their reception. Each engine and machine stands in a cast-iron bed plate 12ft. long, 4ft. 6in. wide, and weighing $2\frac{1}{3}$ tons. These machines stand 7ft. 6in. from the ground. The massive field magnets on each machine are of the finest wrought iron and weigh four tons. The armatures or revolving parts are $16\frac{1}{2}$in. in diameter, and 3ft. long, and are carried on spindles $5\frac{1}{8}$in. diameter in the centre. No less than $5\frac{1}{2}$ miles of copper wire have been used in their construction. Each machine will be driven direct by a Willans high-speed compound engine of latest type. Each dynamo is intended with ordinary running to give an output of 120 amperes current at a pressure of 600 volts, equal to nearly 100 horse-power—that is to say, these machines will be capable of supplying the power of about 3,600 16 candle-power incandescent lights, which in practice are to be supplied through accumulators. Messrs. Crompton have been entrusted with the contract for the boilers for the installation, and also the whole arrangement of the engine and machine rooms, which arrangements have been got out after careful consultation with the Vienna Company's engineer, M. Monier. When finished the installation will be one of the most important yet attempted, and will, it is hoped, be so successful in its results as to induce many local bodies and corporations to erect central lighting stations in this country.

A SUGGESTION.—"Railroad men," says the *St. Louis Globe Democrat*, "have recently been considering the feasibility of using the electric light as headlights to their engines, and for the purpose of generally illuminating trains. The difficulty in the way seems to be that the jar of the locomotives and coaches is liable to cause uncertainty in the continuity of the light. But there is one method that does not appear to have been discussed to which this objection will not apply. That is, utilising the existing telegraph poles and wires for the purpose of making a continuous illumination along the railroad tracks. There are thirty telegraph poles to the mile, and if on every other one of these were hung an electric lamp, the entire track could be made as light as day. This would do away entirely with the need of the expensive and cumbrous headlights, and, to some extent, with the necessity for using oil-lamps in the train. It would also obviate all the dangers to railroad traffic that are now incident to the darkness. Accidents resulting from washouts, or fallen trees, or landslides would be things of the past. Obstructions placed by malicious persons on the tracks would be seen at once, or, were the malefactors to take the precaution of cutting the wires before attempting to wreck the train, that would at once extinguish all the lights within the circuit, and give warning to the train officers that danger was ahead. Moreover, suppose the case of a train despatched on mistaken orders, as soon as the case was discovered, the operator at the battery could, by a simple movement of the hand, extinguish the lights, which would be a signal for the train within his circuit to come to a stand and wait for orders. It way be urged against the suggestion that some of the lamps might get out of order and remain so, unless a close and expensive system of supervision were maintained. This difficulty can be met by a further suggestion that, with a simple system of lettering and numbering the lamps, the engineers of passing trains could report to the next station what particular lamp or lamps might happen to be out of order. At any rate, the plan, which has been suggested by a practical railroad man of great experience, presents so many points of apparent advantage that it must be worth examination. To the public at large it would certainly give a greater feeling of security than is possible under the present system; and if the economical questions connected with it can be satisfactorily adjusted, it would undoubtedly be considered a great step in advance."

THE ELECTRIC LIGHT AND LIGHTHOUSES.—The shipping trade of the Firth of Forth has rapidly increased during recent years, and loud calls for more lights have been made, and these are being gradually supplied. St. Abb's Head, near the mouth of the Forth, was crowned with a ten second flashing light in 1862, and from the Island of Fidra, which lies nearly opposite North Berwick, a group-flashing white light (the first of its kind in Scotland), showing two flashes in quick succession, with intervals of about fifteen seconds between the groups, was exhibited for the first time on 15th April last. The Fidra light is shown from a tower at an elevation of upwards of a hundred feet above high water, and is visible about seventeen nautical miles. In order to guide vessels through the somewhat intricate navigation leading to Queensferry, Bo'ness, and Grangemouth, a tower has been placed on the Oxscares Rock, which lies to the east of Inchcolm, and in all likelihood the light will be shown from it before winter sets in, as the work is rapidly approaching completion. When all these lights have been exhibited, the sailor will have no cause of complaint so far as the chain of lights on the south side of the Firth is concerned. But the most powerful of all the lights will be that of the electric light on the Isle of May. Messrs. Stevenson, engineers to the Northern Lighthouse Board, prepared designs for the requisite additional buildings, and also for the optical and electrical apparatus for the installation of the new light, and a contract has already been entered into for the erections on the island, and some progress has been made with the buildings. Messrs. Stratton, the contractors, taking advantage of the good weather, have also landed on the island a large quantity of materials, and are vigorously pushing on the works. The optical apparatus for this light is of a novel description, on the condensing principle of Mr. Thomas Stevenson, and will show four flashes in quick succession every half minute, while a small arc of fixed white electric light will be shown in the direction of the North Carr Rock in supplement of the present low light. As indicative of the intensity of the proposed light, it will probably be nearly a thousand times stronger than the present powerful oil light. Provision has also been made for dipping the light during fogs, so as to increase the power at nearer distances to the lighthouse than the horizon. The increase in the power of the light is gained, not by adopting unusually powerful electric apparatus, but is due to the special optical apparatus which is to be employed. When the electric light has been established, the Isle of May lighthouse will have passed through all the changes in the art of lighthouse illumination, from the open coal fire to the latest development of optical and electrical apparatus.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.

BY OLIVER HEAVISIDE.

(Continued from page 291.)

As regards other causes influencing the electric field in the space external to the conductors, there remains the problem (*a*) of the last section. If, in it, we put $e=0$, we reduce it to the common electrostatic problem :—Given the volume electrification within, and also the charges upon equipotential surfaces bounding the nonconducting region (at least when they require to be independently stated, apart from the volume electrification), show that the field of force is determinate. We might take this for granted, and confine our attention to impressed force only; but as it makes scarcely any difference to include electrification, we shall do so. We have then the conditions

$$\text{div.}c(e+\text{F})=4\pi\rho, \qquad \text{curl}\text{F}=0,$$

to be satisfied by F within the non-conducting region; and, at any bounding surface,

$$\Sigma\text{DN}=q, \qquad \text{VFN}=0;$$

the first of these expressing that the given charge q on the surface is the total normal displacement from it into the non-conductor, and the second that the force has no tangential component at the surface, or is normal thereto, or that the surface is equipotential.

Assuming F to satisfy the above, alter it to $\text{F}_1=\text{F}+f$ in any way that does not alter the electrification or the charges. That is, subject f to

$$\text{div.}cf=0, \qquad \Sigma\text{N}cf=0$$

within the region, and at a surface, respectively. We have merely to show that this change increases the electrostatic energy $\Sigma\text{F}c\text{F}/8\pi$, a quantity that must have a minimum, to show that F is determinate, by reasoning used before, which need not be repeated; and, since

$$\Sigma\text{F}_1c\text{F}_1=\Sigma\text{F}c\text{F}+\Sigma fcf+2\Sigma\text{F}cf$$

wherein the second sum on the right is positive, we have only to show that $\Sigma\text{F}cf$, the third sum, vanishes. Now, by the first condition for f, we have cf perfectly continuous within the region; and, by the second, as much enters as leaves any bounding surface. That is, cf is any closed flux whatever, either closed entirely within the region, or else partly or wholly through the rest of space. Therefore $cf=\text{curl}\text{Z}$, Z being any function whose curl is cf, and

$$\Sigma\text{F}cf=\Sigma\text{ZVNF}=0;$$

the first summation extending through the region, the second over the bounding surfaces, and vanishing because $\text{VNF}=0$ at every point thereof.

This finishes the question of the determinancy of F. In any conductor it is settled by the distribution of impressed force and of conductivity therein, and the interior displacement and electrification follow. Then, knowing the tangential force set up at the boundaries of the non-conductors due to impressed force in the conductors, this is sufficient to settle the force all through the non-conductors when the distribution of capacity is given, provided there be no electrification in them, or impressed force, or boundary charges. No electrification or charges will be produced, as the displacement in the non-conductors can be closed through the conductors. Should there be electrification, &c., in the non-conductors, these have no effect on the conductors, produce no boundary tangential force, and their effect in the non-conductors may with convenience be separately considered. Knowing F to be determinate through all space, we may construct a potential to suit it, fixing its value arbitrarily at any one point. Should we, however, make the potential the direct object of attention in our investigations, instead of the force, we should greatly complicate certain parts of them. For example, to show that e in the conductors fixes F in the non-conductors when there is no electrification, &c. If there are n conductors, n fields of force (namely in them) are found by the conductivity conditions. The potential is therefore known over the surface of all the conductors, except as regards a constant for each. If we assume these constants to be known, we may prove that the thus fixed boundary potential fixes the potential throughout all the non-conducting regions. But the resulting fields of force in them will be (except by extraordinary accident) entirely wrong. For the potential thus determined gives charges to the bounding surfaces, whereas there should be none. We must therefore, to get matters right, communicate to the bounding surfaces exactly equal charges of the opposite kind, and distribute them in such a manner as not to disturb the already correctly settled tangential force, *i.e.*, distribute them equipotentially. The field of force will then get right, and the potential will be the sum of the wrong potential and that due to the charges added to cancel those given by the wrong potential.

As regards e in the non-conductors, it may be due to thermal or chemical causes, or be any other impressed electric force. Intrinsic electrization is also included under e; thus, if J be its intensity, $\text{J}=ce/4\pi$ gives us the value of e to correspond. (See p. 230.) So far as producing polar force is concerned, a distribution of e acts in precisely the same manner as would a distribution of electrification of volume density $\sigma=\text{conv.}ce/4\pi$. Here, however, the similarity ceases. It is quite different as regards the displacement and the energy, as e contributes to the displacement equally with polar force, thus $\text{D}=c(e+\text{F})/4\pi$. Sometimes F acts to assist e, but more frequently it is the other way. We should also remark that this *false* electrification σ may, like ρ, the real electrification, have surface distributions over conductors; whenever, in fact, ce is not tangential. The surface density is then $-\text{N}ce/4\pi$. But, unlike a real charge, which can be varied in distribution by influence, the false charge is fixed under the same circumstances. It (σ) should never be referred to as electricity or electrification without the prefix *false*, or some other qualification to distinguish it from Maxwell's electrification or free electricity, which is always discontinuity produced in the elastic displacement, only to be got rid of by conduction, with dissipation of energy in producing heat. In fact, σ is as false electrification as the distribution of electric current round a bar magnet, which would correspond to the same magnetic field, is a false electric current.

Various Expressions for the Electric Energy.

There being any steady state, with impressed forces both in the conductors and in the non-conductors, also electrification and surface charges, let us obtain expressions for the electric energy. We may consider the whole field of displacement as four fields, viz., that in the non-conductors due to impressed force in the conductors; ditto, due to impressed force in the non-conductors; ditto, due to electrification and surface charges; and lastly, that in the conductors. The total electric energy will be the sum of the energies of the separate fields, together with their mutual energies, if they be not conjugate. We shall denote the four fields by the suffixes 1, 2, 3, 4; in all other respects employing the same notation.

1. First, let U_1 be the electric energy in the non-conductors due to e_1 in the conductors. Then,

$$\text{U}_1=\tfrac{1}{2}\Sigma\text{E}_1\text{D}_1=\tfrac{1}{2}\Sigma\text{F}_1c\text{F}_1/4\pi=\tfrac{1}{2}\Sigma\text{P}_1\text{D}_1\text{N}=\tfrac{1}{2}\Sigma\text{Z}_1g_1 \quad . \quad (96)_1$$

Here the first form of U_1 is the form common in all cases, the energy per unit volume being half the scalar product of the force and the displacement. The second form is virtually the same, only putting the displacement in terms of the force, which is polar. These summations of course extend throughout the whole non-conducting regions. The third form is a surface summation over the whole boundary, of half the product of the scalar potential and the normal displacement. The fourth form is also a summation over all the boundary, of half the scalar product of the vector potential Z_1 and the false magnetic current g_1. We have

$$-\text{curl}\text{Z}_1=4\pi\text{D}_1, \qquad \text{VF}_1\text{N}=4\pi g_1.$$

Z_1 is the magnetic impulse, or time-integral of the transient magnetic force during the variable state which would occur if the impressed force were suddenly cancelled, ending in the removal of the displacement D_1 in the non-conductors. Or, without altering the value of the summation, we may take Z_1 to be the time-integral of the actual magnetic force, taken

Digitized by Google

negatively, arising from putting on the impressed force, though this is less convenient in general. Should there be no electric current finally, $e_4 + F_4 = 0$, if F_4 is the polar force in the conductor, and therefore $4\pi g_1 = V\mathrm{N}e_4$. In this case also,

$$U_1 = \tfrac{1}{2}\Sigma e_4 \int \Gamma dt,$$

Γ being the true current at time t after starting e_4, so that $\int \Gamma dt$ is the total displacement, elastic and conductive. The other half of the work done by e_4 is spent in heat. Observe that it is necessary for the impressed force in the conductor to reach to its boundary, and to have a tangential component there, for it to be able to set up displacement outside without at the same time producing current in the conductor.

2. Next, let U_2 be the electric energy in the non-conductors due to impressed force in them only. Then,

$$\left.\begin{aligned} U_2 &= \tfrac{1}{2}\Sigma E_2 D_2 = \tfrac{1}{2}\Sigma e_2 D_2 = \tfrac{1}{2}\Sigma Z_2 g_2 \\ &= \tfrac{1}{2}\Sigma e_2 c e_2/4\pi - \tfrac{1}{2}\Sigma F_2 c F_2/4\pi = \tfrac{1}{2}\Sigma e_2 c e_2/4\pi - \tfrac{1}{2}\Sigma P_2 \sigma \end{aligned}\right\} \quad . \quad (96)_2$$

The first form requires no remark. The second results because $E_2 = e_2 + F_2$, and $\Sigma F_2 D_2 = 0$. In the third form Z_2 is the magnetic impulse (of e_2 now, of course), and

$$-\mathrm{curl} Z_2 = 4\pi D_2 \qquad -\mathrm{curl} e_2 = 4\pi g_2;$$

the object of introducing 4π's being to harmonise as well as possible with the usual electromagnetic formulæ. In the fourth form we have the difference of two sums, the first a constant, the second the energy of the field of the polar force by itself, as if due to electrification. In the fifth form the energy of the polar force is expressed in terms of its potential and the false electrification σ. All the summations are taken throughout the non-conductors. There may possibly be surface summations as well, if e_2 exists at the boundaries. All the formulæ in $(96)_2$ are the same as if there were no conductors present.

3. Let U_3 be the common electric energy due to electrification ρ and surface charges q_1, q_2, &c.

$$U_3 = \tfrac{1}{2}\Sigma E_3 D_3 = \tfrac{1}{2}\Sigma F_3 D_3 = \tfrac{1}{2}\Sigma P_3 \rho + \tfrac{1}{2}\Sigma P_3 q \quad . \quad . \quad . \quad (96)_3$$

The first and second forms are identical, the force being polar. In the third form the energy is expressed in terms of the potential and electrification. We may also here employ the magnetic impulse, by a device, but with no utility.

4. Let U_4 be the electric energy in the conductors due to e_4 in them. Then

$$U_4 = \tfrac{1}{2}\Sigma E_4 D_4 = \tfrac{1}{2}\Sigma(e_4 + F_4) D_4 = \tfrac{1}{2}\Sigma e_4 D_4 + \tfrac{1}{2}\Sigma P_4 \rho_4 \quad . \quad . \quad (96)_4$$

Here F_4 is the polar force in the conductors due to e_4, and P_4 its potential; ρ_4 is the interior electrification, if any. Should there be none, D_4 is closed within the conductor, and we may write

$$U_4 = \tfrac{1}{2}\Sigma Z_4 g_4$$

if $\mathrm{curl} Z_4 = -4\pi D_4$ and $\mathrm{curl} e_4 = -4\pi g_4$. It is clear that a similar form exists for the energy in any volume in which there is no electrification, g being represented by the tangential boundary force turned through a right angle, besides the part depending on e_4 if it exist in the volume. (Here e_4 is the same as in the previous concerning U_1.)

5. Lastly, there are the mutual energies. We get rid of U_{14}, U_{24}, and U_{34} at once by observing that the fourth field is in a different place from the first, second, and third, so that these quantities are zero. We can also get rid of U_{13} and U_{23}; the first and third fields, though coexistent, are conjugate, and so are the second and third. Thus,

$$U_{13} = \Sigma D_1 F_3 = \Sigma Z_1 V\mathrm{N} F_3 = 0$$

Z_1 being the same quantity as before. The second summation extends over the boundaries, and vanishes because F_3 is normal to them. Similarly show that U_{23} vanishes. There remains only U_{12}, which does not necessarily vanish.

$$\left.\begin{aligned} U_{12} &= \Sigma E_1 D_2 = \Sigma E_2 D_1 = \Sigma P_1 D_2 \mathrm{N} = \Sigma P_2 D_1 \mathrm{N} \\ &= \Sigma Z_1 g_2 = \Sigma Z_2 g_1 = \Sigma e_2 D_1 \end{aligned}\right\} \quad . \quad (96)_5$$

Here the quantities are the same as before used in treating U_1 and U_2. Finally, U being the complete electric energy in all space

$$U = U_1 + U_2 + U_{12} + U_3 + U_4.$$

Here the first three components of U may be taken together conveniently. Let the impressed forces in the conductors and the non-conductors start at the same moment, and Z be the magnetic impulse, = former $Z_1 + Z_2$, then

$$U_1 + U_2 + U_{12} = \tfrac{1}{2}\Sigma Z g$$

where g = former $g_1 + g_2$, that is

$$4\pi g = -\mathrm{curl}(E_1 + E_2)$$

with the equivalent boundary representative.

Finally, we may, by means of the various conjugate properties, put together the potential results. Let P be the resultant potential from all causes; ρ the electrification density whether in conducting or non-conducting matter, defined by $\rho = \mathrm{div.D}$, including in it surface electrification; σ the density of false electrification, defined by $\sigma = \mathrm{conv.}ce/4\pi = \mathrm{conv.J}$, if J be the (equivalent) intensity of electrisation, *i.e.*, $J = ce/4\pi$, whether in the conductors or not; then

$$U = \tfrac{1}{2}\Sigma eJ + \tfrac{1}{2}\Sigma P(\rho - \sigma) \quad . \quad . \quad . \quad . \quad (97)$$

expresses the total electric energy, the summations being through all space. Notice the minus sign before the false electrification. (97) may also be easily proved directly.

Here, and in any of the summations containing a scalar potential, any constant may be added to the potential, owing to the sum of the electrification being zero, ditto of false. There is an apparent exception when, as may be imagined, tubes of displacement go out to infinity, though this cannot really occur. In such a case, we must choose P to vanish at infinity. But we may get over this by regarding the end of space as an electrified surface. The surface density will be infinitely small, but the charge on it finite, being the exact negative of all the other electrification. Counting it, the constant in P again becomes arbitrary.

We may extend the results to apply to transient states by including in e the electric force of induction, $= -\dot{A}$, if A be such that $\mathrm{curl} A = B$, the magnetic induction. Considering U_1 during the transient state, we find

$$U_1 = \tfrac{1}{2}\Sigma Z_1 G_1 + \tfrac{1}{2}\Sigma Z_1 g_1$$

at any moment, Z_1 being the magnetic impulse that would arise from removing e at that moment, G_1 the *real* magnetic current $\dot{B}/4\pi$ at the moment, and g_1 as before the false magnetic current at the boundary. The first summation extends through the non-conductors. When the steady state is reached, $G_1 = 0$, and Z_1 and g_1 arrive at their before used steady values. Similarly for U_2, U_4, and U_{12} during their transient state.

(To be continued.)

THE STEAM ENGINE INDICATOR.—VII.*

BY AMICE.

The mode of working the indicator has now to be considered —that is to say, the means by which a movement of the indicator barrel exactly synchronous with that of the steam engine piston is obtained. This is not so simple a matter where exactness is required as is usually supposed, and although it is not desirable to insist upon mathematical precision and perfection of fitting of indicator gear, and on the necessity for perfect inextensibility in the communicating cord, it is essential that some thought and care should be bestowed on these matters. It is especially necessary that the indicator card should move in as perfect unison with the piston as though it were attached to it. To obtain this, the gear by which the stroke of the piston is converted into the shorter one of the indicator card should be rigid but light in construction, and the best cord that is made should be used to connect the gear with the indicator barrel. Some engineers prefer to use fine hard brass or steel wire for this purpose. In order to make clear the inaccuracies which accrue in the indicator diagram, through imperfection of the reducing and communicating gear and cord, it is necessary in the first place to describe the arrangements of gear more commonly employed. We will assume that we are dealing with a horizontal engine, although the gear we shall

* For Art. 6, see *The Electrician*, 15th May, 1885.

Digitized by Google

describe will, as shown, or with very slight addition or modification, be equally applicable to vertical engines. With few exceptions the horizontal and the vertical include all types, though the multiplication of levers and rods in marine engines sometimes makes it difficult in the usually confined space of an engine room to fit up satisfactory indicator gear. The gear necessary for working an indicator on an oscillating cylinder engine is of a different character, and these diagrams are more difficult to take, in consequence chiefly of the movement of the cylinder.

In Fig. 33 we have a diagram illustrative of a very usual form of reducing gear. Attached to the bolts that hold the guide bars in place are the legs D of a stiff standard for holding the spindle or the pivot p upon which the swinging arm A is pivoted. C is the engine crosshead, and in this a pin is fixed for communicating the movement of the piston to the arm A, the difference between the circular path $x\,x$ of a point in A and the straight path of the crosshead C being accommodated by the slot in the end of A. In some cases the lever A is made of wood, but it can be much more satisfactorily made in metal. The lower end of the arm A moves through a distance equal to the stroke of the piston, and a synchronous movement of shorter range, it is obvious, may be imparted to anything, say an indicator, connected by cord to the arm A at any point, y (not shown), intermediate between C and p. The relation between the ranges of motion of indicator card and of the piston will of course be that of the length p C to $p\,y$. Ordinarily, the cord or wire G by which A communi-

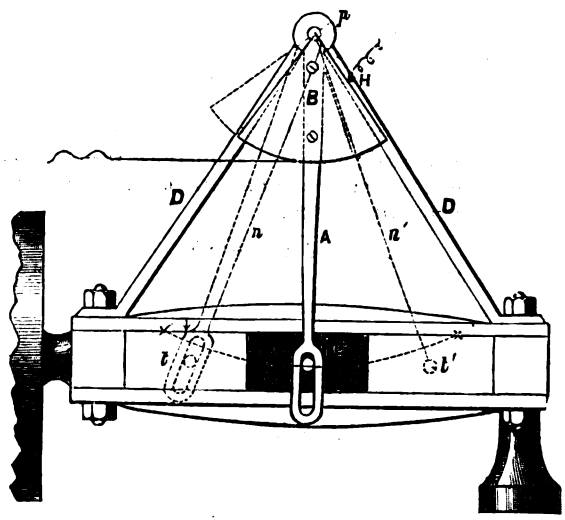

Fig. 33.

cates movement to the indicator barrel is attached to a pin screwed into A or into a piece of wood fastened thereto for the purpose. But the practice is becoming more general to attach a piece of wood of the segmental form shown at B, the radius of which is such as to give the desired length of stroke to the indicator card. Thus, suppose the stroke of the engine to be indicated be 30in., the length p C, say 36in., and it is desired to take diagrams which shall be 4in. in length, the radius of the segment B, or the distance of a pin for the cord from p must be $r = \frac{\text{length of arm A}}{\text{stroke of engine} \div \text{stroke of card}}$, or we have $r = \frac{\text{length of arm A} \times \text{stroke of card}}{\text{stroke of engine piston}}$, giving, in the case assumed, a radius of $\frac{36 \times 4}{30} = 4{\cdot}8$in.

The advantage which attends the use of the segment is that as the cord is always at the same vertical distance from p there is not that loss of horizontal movement in the cord due to the difference between the lengths of the chord and of the arc described, which would result from its following the angular movement of a pin at distance from p = the assumed radius r. The difference between the chord and the arc of the path of the pin is not great, but whether the indicator be near or far from the reducing gear it is sufficient to make an appreciable and sometimes important difference in the diagram. When the gear is very close to the indicator barrel the difference may be magnified. It may, however, be noted that as the pin in the crosshead C moves in its straight path, and the arm A moves in an angular path to n, the pin in the crosshead takes a new place in the slot; it is at a distance from p, which is greater than when the arm A is in midstroke, as shown, by the distance between the pin t and the arc $x\,x$. The length of the arm A is thus virtually increased, the relation between p C and $p\,r$ no longer remains the same, and the result is that the piston of the engine and the crosshead C move through a horizontal distance which is greater than that communicated to that part of A where the pin stood at midstroke, by half the difference between the length of the chord of the arc described by it and of the stroke $t\,t'$. The reality of this

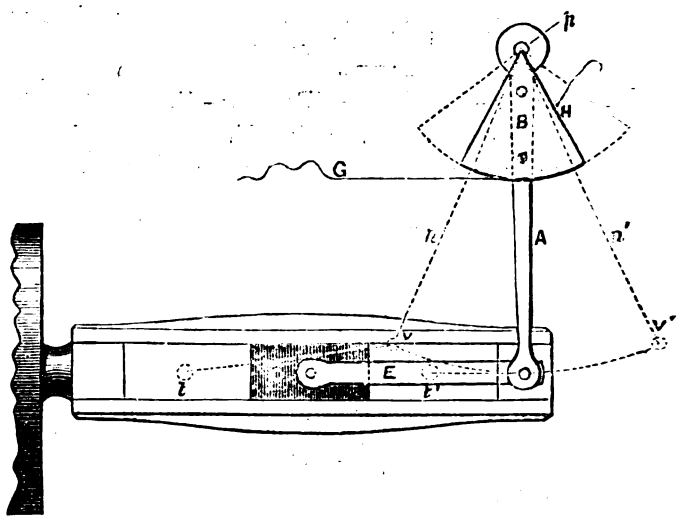

Fig. 34.

movement of the piston without proper corresponding movement of the arm may be easily seen by imagining the arm A pivoted at, say, one-fourth the distance above C, and the slot made of the extra necessary length. This difference it will be seen tends to aggravate the errors

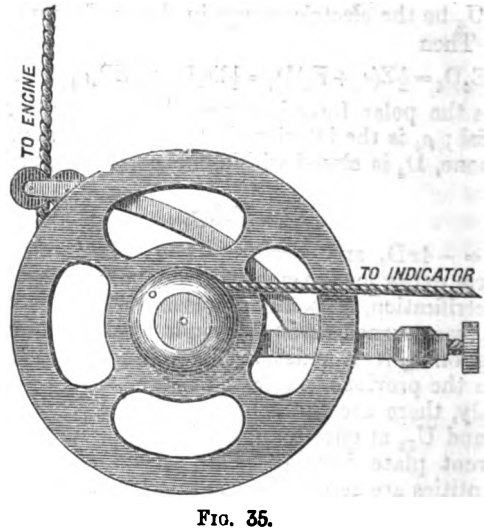

Fig. 35.

produced at either end of the diagram. The error is lessened in very rapid ratio with increase in length in the arm A. As far as the error is due to string attachment to a pin in A at the necessary distance from p, this is overcome by the use of the segment, which must be specially made for each case, as shown; and to avoid, the error as caused by the use of the slotted lever, shown at Fig. 33, the arrangement shown at Fig. 34 is generally preferred. Here the loss of movement is only that due to the angular movement of the connecting rod E, and is equal to the versed sine of the arc described. This, it will be seen may be made quite inappreciable by giving the rods E and A considerable length. It will be observed that

Digitized by Google

this loss of movement or inaccuracy at the two ends of the cord happens when the engine piston is moving most slowly, and it becomes an important matter when, as in the case more especially of gas engines, it is desired to find the time occupied in acquiring the maximum pressure. In Fig. 34 the mode of supporting the pivot of the arm A is not shown; but this, as in the case of Fig. 33, may be of any form most easily made, provided it be rigid and the bearings and pins properly fitted. The cord or string G is attached to a pin in the side of the segment at H. By using the segment B the string G may be led to the indicator in whatever position in a vertical plane it may happen to be without affecting the proper movement of the card, the segment having the necessary length of arc, and being attached to A in a suitable position. The segment is shown with its centre line coincident with that of A, but it need not, of course, have this position. Instead of a segment a circular disc may be used.

When a segment or a disc is not used, but only a pin, as above mentioned, to which to attach the string G, care must be taken that a line connecting the pivot p and the pin be normal to the indicator string when the piston is at half stroke, as it is in the diagrams (Figs. 33 and 34).

A form of reducing gear made by Messrs. Elliott Brothers is illustrated by Fig. 35. By means of this there are none of the inaccuracies due to what we may term angular causes already explained, the reduction being effected by the use of rollers or pulleys, the radii of which bear the same relation to each other which must be borne by the arm A and distance r already given. The apparatus necessitates different wheels for different strokes and lengths of diagram. It may be attached direct to the indicator, or elsewhere if more convenient, and is a handy form for oscillating cylinder engines. It necessitates the use of two strings or wires instead of one, and thus, although it avoids all the levers and supports we have described, it incurs whatever objections may be made to strings or wire. In all cases care must be taken that the string G is of the proper length, so that the indicator barrel is not pulled to or let back to either of the stops.

THE NEW SIXPENNY TELEGRAM FORM.

We are able to present our readers with a copy of the form which will come into use for the sending of telegrams at the reduced rate on the 1st of October. It will be seen that the chief difference between the old and the new form is that on the latter there is no space provided for the name and address of the sender. This information, if it is to be signalled, will have to be added at the end of the message like a signature. A space is provided at the back of the form for the insertion of the "Name and Address of Sender (for Reference Only)," when these particulars are not to be telegraphed; but their insertion anywhere apparently is not compulsory. The copy here given is rather less in size than the original :—

LIGHTHOUSE EXPERIMENTS AT THE SOUTH FORELAND.

The delay in publishing the results of the experimental tests which were completed last winter at the South Foreland has been partly due, no doubt, to the circumstance referred to in our issue of the second week in December. Besides the regular observations of those entrusted with the experiments, observations were invited from captains of vessels passing the Foreland, and books were provided in which careful records could be made. Some time must necessarily have elapsed before these documents could be got in; but it is satisfactory to note that the general conclusions which we indicated last February as having been arrived at by the officials on the spot have apparently not been disturbed in any degree by the later evidence afforded by passing ships. These conclusions, so far as the efficiency of the Electric Light is concerned, were entirely satisfactory. It was stated at that time that with their lights at full power gas and oil failed to project any illumination beyond ten miles, whereas the beam of light from the electric arc was pronounced good at fourteen and a half miles. The full official report is not yet made public, but such portions of it as have been already supplied to the press substantially bear out this statement, as also the contention that in penetrative power through fog, rain, or haze, the electric light was superior to that of either gas or oil.

We gave full details of the apparatus and appliances employed for producing the electric light for these trials several months ago, and need not recapitulate them here. Apart from the special question of lighthouse illumination, they were interesting as having established the superiority of certain classes of carbons and the defects of others. Everything was no doubt of the best in other respects, though some may say not of the very best that might have been furnished for such a thoroughly representative trial. But we have no reason to complain on this score; for there is not a doubt as to the supreme excellence of the gas and oil appliances respectively which were pitted against the electric current. The relative merits of the Wigham and Douglass systems have long been in dispute—a dispute with which we have nothing to do here—but there is no question as to their being the most powerful appliances for long distance illumination of their kind that are anywhere known. Thus the competition was a severe one; and that the electric light, which is comparatively in its infancy, has fared so well in the contest will be highly gratifying, though not in the least surprising, to our readers.

The conditions of the trials appear to have been unexceptionable. Three towers of similar height were erected at distances apart sufficient to prevent the blending of the lights when exhibiting together. To a large extent the observations were taken on land, the flat unbroken country of the district favouring this arrangement, where competent observers were stationed at suitable points both for taking eye measurements and more accurate records with the photometer. At longer distances the coastguardsmen by the shore towards Dover, and the lightsmen on board the several neighbouring lightships out at sea, were called into requisition. Upwards of 4,000 trustworthy records were taken during the summer and winter months of last year, and tabulated analyses have now been drawn up upon which decisive conclusions can be based. Between seven and eight hundred of these observations were made with the distinct object of comparing the electric light with the highest powers of the other two lights, and the result was that, under all conditions of weather, it showed an advantage of from 35 to 40 per cent. over them, whether as a fixed or revolving light.

An important section of the Report deals with the subject of fog and mist; and here the verdict is hardly less favourable. It has often been stated, and it is, we believe, commonly supposed, that the electric light is almost useless, or, at all events, less useful than gas, in foggy weather. But the experiments at South Foreland dispose of this error. With one or two exceptions, the reasons for which are stated, electricity proved itself superior to either gas or oil under every atmospheric condition. The season, it is true, was not favourable to the observations under this head—that is to say, the year was unusually free from dense fog and mist. But such as came under observation revealed the fact that the most powerful lights of every kind become invisible in thick fog at very short distances, and their relative difference of penetrating power is so small as to be not worth considering. In weather not absolutely foggy, however, but thick with mist or haze, the electric light is seen so much farther as to be of practical advantage to the mariner. The greatest visibility at short distances, it would seem, is obtained by sending the current from one or more machines through a single arc.

The tables of exact measurements furnished by Mr. Dixon lead to the same general conclusions. Gas and oil are equally affected by atmospheric variations; and he adds that electric light is absorbed more largely by haze and fog than either; but this only shows that the former can spare its light more liberally, for Mr. Dixon concludes that in all weathers and at all distances the electric light proved superior to both its competitors. Moreover, the Committee in summing up the evidence are even more explicit, describing the electric light as having

Digitized by Google

the greatest penetrative power in fog; and the first part of their Report concludes with the declaration that for salient headlands, important landfalls, and places where a very powerful light is required, electricity offers the greatest advantages. For other situations the decision is in favour of mineral oil, on the practical grounds that, whilst its inferiority to gas as an illuminant is hardly appreciable, its superiority in point of cheapness is very considerable. The difference in expense alone would not have weighed with the Committee if the differing efficiency had been worth considering. We may therefore conclude that for the future lighthouse illumination will be shared between oil, with a wider if humbler field of operation, and electricity, which will occupy, perhaps, the fewer but far more commanding situations. The cost of installing and maintaining it is, judged by the experiments at North Foreland, far in excess of oil, and probably always will be; but extra cost has not precluded the use of gas hitherto, nor will the introduction of electricity be so hindered. It is at this moment being permanently installed on the Isle of May at the important entrance to the Firth of Forth; and we have no doubt that it will rapidly come into use wherever its superiority may in any degree contribute to the safety and well-being of the seafaring world.

CORRESPONDENCE.

IDEAS, WORDS, AND SYMBOLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: However desirable it may be that writers on electrotechnics should use a common notation, at least as regards the frequently recurring magnitudes concerned—which notation should not be a difficult matter to arrange, provided it be kept within practical limits—it is perhaps more desirable that they should adopt a common language, within the same practical limits, of course. For whilst the use of certain letters for certain magnitudes requires no more explanation than, for instance, "Let us call the currents C_1, C_2, &c.," it is otherwise with the language used when speaking of the magnitudes, as more elaborate explanations are needed to identify the ideas meant to be expressed.

As regards electric conduction currents, there is a tolerably uniform usage, and a fairly good terminology. It is seldom that any doubt can arise as to a writer's meaning, unless he be an ignoramus or a paradoxist, or have unfortunately an indistinct manner of expressing himself. I would, however, like to see the word "intensity," as applied to the electric current, wholly abolished. It was formerly very commonly used, and there was an equally common vagueness of ideas prevalent. It is sufficient to speak of the current in a wire (total) as "the current," or "the strength of current," and when referred to unit area, the current density. (In three dimensions, on the the other hand, when everything is referred to the unit volume, and the current density is meant as a matter of course, it is equally sufficient to call *it* the current.)

It is a matter of considerable practical advantage to have single words for names, instead of groups of words, and it is fortunate that the existing conduction current terminology admits of very practical adaptation this way. Thus, "specific resistance" may be well called "resistivity," and specific conductance "conductivity," referring to the unit volume. Resistivity is the reciprocal of conductivity, and resistance of conductance. When wires are in parallel, their conductances may be more easy to manage than their resistance. We have also the convenient adjectives "conductive" and "resistive," to save circumlocution.

Passing to the subject of magnetic induction, there is considerable looseness prevailing. There is a definite magnitude called by Maxwell "the magnetic induction," which may well be called simply "the induction." It is related to the magnetic force in the same manner as current density to the electric power. ($B=\mu H$.) Their ratio μ is the "magnetic permeability." This may be simply called the permeability, since the word is not used in any other electrical sense. Induction and permeability may not be the best names, but (apart from their being understood by mathematical electricians) they are infinitely better than the long-winded "number of lines of force" (meaning magnetic) and "conductivity for lines of force," the use of which, though defensible enough in merely popular explanations, becomes almost absurd when the electrotechnical user actually goes so far as to give them quantitative expression. Conductivity should not be used at all, save in pointing out an analogy. It has its own definite meaning.

"Permeability," however, does not admit of such easy adaptation to different circumstances, like conductivity. Permeability referring to the unit volume, the word permeance is suggested for a mass, analogous to conductance. We have also the adjective "permeable." By adding, moreover, the prefix "im," we get "impermeable," "impermeability," and "impermeance," for the reciprocal ideas, sometimes wanted. Thus impermeability, the reciprocal of μ, would stand for the long-winded "specific resistance to lines of magnetic force." (The permeance of a coil would be $L/4\pi$, if L is its coefficient of self-induction. In the expression $T=\frac{1}{2}LC^2$ for the magnetic energy of current C in the coil 4π does not appear, whilst it does in the form $T=\frac{1}{2}$ magnetomotive force × total induction through the circuit $\div 4\pi$. It is $4\pi C$ that is the magnetomotive force, and LC the induction though the circuit. Thus we have oppositely acting 4π's. I may here remark that it would be not only a theoretical but a great practical improvement to have the electric and magnetic units recast on a rational basis. But I suppose there is no chance of such an extensive change.) It must be confessed, however, that these various words are not so good as the corresponding conduction current words.

But now, if, thirdly, we pass to electric displacement, the analogue of magnetic induction (noting by the way that it had better not be called the electric induction, on account of our already appropriating the word induction, but be called the displacement), the existing terminology is extremely unsatisfactory; and, moreover, does not readily admit of adaptation and extension. Corresponding to conductivity and permeability we have "specific inductive capacity," or "dielectric constant," or whatever it may be called. I usually call it the electric capacity, or the capacity. It refers to the unit volume. But here it is very unfortunate that it is not this specific capacity c (say), but $c/4\pi$ that is the capacity of a unit cube condenser (such that charge = difference of potential × capacity). D, the displacement, is the charge (+ or −, according to the end), and we have $D=cE/4\pi$, E being the electric force. We may get over this trouble by putting it thus, $D=sE$, and calling s (or $c/4\pi$) the specific capacity. Then the capacity in bulk is got in the same manner as conductance from conductivity.

Supposing we have done this, there is still the trouble that capacity gives the extremely awkward inverse "incapacity," and the adjectives "capacious" and "incapacious," besides not giving us any words for use in bulk, like conductance and resistance. And, in addition, the word capacity is itself rather objectionable, as likely to give beginners entirely erroneous notions as to the physical quality involved. It is not that one dielectric absorbs electricity more readily than another. Electric displacement is an *elastic* phenomenon, one dielectric is more yielding (electrically) than another. The reciprocal of s above is the electric elasticity, the electric force required to produce the unit displacement. Thus s should have a name to express the idea of elastic yielding or distortion, and its reciprocal also a name (not strings of words), and they should be readily adaptable, like conductivity, &c. (Perhaps also a better word than permeability might be introduced, although, as we see, it is tolerably accommodative.) Displacement itself might also be replaced by another word less suggestive of bodily translation; although, on the other hand, it harmonises well with "current," the displacement being the accumulated current, or the current the time-variation of the displacement.

All these things will get right in time, perhaps. Ideas are

Digitized by Google

of primary importance, scientifically. Next, suitable language. As for the notation, it is an important enough matter, but still only takes the third place.—Yours, &c.,

OLIVER HEAVISIDE.

TREATMENT OF SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Without wishing to detract from the merits of Sir David Salomon's experiments, I would point out that it is absolutely essential that the cells should regularly be fully charged and not left exhausted. We made several conclusive experiments both with thick and thin plates, which were charged continuously for long periods, and found that the working condition of such cells was apparently not in any way affected.

Our working instructions will be found to refer not to cells which are charged before the rest, but to any cell which may be lower than the remainder.

In this case we point out the necessity of charging it with the rest, and cutting it out of the discharging circuit in order to get it again fully charged.

Although the resistance recommended by Sir David might be used with impunity in such skilled hands as his own, I should be very sorry to see it adopted in regular work; and the gain is not very apparent, as the energy is equally wasted whether it is consumed in the production of heat or gases.

I shall be happy to show Sir David some of the overcharged plates referred to, which are a clean dark brown colour throughout, and although I shall always be delighted to hear the results of his experiments with our cells, I trust he will not take it to heart if exception is taken to such of his conclusions as would be likely to interfere with the satisfactory working of the cells when in unskilled hands.—Yours, &c.

BERNARD DRAKE, Managing Engineer, Electrical Power Storage Company (Limited).

DOUBLE POLE SWITCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having had an opportunity of carefully examining the American system of electric light fittings and comparing their efficiency with those employed here, may I be allowed to make a few remarks on your correspondent's letter?

Double pole switches are the exception and not the rule in the United States. They were not fitted in many of the installations of the Edison Company which I visited last year, and are not used at all by the other important companies. The double pole Edison cut-out has been found of service in preventing accidents due to ground circuits or contact with telephone or telegraph wires, but it is clumsy in appearance, and a short circuit may occur on the block itself between the two fusible plugs.

Mr. Woodbury, of the Boston Fire Underwriters' Union, recommends "a separate cut-out to be placed on each wire," but it is only in exceptional circumstances that more than one wire of the circuit is protected.

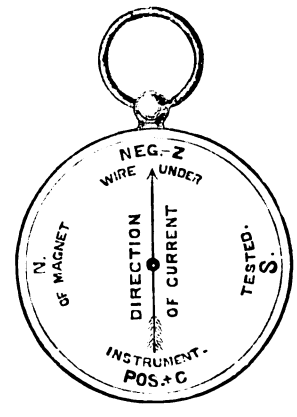
I do not think English electrical engineers would profit by using American fittings; at any rate, none of the switches exhibited at Philadelphia were superior as regards workmanship to the well known type made by Crompton, Lundberg, or the Globe Company. It is true that the Edison main switches are generally constructed with more pleasing exteriors and ornamental cases, but they are very much dearer than those in general use here. Although double pole switches may be advisable sometimes, I think the needless complication of the fitting may be avoided by fixing a separate plug switch on one lead, to be used on emergency only. In conclusion, allow me to state that the idea is not new, as I exhibited a switch with connections to open the circuit on both wires at the Crystal Palace Exhibition, and I believe a large number have been manufactured.—Yours, &c.,

August 26th. KILLINGWORTH HEDGES.

A NEW TESTING INSTRUMENT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I beg to enclose a sketch of a little testing instrument which may commend itself to your readers. This simple apparatus consists of a floating-card compass, with the card suitably lettered for the required purpose. When placed over a wire conveying a current it at once indicates the direction, &c., of the same, and if used to test a magnet, shows the north or south pole. These can be retailed at one shilling



each, if a fair number were required to make it worth while for a manufacturer to take them up.—Yours, &c.,

Brighton, August, 1885. M. VOLK.

[We fear that, as the accuracy of this instrument would depend upon the needle not losing its magnetism, for the purpose, at all events, of testing the direction of a current from a dynamo, that Mr. Volk's very ingenious contrivance would not be quite so reliable as it might be.—ED. *E.*]

THE HEART OF THE ENGLISH TELEGRAPHS.

A few days ago, by the courtesy of Mr. May, the acting Controller of the Central Telegraph Station during the absence of Mr. H. C. Fischer, we were enabled to pay a visit to the Heart of the English telegraphs, or, in more prosaic language, to the great central station of the Post Office Telegraphs. This mammoth building, which, it will be remembered, superseded the less elegant and commodious structure in Telegraph-street some ten years or so ago, stands upon a site exactly opposite St. Martin's-le-Grand, and was erected from the designs and under the superintendence of Mr. James Williams, of Her Majesty's Office of Works and Public Buildings. It was built by Mr. William Brass, whose tender amounted to £129,718; and the site cost £300,000, making in round figures a total of £430,000. The foundations were commenced in 1869, and the first block of stone was laid by Mr. Ayrton on the 16th of December, 1870. In shape the building is rectangular; its frontages, which are composed of the hardest Whitbed Portland stone, enriched by the chisel of Mr. Burnie Philip, extend some 286ft. on the St. Martin's-le-Grand and Bath-street sides, and on the Newgate-street and Angel-street angles about a hundred and forty-two feet less. The whole building as originally designed rose some 84ft. from the street level, on a solid base of granite from the famous De Lank quarries, and was four-storied, exclusive of the underground premises.

During the last two years, however, a fifth story has been added, in which is located the metropolitan gallery; and additional premises have also been acquired in Angel-street for the accommodation of the male and female staff. The basement of the main building is partly occupied as office rooms, department of telegraph engineers, and contains the very large battery room. The third floor is appropriated to the executive officers of the staff, &c., and on the fourth and fifth are the instrument rooms, the rest of the building being taken up by the postal authorities. In the north court are the beam engines employed in compressing and exhausting the air for the pneumatic system, and in the south court adjacent are

Digitized by Google

situated the mechanical repairing shops. From here a huge shaft ascends, its cap being some ten or fifteen feet above the roof, whence, we are informed, during a more than usually strong wind it nods in a threatening manner, as if half inclined to demolish the puny mortals below who persist in sullying its interior with even the best, if there be a best, of smoke.

Having ascended by easy stages to the proper altitude, we resigned our hat and umbrella to the care of an imposing personage in scarlet, and under what proved to be very able guidance entered the principal instrument room. The effect was bewildering in the extreme. We had imagined in our ignorance that we were about to emerge from the solitude of the corridors upon a scene of indescribable noise, if not of confusion. We had pictured to ourselves (little appreciating the admirable system that prevails at the Central Station) the simultaneous clicking of a thousand instruments, and the tumult which, however subdued, must seemingly accompany the united operations of twice that number of people. Here, however, save for a hum as of a multitude of distant bees, nothing was perceptible to the ear. Order, method, almost quietude, reigned supreme. There was a general air of relaxation, of quiet ease, about the place that, upon the first glance, conveyed a very false impression as to what was actually being done by the busy workers, and it was not until we began to look into details that we fully recognised the fact that each of the skilled operators before us was being taxed to perhaps the full extent of his or her energies. As might have been predicted, upon the exclusive adoption of the Morse code by the Government authorities many of the instruments which did such good work in the past have gradually died out of use; the sounder and the Wheatstone automatic transmitter and receiver replacing them, and with advantage in every case where economy and accuracy, combined with great speed, are ruling considerations. In all "T. S." there is not a Hughes type-writer and but a single Bright's bell. Some at least of our readers, however, will remember how efficient an instrument the bell was in conjunction with the old "magnetic" code, and how often on busy circuits, such as the London and Liverpool Stock Exchange and the Leeds and Belfast wires, it was resorted to when a block somehow or another had to be worked off. Of the A B C instrument there are but four left, one of them, by the way, devoted to the "Universal Provider," and not one double needle. There are, however, 161 single needles at work on the minor metropolitan circuits.

To return to our subject, the instrument rooms, to give a cut-and-dried description of them, are divided into two principal portions, the provincial and the metropolitan. These main sections are again sub-divided into divisions and groups, viz., ten in the provincial, exclusive of the news division, and the same number in the metropolitan department. The north-east, north, and north-west wings of the instrument room are entirely set apart for the instruments communicating with the various metropolitan and suburban telegraph offices, of which there are over 400. In the metropolitan section there are 388 instruments, made up as follows:—50 duplex sounders, 75 duplex Morse, 71 ordinary Morse, 55 sounders, 133 single needles, and four A B C's. The remaining wings and the central gallery are devoted to the circuits communicating with the provinces and Scotland and Ireland, and the news and special racing circuits, the latter being apart by themselves in the south western wing adjoining the rooms occupied by the Intelligence Department, where news and other matter is passed on its receipt and prepared for further dissemination and delivery. The north of England, Ireland, and Scotland are spoken with from the southern gallery, and the southern, eastern, western, and the home counties from the south eastern and central gallery. There are numerically fewer instruments in the provincial than in the metropolitan section, but they embrace a large number of the fast-working automatic apparatus. In all there are 329 instruments in that section, of the following descriptions:—32 Wheatstone duplex, 58 Wheatstone automatic, 17 quadruplex (of these the Birmingham instrument, a sounder, negotiates about 250 messages per hour), including one spare; 18 duplex recorders, 93 duplex sounders, 45 Morse, 37 sounders, 28 single needles, and one Bright's bell. The number of messages dealt with each day at the central station alone ranges between 45,000 and 60,000, nearly half of which are transmitted messages, and are therefore practically two telegrams, although only counted one in the total. Besides the large bulk of the traffic passing between the provinces and London, there are daily from 5,000 to 7,000 local messages, *i.e.*, emanating from one part of London or the suburbs for delivery in another part, besides a vast quantity of news messages, which on busy parliamentary nights not unfrequently exceeds half a million words per night.

In conclusion of our cut-and-dried remarks, we may mention that the total number of telegraphists employed in this gigantic establishment is 1,800, of which no fewer than one-third are females.

On entering the provincial room at the news division end a feature of interest presented itself in the long array of pneumatic punchers which are used to prepare the "slip" for the Wheatstone transmitters. These have been improved upon from time to time until they are seemingly as perfect as human skill can make them. The pneumatic puncher is of course by no means new, but ten years ago it was thought impossible to punch more than one slip at a time with each set of apparatus. A very ingenious arrangement has, however, been contrived by which three or more slips can be punched simultaneously either by using triply-wound paper or by super-adding one puncher upon another in a frame provided for them. Of the transmitters, we were kindly informed, there are on busy nights about seventy going at once, of which about thirty-five are duplexed. Every effort has apparently been made to ensure economic working, where economy has been found to be compatible with efficiency. The duplex and quadruplex sounders, the multiple punchers, and the "fork lines" are in themselves sufficient evidence of this. The latter are more properly junction circuits, Dublin, Cork, and Belfast being included in one and the same circuit, and so on. Each Wheatstone receiver, however, is arranged for ordinary duplex working during times of decreased pressure, a simple switch cutting out or putting in the transmitter as required.

Another very interesting piece of mechanism is the automatic "chronifer" for transmitting the Greenwich time signals to various towns in the United Kingdom, about 40 of the principal of which we observed were connected up. Every clock in the building is also synchronised by means of this very ingenious apparatus. Close by it was the switch-board, which, together with its prototype in the metropolitan room, presented an apparently interminable array of connections.

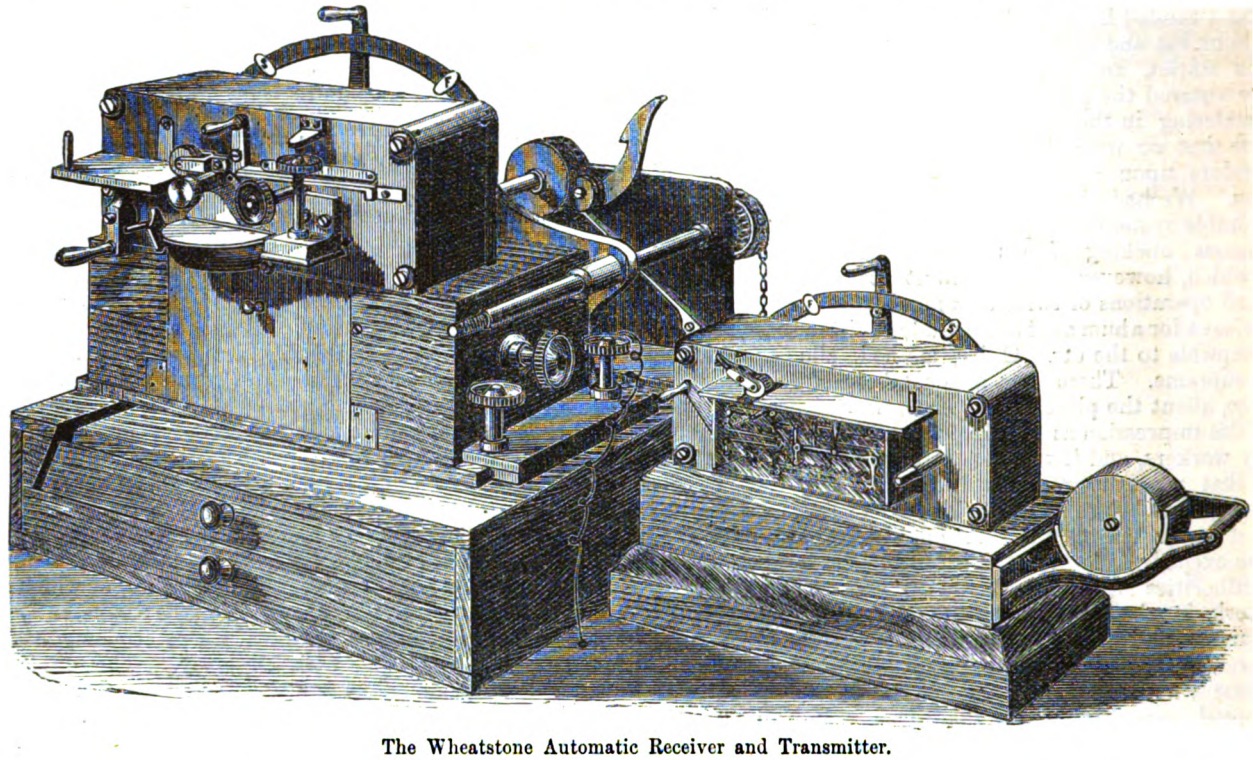
The central station is, however, by no means entirely dependent upon electricity for the dissemination of, at all events, a portion of its traffic. A most important and most useful auxiliary is the pneumatic tube. To this apparatus is due also in some degree the absence of anything like confusion, for it enables a very large number of collectors to be dispensed with, tubes conveying the messages between the different divisions and departments. In Telegraph-street, if we remember rightly, much the same sort of thing was done by means of overhead double shafting, driven by steam-power, the the messages being pushed between the bands and transmitted to the collecting tables. Of these local tubes there are in all some 28, of the ancient pattern—that is to say, with the form of valve designed by Mr. Latimer Clark. Of the more important ones connecting the central station with the principal offices in the City and the West End there are 30, worked on the double sluice valve system of Messrs. Siemens and Halske. Some of these are intermediate, Cannon-street and Lower Thames-street being, for instance, on one tube, Cornhill and Royal Exchange on another, Commercial Sale Rooms and Lothbury on another, &c., &c. A few of the branch stations are fitted with two tubes, one "up" and the other "down," or in other words, one vacuum and the other pressure. Several of the cable companies are also connected with the central office, for which purpose there are eight tubes. The longest lines are those working to the offices at the House of Commons, West Strand, and Lower Thames-street. The length of the former is about 2½ miles, and carriers containing

Digitized by Google

messages are blown through in from five to seven minutes. The latter are about two miles in length, and the times occupied in transit are from 3½ to 4½ minutes. The tubes to the Stock Exchange and Charing-cross are somewhat larger than the others, being of a diameter of three inches. In connection with the latter is a device fixed midway in the line,

Having got so far, and becoming, in truth, a little afraid of wearying our kind *cicerone*, we made haste to reclaim our impedimenta and descend to the basement, where still more wonders awaited our inspection.

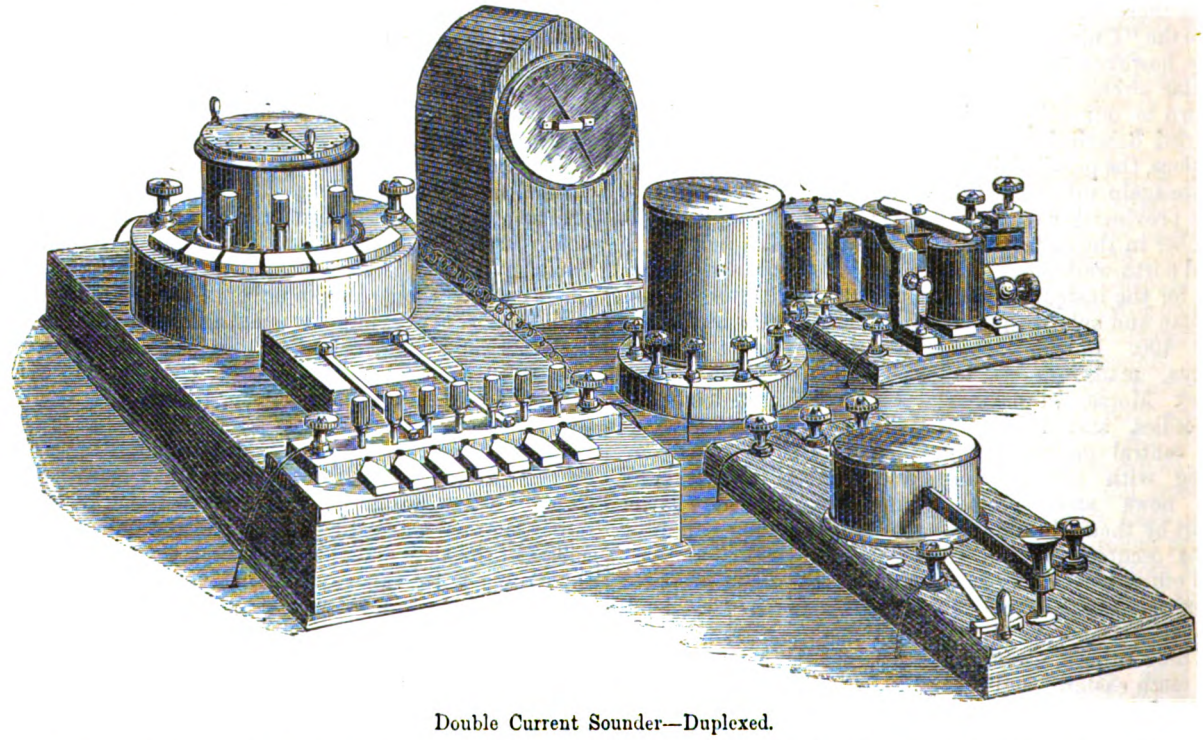
Here, again, we found economy and utility exemplified by a paper-making machine, busily engaged in grinding old



The Wheatstone Automatic Receiver and Transmitter.

which, upon being touched by the carrier in transit, electrically indicates its position to both stations; and another carrier is then, to avoid unnecessary delay, immediately sent forward. This line is one mile eight hundred yards in length, and the

message forms into pulp, which, after being passed on to a vacuum pump for the purpose of having all the moisture extracted from it and forced through a pair of rollers, finally emerged in the shape of coarse paper. The real object of this



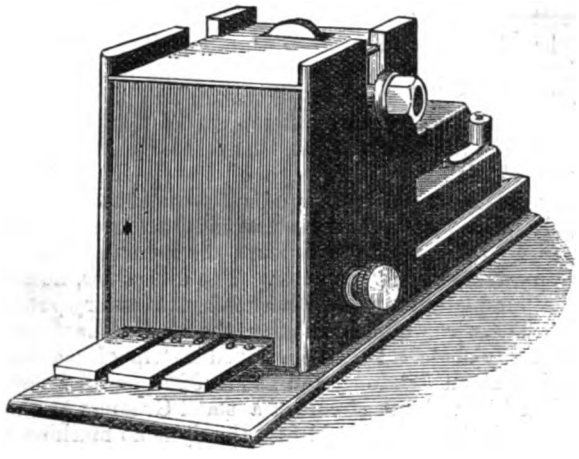
Double Current Sounder—Duplexed.

carriers occupy about four minutes in transmission. To the Stock Exchange, a distance of 700 yards, a higher rate of speed has been arrived at, fifty seconds in this case sufficing for the journey. The tubes, we believe, are served by messengers, under the control of responsible persons.

machine is, no doubt, the effectual obliteration of the messages. Close at hand were two 12 horse-power Easton and Anderson's beam engines at work in connection with an artesian well 630ft. in depth; and two small dynamos—one Elwell-Parker and one Siemens—giving a difference of potential at the

Digitized by Google

terminals of about fifty volts. These are used to charge accumulators for experimental purposes. At present there are seventy-eight Elwell-Parker accumulators under trial, and these, we were informed, give greater satisfaction for electric lighting purposes than any others that have as yet been tried. For telegraphy, Dr. Tribe's cells have been found to yield excellent results, and of these there are at present about eight, working thirty of the metropolitan circuits. Ranged about the main battery room, which serves the provincial section, are approximately 30,000 cells, including 12,000 Fullers, and 1,500 agglomerate Leclanchés, the latter being used for bells and local signals, as well as for the "chronifer," which has a battery of 140 cells. For all circuits under one hundred miles the Daniell is used, for greater distances the Fuller.



Pneumatic Puncher.

To look after this army of pots, and what not, there are, to the credit of everybody concerned be it said, but thirteen men, and we are glad to be able to testify to the admirable and systematic way in which it is done. For the benefit of those of our readers who do not fully recognise what an amount of thought and labour must have been bestowed upon the organisation of this department, we may mention that each group of cells bears a special number both on the shelf belonging to it and upon the test-board, and is brought direct to one of the 4,000 terminals on that board. For these connections 470 miles of wire have been used in the main battery room alone, and probably as much more in the connections with the test-board in the provincial instrument room; while the shelves upon which the various cells rest are about three miles in length.

In another and smaller room near by are the batteries for supplying the metropolitan circuits, each line taking about five elements. Here, in addition to the Fuller and single Daniell, we noticed some of the old pattern trough Daniells, which at one time were put forward as types of perfection.

Thence, from the domain of current, we wandered into the region of pneumatics, or rather into the really magnificent engine room, where four 50 horse-power (normal) beam engines, really models of workmanship and construction, serve to actuate the pneumatic system in active operation above. Three of these engines only were in action, one being always in reserve; two are used for exhausting, and the other in compressing the air. The room itself was everywhere bright, with the brightest of steel gratings. Each of the enormous beams of the engines rose and fell between three rows of double columns, conspicuous both for ornament and strength. On one of the walls three gauges indicated the steam and air pressure and the vacuum. These were respectively 50, 15, and 19lb. on the square inch. Below the gratings were to be seen the cylinders and the large air-pumps; while, above, a sleepy though civil attendant, who informed us that the normal horse-power was rarely, if ever, exceeded, completed the list of objects, inanimate and human. The air reservoirs formerly in use have been dispensed with, an 18in. pipe, of square section, connecting the pumps with the tubes in the various galleries, and forming a very efficient substitute for the more cumbersome apparatus.

Such was our experience of a visit to what we have called the Heart of the English Telegraphs; and if any of our readers take exception to the metaphor, we can only advise them to follow in our footsteps and see for themselves if the similitude is overdrawn.

THE LIFE OF INCANDESCENT LAMPS.

The following is a statement of the life of incandescent lamps at the Royal Courts of Justice from January 10th, 1885, to present vacation. The lamps are Edison-Swan 85 volts 20 nominal candle-power. The actual number of hours burning were not recorded until the beginning of this year :—

Name of Circuit.	No. of lamps on Circuit.	No. of hours burning. Average.	Total lamp hours.	Lamps changed.				Remarks.
				Burnt out.	Broken lugs.	Accidental breakages.	Total.	
Courts	446	155	69,130	15	2	2	19	Some Courts burn more than others.
Corridors	159	197	31,323	18	2	3	33	
All Day Circuit	56	1,298	72,688	60	1	2	63	
Engine Room	16	1,298	20,768	27	1	9	37	E.M.F. kept at 87 in engine room.
New All Day Circuit	28	480·5	3,454	*1	—	1	2	*Carbon broke first day.
Total	705		197,363	121	6	17	144	

Average life of lamps burnt out 1631·1 hrs, or average life, calculating losses from all sources, 1370·43 hrs.

We may add a few remarks as to the installation at the Law Courts under the charge of Mr. Grundy. After the installation was started last year, it was found desirable to extend it, partly on account of the dynamite scare and partly from other reasons, so some 70 lights were added to the all-day circuit. There are usually 100 lights running all day, fed from two Mather and Platt's dynamos, giving 90 volts and 70 amperes at 1,000 revolutions. These machines are connected to a Crompton collecting switch-board, which allows either or both machines to be worked at will. The dynamos are driven by a 10 horse-power vertical engine running about 165 revolutions. The all-day circuits, the engine room, and some of the courts are fitted with Grundy and Ready's holder (*vide The Electrician*, p. 182, July 17), and others will be fitted during the vacation. During the year's work it is gratifying to learn that only one hitch has occurred in the lighting, and that was through the slipping of a belt, which was remedied inside of two minutes. The table of the life of the incandescent lamps at the Law Courts is perhaps the most important ever published, in that it comes from an absolutely independent source. We have no hesitation in saying that a great advance is shown in the manufacture of lamps by these tables, and that lamps having an average life of 2,000 hours are to be expected in the immediate future.

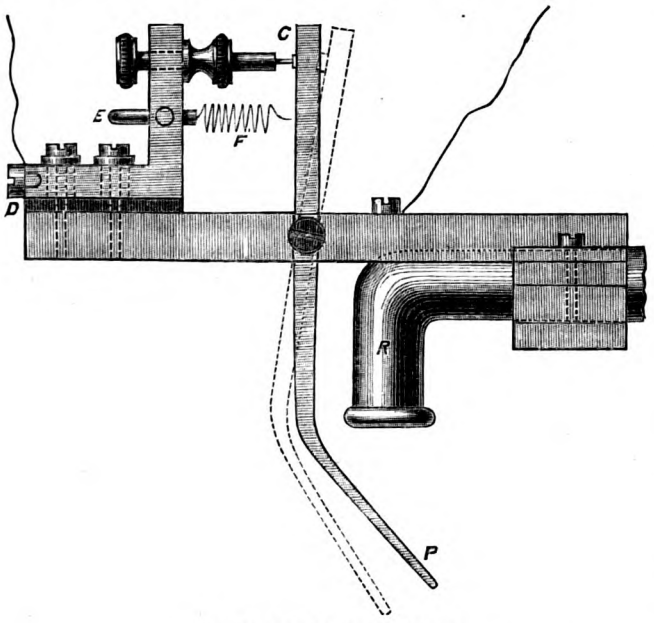
AN ALARM TO REPORT FAILURE OF WATER SUPPLY IN AN OTTO GAS ENGINE.

BY PROFESSOR PH. CARL, MUNICH.

During the past winter it was several times my misfortune to have the water supply in the neighbourhood of my laboratory cut off, without receiving any previous notice of the same. One of the results of this was a failure of water for my Otto gas engine. On making inquiries I discovered that the same thing frequently occurred in other places where gas engines were in use, and this led me to design a contrivance,* which put an alarm bell into action at the instant when the water ceased to flow, and so enabled any overheating of the gas engine and injuries thereby resulting to be prevented in time.



Gas Engine Water Indicator.

This very simple arrangement, represented full size in the annexed figure, is screwed down directly to the water outflow pipe R. Before the aperture of the pipe is a lever with a disc, P, on one arm, on to which the issuing water infringes, thereby keeping the lever in the position indicated by the dotted lines. The effect of this is to break the platinum contact at C, and so interrupt the circuit of an alarm bell placed in a suitable position. Suppose the water ceases to flow, the spring F comes into play, contact is made at C, and the bell keeps on ringing till some one comes to stop it.

It is almost needless to remark that the disc D and the pin E are composed of insulating material such as vulcanite.

A STANDARD OF LIGHT.†

BY PROF. J. TROWBRIDGE.

The discussion in the Paris Conference of 1881-4 upon the subject of a standard of light, which resulted in the adoption of the light emitted by a surface of platinum at the point of solidification, seemed to assort ill with the discussions which led to a reaffirmation of the C.-G.-S. system of absolute physical units, and a recognition of the relations between work and heat and electrical energy.

The solidification point of platinum may be a fixed point in nature; but it has not been shown how this fixed point can be connected with the great web of physical instruments which have been woven by Weber, Helmholtz, Thomson, Maxwell, and other physicists. It is true that during the discussions of the Conference reference was made to a proposition from Schwendler that the light emitted by a strip of platinum, rendered incandescent by a known electrical current, should be taken as a standard. The proposition, however, received little support, and the Conference finally adopted the light emitted by solidifying platinum as a standard.

It seems highly desirable that any standard of light which may be adopted should be connected with the present system of absolute measurements. The suggestion of Schwendler, therefore, seems to merit more attention that it has received. The suggestion of employing the light from a strip of platinum, rendered incandescent by an electrical current, is really due to Dr. J. W. Draper, of New York, who, in 1847, enunciated it as follows:—"A surface of platinum of standard dimensions raised to a standard temperature by a voltaic current will always emit a constant light. A strip of that metal one inch long and one-twentieth of an inch wide connected with a lever, by which its expansion might be measured, will yield at 2,000 degs. a light suitable for most purposes."

It has been urged against this standard that different specimens of platinum will emit different amounts of light with the same difference of potential; and that it would be difficult to carry out a measurement of the light and the strength of the current at the same instant. With a view to obtaining a knowledge of the practical difficulties in this measurement, I interposed a fine platinum wire between the poles of a battery and endeavoured to measure the light emitted, together with the amount of current which passed through a tangent galvanometer. The difficulties, however, in using a fine platinum wire with a moderate battery power were great. The wire would fuse before the measurements could be satisfactorily made. I then employed a strip of platinum foil $5^{mm.}$ wide, about $5^{cm.}$ long, and about $\cdot02^{mm.}$ in thickness. This was placed in a shunt circuit of a small Gramme machine, in order that if the strip should fuse the dynamo machine should not race. With the proper speed and a suitable adjustment of resistances the light from the platinum strip could be maintained very constant. The strip was placed in a long Ritchie photometer box, which was provided with two mirrors inclined according to the plan of Ritchie. One half of the photometer disc was illuminated by the incandescent strip, and the other half by a sperm candle. The electrical current was measured by a tangent galvanometer, of which the reduction factor was ·44 in the C.-G.-S. system. The difference of potential at the ends of the strip was measured by a Thomson quadrant electrometer, the deflections of which were compared with that of a Daniell cell, the electromotive force of which was approximately 1·09 volts. A Thomson voltmeter was also used. The indications of this instrument agreed with those of the electrometer. The following table gives the deflections of the instrument:—

Deflection of tan. galv. in deg.	Deflec. of electrometer in centimetres.	Remarks.
63	5·3	Light the colour of
61	4·9	a candle.
59	4·6	
57	4·3	
54·5	3·8	
53·75	3·4	Light very dull red.

One Daniell cell gave a deflection with the electrometer of $1\cdot3^{cm.}$ The resistance of the platinum strip when cold was ·2 of an ohm. It will be seen from the above results that the current varied approximately from 8 to 6 amperes (webers) with an electromotive force of from 3·8 to 2·6 volts, while the resistance varied from ·47 to ·44 of an ohm, the resistance when cold being ·2 of an ohm. The range of the indications of the electrical instruments was comparatively small, while the light varied enormously. It is evident that the chief difficulty of this method is in measuring a strong current with accuracy; for an increase in the current, represented by a fraction of a degree of the tangent galvanometer, will result in a very large increase in the light from the incandescent strip.

I next endeavoured to ascertain if a thermal junction enclosed in an Edison incandescent lamp at the centre of the carbon loop would be sensitive to changes in the heat radiation of the lamp. It is evident that, if this were the case, the carbon loop

* This arrangement was actually adopted by Herr A. Zettler, of No. 3, Zweibrüchenstrasse in this town.

† American *Academy of Arts and Sciences.*

Digitized by Google

might be raised to the same point of incandescence in successive times, assuming that the thermal junction at this point of incandescence receives the same amount of radiant energy. Mr. Edison kindly provided me with a lamp in which one thermal junction of an alloy of iridium-platinum and platinum was inserted as the centre of carbon loops. The other junction was placed in ice and water. The thermo-electric force of this combination, however, was extremely feeble. The difficulty of inserting wires of other metals into glass prevented me from carrying this idea further. Instead of the thermal junction, a small loop of extremely fine platinum was placed at the centre of a carbon loop in an Edison lamp. This fine wire constituted a bolometer strip, and made one branch of a Wheatstone bridge, it being my intention to place a similar strip in another branch of the bridge, thus making a bolometer. The lamp was placed in a photometer box, and its light was compared with that of a candle as it was raised from a red glow to that of a light of 15 candle-power. At the same time the resistance of the fine platinum wire was measured by a Wheatstone bridge. The following table gives the results:—

Resist. of the Strip in ohms.	Dist. of Carbon Lamp from Photometer Disc.	Dist. of Candle from Photometer Disc.
	cm.	cm.
14·42	70	40
14·45	85	40
14·55	98	40
14·62	108	40

This method seems to be quite sensitive. The change in resistance is large when estimated by the number of ohms necessary to restore a balance to the bridge. It was noticed that at a certain point a comparatively small increase in heat radiations was accompanied by a large change in the amount of the light emitted.

This phenomenon had been noticed early by Dr. J. W. Draper. One Leclanché cell, with 5 ohms in the circuit, besides the resistance of the strip, was sufficient to raise the latter to a red heat, and precautions were then necessary to prevent a change of resistance from the heating effect of the battery employed with the Wheatstone bridge. Being desirous of ascertaining whether the resistance of the platinum wire changed after it had been heated to a red heat and had been allowed to cool, I arranged the resistance of the battery circuit outside the bridge, so that the wire could be raised to a red heat, and then, having quickly weakened the battery circuit, remeasured the resistance of the strip. No difference could be perceived in the resistance of the strip. This illustrated the fact discovered by Prof. Langley, that thin strips of metal arranged as bolometer strips give up heat very quickly.

The results of this experiment led me to think that a bolometer strip of definite surface could be placed at a fixed distance from a carbon loop of definite dimensions inside an exhausted glass vessel. The amount of radiation which the bolometer strip receives could be calculated, and we might base our standard of light upon the point of incandescence, which would give a definite radiation at a fixed distance. We could not distinguish by this method the energy produced by rays of definite refrangibility. It seems desirable, however, to substitute for the uncertain estimation of coloured lights by the eye an instrument which will measure the energy produced by the radiating source at a certain distance. Within certain limits I found that the bolometer strip would indicate an increase or decrease of the amount of radiant energy received, while the difference in the colour of the incandescent lamp made the observer at the photometer entirely uncertain of his measurements.

Owing to the difficulty of obtaining the proper apparatus for the prosecution of the study of this method, I then studied the question of the practicability of employing a thermopile to measure the amount of radiation from an incandescent strip of platinum at a fixed distance. Within a long photometer box was placed a thin brass vessel containing water. Steam was passed by means of a rubber hose into the water in this vessel, which was thus maintained at a constant temperature of about 94°C. The outside of the vessel was about 92°C. This was ascertained by making the side of the vessel constitute one metal of a thermal junction. Between this vessel and the platinum strip, which was made incandescent by a current of from eight to nine amperes (webers), was placed a thermopile. The face of the thermopile was thus exposed to the radiation from a given amount of heated surface at a constant temperature, while the other was exposed to the radiation of a given surface of platinum. The faces of the thermopile were provided with the customary cones, and a series of diaphragms of thick cardboard extended between the radiating surfaces of the vessel containing the heated water and the platinum strip. The thermopile was connected with a short coil galvanometer, and was moved until the galvanometer needle came to zero. This arrangement was extremely sensitive—a movement of a centimetre in the position of the faces of the pole being sufficient to drive the spot of light from the galvanometer mirror off the scale, corresponding to a movement of nearly fifty centimetre-scale divisions. There is no difficulty in effecting a balance as quickly as an ordinary photometric measurement is made. While one observer compares a candle or other source of light with the light from an incandescent strip of platinum, another could make the measurements with the thermopile, and could obtain the amount of energy radiated by the incandescent strip in terms of the constant source of heat. It is necessary to reverse the faces of the thermopile, or to place a second constant source of heat on the same side upon which the incandescent strip is placed. The following table indicates the character of the results:—

Deflec. of tan. galv.	Temp. of water.	Dist. of face and pole from water.	Dist. of face of pole from strips.	Remarks.
°	°C.	cm.	cm.	
57·5	95	26·5	49·5	Dull red.
56·5	95	28	48	
61	96	25·5	50·5	Bright yellow
62·5	96·5	24·5	51·5	„ „
62·5	96	23·0	53·	„ „
60·5	97	25·7	50·3	„ „
58·5	97·5	26·7	49·3	„ „
60	95	24·2	51·8	„ „
62·2	94	23·7	52·3	„ „

The reduction factor of the galvanometer was ·44 in the C.-G.-S. system. When the photometric indications were the same, the thermopile indicated a large change in the amount of heat received. Thus the heat indications within the range in which the experiments were taken were far more sensitive than the photometric indications.

It seems possible, therefore, to assume as a standard of light an incandescent strip which radiates a definite amount of energy, this energy being measured at a fixed distance which will best agree numerically with the absolute system of measures now universally adopted in heat and electricity. The method of Draper and Schwendler could be combined with the methods I have described above. For a practical standard, a carbon loop in an exhausted vessel raised to such a point of incandescence that it will radiate a definite amount of energy. This energy, being measured by a bolometer strip or the thermopile at a definite distance from the carbon loop, and also being measured by the formula $J H = C^2 R t$, would have a greater range than an incandescent strip of platinum placed in free air. The latter method, however, for the incandescence which produces a light similar in colour to that of a sperm candle, is extremely sensitive, and can be made, I think, more exact than present photometric tests. Both methods have the great advantage of substituting a measure of energy for a relative indication by the eye, which is not connected with any absolute measurement. These remarks apply to the question of a standard of light for practical purposes, which should also be scientific in so far that more refined scientific investigation can connect this standard at any time with more precise methods of measuring the exact amount of heat given by radiations of definite wave-lengths. By means of a "Rowland" concave grating, and with a bolometer strip, one can at present measure the energy of definite radiations. We can say that our scientific standards

Digitized by Google

for light of definite colours shall be based upon the energy received upon a definite surface at definite points in the diffraction spectrum.

Jefferson Physical Laboratory, Harvard College.

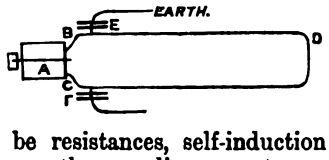
ON AN UNNOTICED DANGER IN CERTAIN APPARATUS FOR DISTRIBUTION OF ELECTRICITY.*

BY J. HOPKINSON, F.R.S.

Many plans have been proposed, and several have been to a greater or less extent practically used, for combining the advantage of economy arising from a high potential in the conductors which convey the electric current from the place where it is generated with the advantages of a low potential at the various points where the electricity is used. A low potential is necessary where the electricity is used; partly because the lamps, whether arc or incandescent, each require a low potential, and partly because a high potential may easily become dangerous to life. Amongst the plans which have been tried for locally transforming a supply of high potential to a lower and safer, the most promising is by the use of secondary generators or induction-coils. It has been proved that this method can be used with great economy of electric power and with convenience; under proper construction of the induction-coils it may also be perfectly safe. It is, however, easy and very natural so to construct them that they shall be good in all other respects but that of safety to life—that they shall introduce an unexpected risk to those using the supply.

In a distribution of electricity by secondary generators, an alternating current is led in succession through the primary coils of a series of induction-coils, one for each group or system of lamps. The lamps connect the two terminals of the secondary coil of the induction coils. It is easy to so construct the induction coils that the difference of potential between the terminals of the secondary coils may be any suitable number of volts, such as 50 or 100; whilst the potential of the primary circuit, as measured between the terminals of the dynamo machine, may be very great, *e.g.*, 2,000 or 3,000 volts. If the electro-magnetic action between the primary and secondary coils, on which the useful effect of the arrangement depends, were the only action, the supply would be perfectly safe to the user so long as apparatus with which he could not interfere was in proper order. But the electro-magnetic action is not the only one. Theoretically speaking, every induction coil is also a condenser, and the primary coil acts electro-statically as well as electro-magnetically upon the secondary coil. This electrostatic action may easily become dangerous if the secondary generator is so constructed that its electrostatic capacity, regarded as a condenser, is other than a very small quantity.

Imagine an alternate-current dynamo machine, A, its terminals, B, C, connected by a continuous conductor, B D C,



on which may be resistances, self-induction coils, secondary generators, or any other appliances; at any point is a condenser, E, one coating of which is connected to the conductor, or may indeed be part of it, the other is connected to earth through a resistance, R. Let K be the capacity of the condenser, V the potential at time t of the earth coating of the condenser, U the potential of the other coating, x the current in resistance R to the condenser from the earth, being taken as positive, and the earth potential as zero. We have

$$x = \frac{V}{R}, \quad K(U' - V') = 2$$

whence, since

$$U = A \sin 2\pi n t,$$

where A is a constant depending on the circumstances of the dynamo circuit as well as the electromotive force of the machine, and n is the reciprocal of the periodic time of the machine, we have

$$KR\dot{x} + x = 2\pi n KA \cos 2\pi n t,$$

$$x = \frac{2\pi n KA}{(KR2\pi n)^2 + 1}\{ - 2\pi n KR \sin 2\pi n t + \cos 2\pi n t\},$$

$$\text{mean square of } x = \frac{2\pi n K}{\sqrt{(KR2\pi n)^2 + 1}} . \text{mean square of A.}$$

Let us now consider the actual values likely to occur in practice. Let the condenser E be a secondary generator; let the resistance R be that of some person touching some part of the secondary circuit, and also making contact to earth with some other part of the body; n may be anything from 100 to 250, say 150; K will depend on the construction of the secondary generator—it may be as high as 0·3 microfarad or even more, but there would be no difficulty even in large instruments in keeping it down to one hundredth of this or less. The mean square of A will depend on the circumstances of other parts of the circuit; it might very easily be as great, or very nearly as great, as the mean difference of potential between the terminals of the machine if the primary circuit were to earth at C. Suppose, however, that the circuit B D C is symmetrical, that E is at one end, and that another person of the same resistance as the person at E is touching the secondary circuit of the secondary generator F at the other end of the circuit. In that case, if 2,400 be difference of potential of the machine, mean square of A will be 1,200; in which case we have, taking R as 2,000 ohms, mean

$$\text{square of } x = \frac{2\pi \times 150 \times 0{\cdot}3 \times 10^{-6}}{\sqrt{(2\pi \times 150 \times 0{\cdot}3 \times 10^{-6} \times 2000)^2 + 1}} \times 1200$$

$$= \text{about } 0{\cdot}3 \text{ ampere.}$$

Experiments are still wanting to show what current may be considered as certain to kill a man, but it is very doubtful whether any man could stand 0·3 ampere for a sensible length of time. It is probable that if the two persons both took firm hold of the secondary conductors of E and F, both would be killed. If the person at F be replaced by an accidental dead earth on the secondary circuit of F, the person at E would experience a greater current than 0·3 ampere.

It follows from the preceding consideration that secondary generators of large electrostatic capacity are essentially dangerous, even though the insulation of the primary circuit and of the primary coils from the secondary coils is perfect. The moral is—for the constructor, take care that the secondary generators have not a large electrostatic capacity, say not more than 0·03 microfarad, better less than $\frac{1}{100}$ microfarad; for the inspector, test the system for safety. The test is very easy. Place a secondary generator of greatest capacity at one end of the line and connect its secondary circuit to earth through any instrument suitable for measuring alternate currents under one ampere; put the other end of the primary to earth; the reading of the current-measuring instrument should not exceed such a current as it may be demonstrated a man can endure with safety.

* From the *Phil. Mag.*, Sept. 1885,

DR. ARON'S ELECTRICITY METER.

Herr F. Zacharias, who in his capacity as engineer to the Berliner Elektrische Beleuchtungs Actien Gesellschaft has frequently to experiment with and report on new electrical inventions, with a view to their being adopted by his company, has sent us an article for publication under the above heading. Although we have already described this meter (vide *Electrician* of January 10, 1885), we think a short translation of Herr Zacharias' remarks will be of interest to the reader, as they refer to the actual working of the instruments during the last few months. Without entering into any minute description we may recall to mind that Dr. Aron's meter is a pendulum clock, the rate of accelleration of which, in comparison to standard time, is exactly proportional to the strength of the current. The bulb of the pendulum is replaced by a cylindrical magnet, and below it is placed the coil through which the current flows. The direction of the current is such as to draw the magnet down, increasing, so to speak, the influence of gravity, and thus accellerating the clock. In order that the accelleration may be exactly proportional to the current, it is important to employ for the magnet steel of a certain

Digitized by Google

hardness. The temporary magnetisation it receives from the current can be thus made to correspond to the second term in the equation for the time of oscillation throughout a wide range of current strength, which renders the instrument exceedingly accurate. The advantages of this meter over the chemical meter of Edison are obvious. In the latter the indications vary with the temperature, and the weighing of the plates requires the utmost care. It has also happened that the plates have been short-circuited by the deposit of zinc, and during the time the plates are dried and weighed the meter is out of action. All these disadvantages are overcome in Dr. Aron's meter. The reading does not interrupt the action of the instrument, and errors committed in single readings eliminate each other when added up to arrive at the total quantity of electricity passed during an extended period.

The Municipality of Berlin have, before finally adopting any form of meter, caused experiments to be made with the Edison and Aron meters. These were undertaken at the town gasworks under the direction of Herr Fröhlich, and although the results have not been published, it must be assumed that they were favourable to the Aron meter, as this instrument has been finally adopted.

One of Dr. Aron's meters, designed for a maximum current of 200 amperes, has been in use for some months in the electric light station in the Ausstellungs Park. In this instrument an acceleration of one hour corresponds to 1,356 ampere hours, or 2,260 lamp hours, each lamp hour being equivalent to a current of ·6 ampere flowing for one hour. With a current of about 100 amperes the clock is accelerated about 20 minutes in four to five hours. It will be evident that with such a large rate of advance any slight error in the clock itself or in the reading becomes quite insignificant. The following table, taken from the records of the above installation, will show the method of booking :—

1885.	Standard time.	Meter.	Total difference.	Last difference.	Ampere hours.	Lamp hours.	Value ·04 mark per lamp hour.
July 25.	4^{35}	10^{58}	6^{20}	1^{32}	2088	3480	$139^{\cdot 21}$
Aug. 1..	11^{43}	7^{38}	7^{52}				

For arc light installations working with a constant current a similar instrument is used registering volt-hours. It is suitable for a pressure not exceeding 2,000 volts. One hour accelleration corresponds to 41,022 volt hours, and if there are 25 arc lights in series the rate of advance in five hours is about ten minutes. The booking is similar to the example just given. For instance—

1885.	Standard time.	Meter.	Total difference.	Last difference.	Volt hours.	Lamp hours.	Value ·75 mark per lamp hour.
Aug. 20..	2^{28}	12^{45}	10^{17}	$0^{10\cdot 5}$	7179	156	116 mark
Aug. 21..	$10^{7\cdot 5}$	8^{38}	$10^{27\cdot 5}$				

These meters must be periodically wound up just as any ordinary clock. If, however, it is desired to have a self-winding clock, Dr. Aron adds to his meter a dry cell and an electro-magnetic apparatus which keeps the clock going without any attention whatever being required. The writer has lately seen such a clock which had been going for nine months without having been touched.

THE ELECTRIC LAUNCH "VOLTA."

On Monday, the 31st ult., the "Volta" was successfully launched at Greenwich Ferry, the "christening" ceremony being performed by Miss Stephens, daughter of the senior partner of the firm of Stephens, Smith, and Co., engineers, Millwall, who are the contractors for this new vessel. The hull of the "Volta" is of galvanised steel, and is 36ft. long, 7ft. beam, and 3ft. 6in. deep, built at Mr. Skelton's yard at Millwall; her draught, with a displacement of 5½ tons, is 26in. aft, and 20in. forward. There are several novel features worthy of notice in this boat. Two Reckenzaun motors, arranged in a line with the keel, and placed under the floor, are used for driving the screw propeller in a similar manner as the worm gear is driven in Mr. Reckenzaun's elecric tramcars. By sending the electric current through the motors with their circuits arranged in series or in parallel, or through one motor alone, various speeds and powers are obtained, without introducing artificial resistances, or varying the E.M.F. of the battery. Thus, 4, 7, or 12 horse-power, equivalent to 5, 9, and 15 indicated horse-power of a steam engine, are obtained on the screw shaft at will, with corresponding speeds of the boat. Seventy accumulators of the E.P.S. type furnish the current, which will propel the launch about 40 miles with one charge; these cells are placed at the bottom of the boat, under the floor, so low down as to ballast her in the most perfect manner, such as could not be attained by any steamboat.

There are two masts provided, and sails; the masts fit into sockets, and are speedily placed or removed; these sails have been supplied, in accordance with the specification, to economise the power, when requisite, for longer trips than allowed for in the accumulator.

Considerable interest was evinced by the crowd witnessing the launching ceremony, when the new vessel was towed up the river by another electric launch, both boats being well filled with invited parties. The "Volta" is to make a 40 mile trial trip down the Thames, to which many notabilities will be invited, and afterwards a voyage across the English Channal is contemplated.

THE UNITED TELEPHONE COMPANY (LIMITED).

We have been favoured with advance sheets of a long article on this company to appear in the *Weekly Bulletin*, from which we abstract the following information. Unfortunately, we must say most distinctly that we are not in accord with our contemporary as regards its conclusions. Our opinions about overhead wires, way-leaves, Government interference, &c., have so frequently and plainly been given that it is unnecessary to discuss these questions further at present. We may, however, find it necessary to criticise the statements of our contemporary *seriatim*, and reserve to ourselves the time and moment best suited for so doing :—

"The subscribed capital of the United Telephone Company is £500,000. The accounts are made up annually to April 30th, and submitted in July or August. The working of 1880-81 resulted in a net profit of £370, which was carried forward, but a distribution of 10s. per share was made in 1881 out of moneys received in payment for concessions granted by this company. For 1881-82 a dividend of 5 per cent. was paid; for 1882-83 6 per cent., for 1883-84 8 per cent., and for 1884-85 10 per cent. the accounts showing that 15 per cent. has been earned.

Subjoined is a comparative statement of the annual revenue compiled from the company's published audited accounts, which merits careful investigation.

For the undermentioned years, ended 30th April :—

Receipts :—	1881. £	1882. £	1883. £	1884. £	1885. £

	£289,062	0	0

Those marked * pay dividends.

We repeat, therefore, that the United Telephone Company owns £653,750 nominal capital—with a present selling value of say £300,000—in subsidiary companies.

As an instance of progress in the use of the telephone in the town of

Digitized by Google

Southampton (a comparatively small city) 26 sets of instruments were bought some two months ago, whilst a fresh order for a further 26 has been received within the last few days. This shows a telephone exchange for this small place of 50 upwards, as a commencement. The same procedure is going on with the other companies, and telephone exchanges have now been opened at the following cities, all of which belong either to the United Telephone Company (Limited), or to its children :—

Wigan	Aberdeen	Bolton	Liverpool
Chorley	Dundee	Warrington	Birkenhead
Denbigh	Forfar	Todmorden	Chester
Rhyl	Belfast	Altrincham and Bowdon	Southport
Wrexham	Bradford	Rochdale	St. Helens
Bangor	Leeds	Heywood	Widnes
Holyhead	Huddersfield	Bury	Barrow
Welshpool	Dewsbury	Oldham	Windermere
Newtown	Halifax	Dublin	Ulverston
Flint	Wakefield	Sunderland	Preston
Carnarvon	Birmingham	Newcastle	Lancaster
Llandudno	Wolverhampton	North Shields	Blackpool
St. Asaph	Walsall	South Shields	Fleetwood
Glasgow	Wednesbury	Bristol	Blackburn
Greenock	Dudley	Brighton	Darwen
Paisley	Brierley Hill	Norwich	Accrington
Dumbarton	Stourbridge	Stockport	Burnley
Edinburgh	Nottingham		Colne and Nelson
Kirkcaldy	Manchester		

As instancing the ideas of those living in distant parts, we might here say that the River Plate Telephone Companies have at the present moment, in the City of Buenos Ayres alone, got the comparatively enormous quantity of 2,500 subscribers to its system. In London there are about 4,500 only. Can words say more ?

In America the telephone has been utilised as far as Chicago to New York, some 1,000 miles ; but for some reason (probably cost) this wire has been discontinued for the moment, and the longest distance now open for public communication is between New York and Boston, a distance of 300 miles ; and here it is found to work perfectly.

The sums paid for the rights of any towns in U.S. of 20,000 or 30,000 inhabitants are very large, and increase year by year, as it is felt that the system is what we may term a brand new one as regards past generations, and people there are prepared to discount the future.

Now we will take one American city, viz., Indianapolis, with a population of 74,000. In this town there are no less than 940 subscribers. Chicago has 3,800 subscribers with a population of under half a million, and the same proportion seems to hold good with every city in the Union.

We repeat, that London with a five-million population has barely 4,500 subscribers. If it held its proportion as against Chicago it would have 40,000.

The great difficulty in England seems to be the way-leaves, viz., the getting permission to carry the wires over the different houses, but we have reason to hope that in the next Session of Parliament a short Bill will be brought in which shall render it compulsory on the owners of house property to permit wires to be carried over the roofs. A committee of the House of Commons has reported that this course must be pursued.

Once let this be done, and telephony will receive a great impetus. But greater still than this will be the start the company will receive when the Government, changing its "dog in the manger" theory, will permit the United Telephone Company to carry its wires along the present existing posts, which posts have of course been the outcome of many years, whether before or after the Government took over the telegraphs.

Now from Richmond alone, the United Telephone Company is constantly getting many grumbles, and no wonder, as it seems ludicrous that this town, only a few miles from London, should not be connected with an exchange.

We are informed that the Government would require a payment of some £10 per wire per mile per annum for this service, and this alone would mean a big sum. For this reason : to connect with Richmond the company would require, say, ten wires, which should leave the City, and gradually reducing its number, eventually end at the town we speak of. It would require, say, ten wires as far as Kensington. One wire should go to a Kensington exchange. This would leave nine wires, one of which should go, say, to Fulham to work an exchange there, leaving eight ; one to Putney, leaving seven ; one to Barnes, leaving six ; one to Mortlake, leaving five ; and so on until one wire would enter the Richmond exchange. In other words, the ten little niggers—nursery tale—would be utilised in the way of telephony.

If the Government would only give the company power to Richmond, watch what would inevitably follow, within a year or two. We should have exchanges at Twickenham, Isleworth, Surbiton, Kingston, every station, in fact every town within a suburban radius of say 20, 30, or 40 miles, and the facilities with which business could then be carried on can be easily imagined. At the present moment the longest telephone wire in existence in England is that worked by Mr. Colman between Norwich and London.

This wire is 120 miles in length, and constant conversations can be carried on between the two points as easily as if the speakers were in one room.

We are perfectly prepared to admit that telephony, as worked in this country, is a monopoly, and is run by a ring. We believe this will never be altered, and aver that with the capital subscribed already by the public, competition—at least serious competition—can never come into dangerous force. What is to prevent other powerful monopolists at the present time from being destroyed ? Only one thing—King Capital —which has got most good things entirely in its clutches, and there it means to keep them.

The United Telephone Company has too much money and too strong backers to fear innovations, and anything serious would at once, as before, be nipped in the bud. The "Mechanical Telephone," the shares of which were allotted lately, is no invention at all, being as old as the hills. It is useless in the same idea as an electrical telephone, and can be made by any one who likes to try an experiment.

When the "United Telephone" patents fall in it will be found that, irrespective of new improved patents, which will give fresh life to the concern, the company will have such a command of exchanges, way-leaves, &c., that it will own an absolute monopoly, and it will be useless for any attempt at competition. A monopoly such as this would be practically unassailable, and shareholders need have no fear of their rights ever being combated.

But not only to our mind have shareholders got all the facts we have printed to look forward to, but we suggest that ultimately the Government will be compelled to buy up and take over the entire system of telephony. We cannot believe that any other course can be pursued, when, as now, the telegraphs have ceased to be individual property. The saving to the country at large would be very great, as the poles would carry both systems of wires. The only extra cost would be the wires themselves—a comparative bagatelle. Telephony must in the majority of cases completely upset the value of the telegraph. There are rumoured discoveries of vibrating instruments which will record conversations by printing. Up to the present the idea is embryonic, but one day it will come to the fore, and then, what will the Government do ?

It *must* purchase existing companies out and utilise its own systems, which by that time will emphatically embrace the telephone."

The International Inventions Exhibition.—The Executive Council of this Exhibition have completed arrangements with the whole of the Railway Companies of the United Kingdom whereby parties numbering 25 and upwards can from the present time and until the close of the Exhibition, obtain at greatly reduced rates through tickets, combining the journey to London, carriage over the Underground Railways, passage through the South Kensington Subway, and admission to the Exhibition, and back. Application for these facilities should be made to any Station Master in the Country.—[ADVT.]

Digitized by Google

NOTES.

NOTICE OF REPAIR.—The cable of the Paris and New York Telegraph Company has been repaired.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended the 4th inst. amounted to £2,951.

LIGHTHOUSE ILLUMINANTS.—The report of the Committee on Lighthouse Illuminants, of which we have already published a full accouut, was issued on Saturday as a Parliamentary Blue-book.

THE TELEGRAPH AND THE TURKISH ISLANDS.—Telegraph offices have been opened in the Turkish Islands of Lemnos and Tenedos. The rates to Lemnos and Tenedos are the same as those at Scio.

THUNDERSTORM.—On the 4th inst. a thunderstorm of great violence was experienced throughout the whole of the Grantham district. The lightning was very vivid, and the rain fell in torrents, doing considerable damage.

LIGHTNING.—On August 20, during a storm, lightning entered a dynamo in the electric-light plant of Erie, Pa., destroying it, and resulting in the extinguishing of all the electric lamps in the streets of the city.

CONTRACT.—We are informed that the contract for putting in the necessary wire for an incandescent light installation in the new State House at Indianapolis has been obtained by Messrs. W. S. Glover and Co., of Detroit, Mich.

THE EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August amounted to £41,987, and to £39,463 for the corresponding period of 1884; increase, £2,524.

NEW ELECTRIC WORKS.—It is said that the Edison Company are about to establish new electric lighting works at Dijon. Operations have already been commenced, and arrangements will be made for an installation of 500 lamps.

THE ELECTRIC LIGHT IN TORONTO.—The Fire and Gas Committee of Toronto Council has been unable to make a contract with the Consumers' Gas Company or with the Electric Light Company, and will ask for new proposals for lighting the streets.

TRANSMISSION OF FORCE AT TERGNIER.—A new installation for the transmission of force has recently been inaugurated at Tergnier, in the Magasins Généraux, to actuate, at a distance of 180 metres, an apparatus which serves to elevate the molasses, &c.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 4th Sept. were £2,254, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE ELECTRIC LIGHT IN PLYMOUTH.—On the occasion of the Architectural Exhibition at Plymouth, the drill hall was lighted at night by electricity. The installation, on the Thomson-Houston system, was put in by Messrs. Laing, Wharton and Down.

THE GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this company for August, 1885, amounted to £24,000; from 1st January to 31st August, 1885, £192,040. For the corresponding months of 1884 they amounted to £182,680; in 1883 to £168,400.

SEARCH LIGHTS AT TORPEDO STATIONS.—Experiments were made at the torpedo station of Newport, R.I., on the night of August 18, with a movable 15,000 candle-power electric search light for use at sea. It was found to work perfectly, minute objects being discernible at great distances.

AN UNFORTUNATE ACCIDENT.—At Atlantic City, N.J., a popular health resort, the blowing out of a cylinder head of the engine driving the electric lighting machinery left the promenade in darkness one evening recently, and produced a little panic, in which two persons were injured.

THE ELECTRIC LIGHT IN NEWFOUNDLAND.—Advices from America state that the Thomson-Houston Company have contracted for 90 arc lights, together with a number of incandescents, for St. John's, N.F. The contract also includes dynamos, engines, and everything necessary for a complete installation.

THE ELECTRIC LIGHT IN FRANCE.—On the occasion of the coming fête at Châtillon-sur-Seine, on the 13th inst., the picturesque promenade of that town will be lighted, at the request of the municipality, by ten arc lamps.—The work of installing the electric light in the Opera House, Paris, is rapidly approaching completion.

THE DELIVERY OF TELEGRAMS.—The United States Supreme Court has just decided that in the case of a telegram addressed to any particular individual the company may, in his absence, cause it to be delivered to his wife. There are times, however, when the most reasonable of beings would object to this course.

THE FRENCH TELEGRAPHS.—The new subterranean line of telegraph connecting Paris with Marseilles has recently been completed. By order of the Minister of Posts and Telegraphs new offices are to be opened in the following districts:—Saint-jean-Brévelay (Morbihan), Cébazat (Puy-de-Dôme), Fyé (Sarthe), and Verneuil (Seine et Oise).

PERSONAL.—The command of the submarine mining battalion of Royal Engineers at Chatham is to be at once taken over by Colonel V. G. Clayton, late commanding Royal Engineers, Jamaica, who will succeed Colonel G. W. Stockley. The latter officer, who is now on leave from Ceylon, has held the temporary command of the battalion.

THE LIGHTING OF DUNDALK.—Despite the recent relapse in the lighting of the town of Dundalk, a constant reader assures us that it will in a few months hold the proud distinction of being the first town in Ireland, and one of the first in the United Kingdom, to be lighted entirely by electricity. We trust our correspondent is correct in his premises.

THE LATEST FROM PARIS!—UN COMBLE.—Le dernier...de la saison:—

Le comble de l'amour électrique?
Un *électro-aimant!!!*
Nous nommerons le coupable, si on nous y force.

l'Electricien.

THE ELECTRIC LIGHT AT HASTINGS.—The electric light came in for sundry strictures on the occasion of a recent meeting of the shareholders of the Hastings Pier Company. Like a good many more penny wise and pound foolish people, the shareholders of that company would rather pocket an extra twopence than encourage the only thing that makes night on the pier at Hastings enjoyable.

ELECTRICITY AND BLASTING.—A mass of granite, estimated to weigh at least 500,000 tons, was displaced recently on the line of the Iron Mountain Railroad, Missouri, by a single blast. A shaft 65ft. deep was sunk, with lateral chambers, in which

Digitized by Google

five tons of powder were stored. After the shaft had been nearly filled to the top, an electric spark from a battery half a mile distant fired the magazine, with the result indicated.

"THE HEART OF THE ENGLISH TELEGRAPHS."—*Correction.* In our article under this heading last week the pneumatic tube system at the Central Telegraph Station was spoken of as being worked on the double sluice valve system of Messrs. Siemens and Halske; and that the local or house tubes had the form of valve designed by Mr. Latimer Clark. We are now requested to state that both forms of valve actually in use were designed by Mr. J. W. Willmot, an officer of the Engineer-in-Chief's Department, G.P.O.

ROYAL COLLEGE OF SCIENCE FOR IRELAND.—Particulars will be found in our advertisement columns of the scientific and technical education, classed broadly under the heads of Chemical Manufactures, Mining and Engineering, supplied at this college. There are four Royal scholarships, each of the value of £50 yearly, with free education, including laboratory instruction. Two of these become vacant each year, and are open to students who have been a year in the college. In addition to this a "Diploma of Associate" is granted at the end of the three years' course.

MORE RELICS.—Mr. Hall, an American electrician, has, says a transatlantic contemporary, just added to his collection of electrical curiosities three new pieces of apparatus. One of these is a battery made and used by Benjamin Franklin in his experiments with electricity. This battery is one of the first used by Franklin, and is an interesting relic. The others are very valuable also, one being the first electro-magnet made by Professor Henry, peculiar in shape and mounting. The other is an old electrical machine made by Nairne, of London. Mr. Hall also has in his possession the model of the first electrical railway, of which he claims to be the inventor.

TRIAL OF AN ELECTRIC LOG.—The Indian troopship "Crocodile" made a two hours' full-power trial of her machinery on the morning of the 9th inst., in charge of two officers of the Portsmouth Steam Reserve, Mr. Mayson representing the factory department. The draught of the ship forward was 18½ft. and 23ft. aft. A mean pressure of 60lb. of steam was maintained in the boilers, and the vacuum in the condensers was also good. The average revolutions per minute was 54. The mean speed realised was 13½ knots. The trial was perfectly satisfactory. During the run Mr. Brunel made a trial of a new electric log for determining the speed of the ship at any given moment. It worked very well for some time, but was eventually carried away by the strain thrown upon the electric connections,

UNDERGROUND WIRES IN BROOKLYN, U.S.A.—There are 5,508 poles, 3,856 1-5 miles of wire and 6·21 miles of cable in Brooklyn. The Electrical Subway Commissioners are daily occupied in the examination of plans submitted for placing the wires underground. They are considering a system by which the wires on certain streets shall be put underground and kept entirely out of sight. The wires will be introduced into buildings under the sidewalks. Another plan under consideration is to bring up the wires at certain intervals and string them along on poles, from which they will connect with subscribers' stations. The poles would be placed a long distance apart, so that the number would be greatly reduced. In districts which are sparsely settled it appears to be the sense of the commission not to put the wires under the surface.

SOMETHING WRONG.—The imagination present in the office of the *Milwaukee Sentinel* is of a pretty high order. The following is the latest production of that ever truthful paper:—"To deter boys from climbing the telephone poles at Fond du Lac the plan of attaching wire to the spikes and connecting them with a battery was conceived, and it worked to perfection. The first day no less than 200 boys attempted to climb the pole, but immediately received such a shock that they retreated in dismay. Later, however, a farmer drove up to the pole and hitched his horses. One of the animals unsuspectingly caught hold of the spike, and immediately there was a start and a jump and the hitching strap snapped and away went the team. The farmer suffered the fracture of three ribs in attempting to stop the runaways, one or more women were run over, and the waggon smashed to atoms."

THE EDISON-SWAN LAMP.—Arrangements are now in progress for the removal of this company's lamp factory from Newcastle-on-Tyne to a new and extensive factory at Ponder's End, in the neighbourhood of London. This step has, we are informed, been necessitated by the large increase of the company's business. Of the 15,558 incandescent lamps lighted at night at the International Inventions Exhibition the Edison-Swan Company have supplied 12,298; in addition to which they have 3,310 lamps in the "Swan' and "Edison and Swan" stalls, so that there are altogether 15,608 of this company's incandescent lamps at the Inventions Exhibition. This number, when compared with the exhibit of 1,200 lamps by the Edison and Swan Companies at the Crystal Palace Exhibition in 1882, serves as a fair indication of the very real progress of incandescent electric lighting during the past three years.

THE EARL'S COURT ACCIDENT.—In the opinion of the *Daily News*, which comments on the inquiry into the recent fatal collision on the Metropolitan District Railway, it is scarcely satisfactory to find that such a serious accident can take place and nobody be to blame. It adds:—"It appears that a connecting rod broke, so that the signal did not answer to the signalman's lever. But there is an electrical apparatus which tells the occupant of the signal box how the signal stands. Why did this fail? The explanation offered at the inquest is that the sudden jerk given by the breaking of the rod caused the electric indicator to lose its hold, and so to testify falsely. It is, perhaps, inevitable that the best machinery should now and then fail; but this case is a new and rather striking illustration of the small things on which the safety of a train and its living load may sometimes depend."

MORE GAIETIES AT BERLIN.—On the evening of the 7th inst. the hospitality of which the members of the Telegraph Conference have been the lavish objects in Berlin culminated in an entertainment given them by the Municipality in the spacious halls of the Rathhaus—an entertainment which was a mixture of a *conversazione*, a classical concert, a theatrical performance, and a supper. The dramatic part of the entertainment consisted in an allegory entitled "Electra," specially written for the occasion by Herr von Wildenbruch, the only poet who in recent years has been thought worthy to be honoured with the Schiller prize. The *dramatis personæ* of the piece were: Mother Nature, Man (Der Mensch), Electra, the Demon of Gunpowder (a most terrific sprite), and Peace (a white robed and palm-branch bearing youth, crowned with a coronet of electric lamps)—and all these parts were played by histrionic "stars" from the Schauspielhaus.

THE TELEGRAPH AT ORMISTON.—The following letter appeared in a recent issue of the *Scotsman*, from a resident of Ormiston:—"A few months ago a movement was inaugurated in Ormiston, East Lothian, to requisition the postal authorities to establish a telegraph and money order office in the village.

Digitized by Google

The necessary guarantee having been raised by subscription, the poles were erected and wires attached to the existing system at Tranent, and the public were informed that operations would begin on 1st August. The money order office duly started operations, but as yet there are no signs of the telegraph making a start, which is a source of great inconvenience to the inhabitants of Ormiston and the surrounding parishes. As one of the guarantors, I am very anxious to know when the public will have the facility of using the telegraph; and as no information can be obtained from the village postmaster, I would feel obliged if you would allow me this mode of eliciting an answer."

THE BRUSH PATENT IN AMERICA.—It was recently decided in the U.S. Circuit Court, District of Connecticut, in the case of Brush *et al. v.* the Naugatuck Railroad Company *et al*, that the plea of the Naugatuck Company, licensees under the Weston patent, which set up privity of estate with their licensor, the United States Electric Lighting Company, the real defendants in the suit of Brush *v.* Condit, involving the Brush and Weston patents, and which set up the judgment in said suit (that the Brush patent was anticipated by the Hager patent) as a bar to the present suit, be overruled, for the reason that the Brush and Weston patents were for different inventions, although the Weston lamp cannot be made without using the Brush clamp, and the judgment in the former suit (which threw the claimed combination open to the public) was not an adjudication of the validity or scope of the Weston patent, so as to make a case of privity of estate in behalf of licensees under it. The plea of William D. Bishop, which set up non-infringement, was overruled under Sharpe *v.* Reissner.

THE ELECTRIC LIGHTING OF TREBERG.—The little town of Tréberg, long known for its manufacture of clocks, contains about 2,500 inhabitants. It is situated at the bottom of the Gutach Valley, some 2,300 feet below the sea level, and is surrounded on all sides by hills of some 1,000 feet in height. The Gutach, it will be remembered, forms, not far from there, a celebrated waterfall, one of the finest in Germany. In the neighbourhood of the waterfall there are a number of factories, but, strange to say, no effort or scarcely any effort has been made to utilise the great flow of water. Up till now the streets of the town have been miserably lighted by petroleum, but, in order to satisfy the numerous visitors to so picturesque and so salubrious a locality, it has been decided to adopt electricity as the illuminant. The installation has been put down by Messrs. Weil and Neumann, of Freiburg, who have used their own plant for the purpose. It includes 12 arc lamps of 1,500 candle-power (of which three are spare), supplied with current by a dynamo driven from a turbine. The total cost has been £744. That of maintenance, &c., is about 50 per cent. greater than with the ancient method, but more than ten times the amount of light is given.

AN AUTOGRAPHIC TELEGRAPH.—The *Scientific American* contains an account of an autographic or copying telegraph instrument, the invention of Mr. Sylvester P. Denison, which is being introduced by the New York Auto-Telegraph Company, of 47, Broadway, New York. With the aid of these instruments, suitably connected by wires, it is possible for any one to send *fac simile* copies of messages from place to place. The message is written upon a narrow strip of bronzed paper, which is placed over a roller at one side of the instrument; the movement of a lever sends an electric current through the machine, out over the line, and through a second similar machine. The current moves a stylus, which vibrates rapidly over and in contact with the bronzed strip; each time the point in its passage across the paper meets the ink of the writing the current is broken, when a second current passes over the line to the other instrument and through a like stylus, moving back and forth across a strip of paper so prepared as to be discoloured whenever the current passes through it. As the two styluses move absolutely in unison, the exact location of each particle of ink that causes a break in the current is reproduced, by electrolysis, on the chemically-prepared strip at the second instrument. The machine requires no attention beyond the switching of the current from the transmitting to the receiving side, as may be required.

THE CITY AND GUILDS OF LONDON INSTITUTE.—The programme of technological examinations for the session 1885-86 has just been issued. In reviewing a work on this kind or in quoting from it the difficulty is not what to put in but what to leave out, so interesting are its contents. The subjects of more general interest to our readers will be, however, those relating to telegraphy, electric lighting and transmission of power, and electrical instrument making. These are very comprehensive in their character, and speak well for the course of instruction given by the Institute. We are acquainted with a few electricians of mature age who would be rather puzzled by some of the questions in the Honours Grade Section of each of the subjects we have mentioned. The following prizes will be given in each subject, provided the merits of the candidates justify the examiners in awarding them :—

Honours grade	1st Prize	£5 and a Silver Medal.	
	2nd „	£5 „	Bronze „
Ordinary grade	1st Prize	£3 and a Silver Medal.	
	2nd „	£3 „	Bronze „
	3rd „	£2 „	„ „
	4th „	£1 „	„ „
	5th „	a Bronze Medal.	

Candidates who have obtained a First Class Certificate in honours may be re-examined in the same grade, provided they have not already obtained a prize in that grade; but candidates who are so re-examined and fail to obtain a prize will not be entitled to a second certificate, and their names will not be entered on the Pass List. W. H. Preece, F.R.S., and Professor A. Fleming, D.Sc., are the examiners in electrical engineering. Two better men could not well be found.

A NEW ASSOCIATION.—We have much pleasure in announcing that an old students' dinner, in connection with the City and Guilds of London Technical College, Finsbury, will take place on Thursday, October 1st, at the Manchester Hotel, Aldersgate-street, commencing at 6:45 p.m. Professor S. P. Thompson, D.Sc., Principal of the College, has consented to be present. After dinner it is intended to form an Old Students' Association. A provisional committee, consisting of Messrs. R. E. Baker, H. N. Lawrence, H. Marks, A. D. Raine, A. W. Slater, A. C. Webb, and S. Williamson has prepared a set of rules to be submitted to the meeting. The following is a draft scheme of the proposed association :—Its object is, primarily, to promote social intercourse among, and forward as far as possible the advancement of, its members; also to encourage in its members a continued interest in the welfare of the college. All old students (day and evening) are eligible until January 1st, 1886, to become members on paying the subscription, but after that date all applicants must be proposed at one meeting and balloted for at the next. The meetings will be monthly during the winter, some devoted to reading and discussing papers by members on scientific subjects, others to concerts or similar amusements. One silver medal will be given from the funds of the association annually to the member whose paper (read at one of the meetings during the year) shall be selected by the commitee as possessing the greatest merit. The objects of this association com-

Digitized by Google

mend themselves to us. We wish its promoters every success.

RAPID PHOTOGRAPHY.—An invention that is creating some interest is the application of electricity to making photographic exposures in quick succession and at regular intervals of time or distance; also making that succession of exposures from different points of view at the same corresponding intervals of time or distance. The apparatus, we are informed, includes three groups of twelve cameras each, for photographing from three points—the side, the front, and the rear. The three groups do their work simultaneously. First the three number one cameras act, then three number twos, and so on until the three number twelves have operated. All this gives thirty-six different views at twelve intervals of time. One round movement of an animal, as a flap up and down of a bird's wing, is shown in twelve different phases, each phase being potographed from three different points. Leclanché batteries of thirty-six cells each are used in connection with each group. The cable connecting the battery with the camera contained thirteen wires, one being a return wire and the others being connected with twelve electro-magnets that are immediately above the twelve cameras. The apparatus can photograph a movement occupying the one five-thousandth part of a second of time. The calculations of the time of the movement of an animal as a whole, or of the motion of any one part of the body in comparison with the motion of any other part, are made by means of the "background," a large square of canvas stretched on a wooden frame, and divided by cords into forty-eight squares. Each of the forty-eight squares is sub-divided by thinner cords into 100 spaces, each two inches square. If the animal to be photographed is white or light in colour the canvas is black and the cords white. If the colour of the animal is dark the canvas is white-washed and the cords black. The background is photographed with the animal, and the mathematical calculations are made upon the positions of the photographed phases of motion along the little squares.

UNIVERSITY COLLEGE, BRISTOL.—The next session of the college will begin on October 6th. Lectures and classes are held every day and evening throughout the session. In the Chemical Department lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. A special practical class for clothworkers and dyers is carried on by correspondence, and excursions to some of the mines, manufactories, and chemical works of the neighbourhood are occasionally made. The department of experimental physics includes various courses of lectures arranged progressively, and practical instruction is given in the physical and electrical laboratory. The department of engineering and the constructive professions is designed to afford a thorough scientific education to students intending to become engineers, or to enter any of the allied professions, and to supplement the ordinary professional training by systematic technical teaching. This department includes courses specially arranged for students intending to become civil, mechanical, or electrical engineers, surveyors, or architects. Those who attend the mechanical engineering course enter engineering works during the six summer months, and in accordance with this scheme various manufacturing engineers in the neighbourhood have consented to receive students of the college into their offices and workshops as articled pupils. The engineering laboratory has recently been provided with a powerful testing machine, and instruction in the use of tools is given in the workshop. Special courses in surveying have been arranged, and excursions for field practice are frequently made. The departments of geology, biology, and zoology include various courses of lectures in all the branches of these subjects, together with laboratory instruction. In the botanical department practical instruction is given by means of the Botanical Gardens, which contain upwards of 1,000 specimens. Courses of lectures and classes are given in mathematics, political economy, logic, moral philosophy, modern history, English literature, Greek, Latin, Hebrew, French and German. Medical education is provided by the Bristol Medical School, which is affiliated to the college. Several scholarships are tenable at the college.

A REMARKABLE ATMOSPHERIC PHENOMENON.—A description of a remarkable atmospheric phenomenon, which was noticed on August 6, has been communicated to the Swiss local press by Prof. Calladon, of Geneva. Until after five o'clock p.m. the sky had been clear and calm all over the valley of the Leman, but half an hour later, although the atmosphere above the lake and neighbouring mountain remained remarkably still, vapours were seen at a great height (evidently produced by a strong and warm south west wind in the upper air) advancing rapidly towards the north east, and taking the undulatory forms which characterise clouds strongly charged with electricity. Three hours afterwards the sky bore a decidedly stormy aspect. The thick cloud masses oscillated wildly, albeit their general movement was still from south west to north east. After nine o'clock these clouds, drawing away, rendered visible the bank of cirrus which stretched above them. The cirrus was phosphorescent, and looked as if lighted up by a bright moon. On the north western horizon the sky along all the chain of the Jura was obscured by thick clouds that from time to time were illuminated by flashes of lightning. It was the same over Mont Galene, above which the lightning played every few minutes. A long black cloud stretching from the Dôle to the Galene presented on each side a broad phosphorescent border, and about a quarter-past nine there became suddenly visible in that part of the cloud nearest the Jura a luminous centre whence escaped two or three phosphorescent rays pointing towards the south-west. This phenomenon lasted some twenty minutes, and was sufficiently striking to be remarked by many observers. From a quarter-past nine to eleven o'clock, moreover, the south-western extremity of Mont Galene was illuminated by a phosphorescent light so intense that its rays were visible from every part of the horizon. The general appearance of this south-west section of the Galene resembled that which is presented by the city of Geneva in the thick weather when the mists of evening are lighted up by the gas of the streets. Some rare instances are on record of forests of resinous trees becoming phosphorescent in stormy weather, but the distance from Geneva was too great to enable observers to determine whether the light resulted from the phosphorescence of the fir trees which cover the sides of the Galene or from that of other parts of the mountain. The Central Meteorological Bureau at Zurich publishes about eight o'clock every morning daily accounts of the general condition of the atmosphere throughout Europe, and special reports from twelve stations in Switzerland at eight o'clock a.m. and one o'clock p.m. These reports are received at Geneva on the following day, and those on August 5 and 6 show that on the dates in question there took place a complete change in the atmospheric equilibrium of western Europe, and that the high pressures which for several weeks previously had prevailed over England and the Channel suddenly ceased and gave place to warm, vapour-charged winds from the south west.

A NOVEL ADVERTISEMENT.—Mr. Edgar Bruce, of the Prince's Theatre, was apparently not aware until recently, remarks a contemporary, that street advertising is subject to

Digitized by Google

the control of the Commissioners of Police, or he would have taken care to obtain the requisite permission before startling Piccadilly with his latest novelty. About a fortnight ago the manager of the Prince's hit upon the odd notion of sending out sandwich-men armed with poles, to the ends of which were fixed electric lanterns containing an advertisement of his house; but the bearers were stopped by the police. In order that the matter might be tested, one of them—George Johnson—was brought up at Marlborough-street. Mr. Wontner was instructed to appear for the defendant, and urged that his client had no knowledge that he was acting against the police regulations. Of course the plea of ignorance could not absolve Mr. Bruce from responsibility, and the magistrate had no option but to inflict a nominal penalty, which he did to the amount of a shilling and costs. One of the arguments used by the police was that the electric burners were liable to frighten horses. It was very pertinently suggested by Mr. Wontner that as the electric light was the light of the future, the sooner horses became accustomed to it the better. Mr. Bruce may yet be able to secure the approval of the commissioner for his ingenious advertisement. With the long dark nights coming on an accession of moving electric lights in the streets would be a distinct boon in many of our present ill-lighted thoroughfares. Mr. Bruce has subsequently written the following letter to the morning papers:—"From published reports of the result of the summons heard at Marlborough-street on Saturday last respecting the electric lighted balloon advertisements of the Prince's Theatre, it might be thought that my men had carried through crowded thoroughfares a number of powerful arc lights to advertise the 'Great Pink Pearl.' I am unwilling that it should be thought I am capable of announcing my entertainments at a risk to the public safety. May I therefore ask you to kindly state the following facts respecting the balloons which apparently have so offended the police? They are constructed of a light wire framework covered in silk, bearing the words, 'Prince's Theatre, "Great Pink Pearl," every evening at nine.' They measure 45in. in circumference, and the light inside is equal only to 5 candle-power, and this is considerably reduced by the colour of the silk, an ordinary pink. The balloons were carried, by the aid of canes, at a height of 10ft. above the pavement, and yet the witnessing constable objected to these dim and elevated lights, his reason being that they frightened horses. My men, when cautioned by the police, were walking quietly along Piccadilly pavement on their way to Kensington with a two-fold object in view, to advertise my theatre, and to add—in a small way, truly—(oh, sarcastic Mr. Bruce!) to the street lighting, which is but indifferent in the neighbourhood of the Inventions Exhibition. By the magistrate's decision it is evident that the police have power to forbid or allow these balloons to be carried in the streets. I am therefore petitioning the commissioners for the necessary permission, which, I am convinced, will be granted me when the harmless nature of the instrument is shown to them. Meanwhile, I am utilising my balloons as a stationary after-dark advertisement outside my theatre only." We see no earthly reason why a 5-candle incandescent light should be considered dangerous, or likely to frighten anything but a supporter of gas, if confined to the pavements. Mr. Bruce's idea is a good one, and if he thought fit to extend his philanthropy from the thoroughfares in the neighbourhood of the Exhibition to the section of the Exhibition itself which contains the electrical exhibits, he would be regarded as a benefactor by others than the general public.

THE TELEGRAPH CONFERENCE.—Advices from Berlin dated the 7th instant state that the sittings of the commission for tariffs and administrative rules on Thursday, Friday, and Saturday gave rise to much discussion on subjects of considerable importance. Proposals respecting the compilation of an official code by the Bureau International in Berne, the mode of counting and charging for words used in code messages, and the reimbursement of the cost of messages sent for the purpose of ascertaining whether a code message has been correctly telegraphed were discussed. The commission, however, decided that no official code should be drawn up, but that the present rule, which permits the use of any word to be found in standard dictionaries of the eight admitted languages, with its legitimate inflections, should be retained; also that the rule allowing fifteen letters in a code word for European messages should be abolished, and the number of letters reduced to ten, but that, as in extra-European code messages, the words might be taken out of any or all of the eight languages, instead of, as at present, out of one language only. Further, that the return of charges for rectifying errors in plain or code language in unregistered European messages should no longer be allowed, but that as regarded extra-European telegrams each State should be at liberty to refund such money if it desired to. There appears to be some probability that the rates between England and Russia and Spain and some other countries will be reduced, and also the rates between England and India and Australia; in the case of India probably by 7d. per word, and in that of Australia by about 2s. 6d. Later reports give the following interesting rules with respect to a prospective system of international telephony, which have been approved in committee, and will in all probability be accepted by the full Conference:—"1. The Administrations of the contracting States may establish, as required, international telephonic communication, either by laying special wires, or by devoting to this service wires already existing. 2. In default of special arrangements between the said Administrations, these wires shall be conducted into a central telephonic office of each, and thence connected either with the telephonic office provided for public use, or with private houses, offices, workshops, &c. 3. The Administrations shall agree upon the choice of materials, and the details of the service, They shall fix in common the rate to be paid for each telephonic line. 4. The unit adopted for the collection of rates and duration of communications is a conversation of five minutes' length. 5. The use of the telephone shall be allotted in the order of applications. The same correspondents shall not be allowed more than two consecutive conversations of five minutes each, except when no other application shall be made, before or during those conversations." The following rules with respect to money orders have also been approved in committee:—"1. Post Office orders may be sent by telegraph between offices which agree to adopt that mode of transmission. They are then to be called telegraphic orders. 2. Telegraphic orders are to be charged for and treated as ordinary private telegrams. They may, on the same conditions as apply to the latter, be submitted to the formalities of urgency, repetition, acknowledgment, and delivery by post or messenger. Besides the prescribed portion hereinafter mentioned, they may contain a private message from the sender to the receiver. 3. Telegraphic orders are to be addressed by the office which has received the money and address to the office which is to pay them. 4. Partial repetition is to be obligatory—namely, of names and amounts. 5. The office receiving orders shall take such measures as may seem advisable for delivery of the order to the person entitled to it, and for the collection of the cost of carriage beyond the lines." It is expected that the Conference will be able to dispose of all its work in a day or two, and to separate next week. Several representatives of private companies have already left.

THE BRITISH ASSOCIATION MEETING.

(FROM OUR SPECIAL CORRESPONDENT.)

ABERDEEN, Wednesday.

The fifty-fifth meeting of the British Association, now being held at Aberden, is likely to be fairly representative so far as mere numbers are concerned, but whether the addresses and papers will be scientifically valuable the future must judge. The business of the Association commenced to-day with the meeting of the General Committee, at which the report of the Council for 1884-5 was discussed and adopted, and one or two formal matters disposed of. The report mentions that Professor Bonney, the secretary, had at the commencement of the year stated his intention of not seeking re-election at the present meeting, and paid a tribute to his powers of organisation and tact, which proved so useful at Montreal. The Council have nominated Mr. A. T. Atchison, M.A., who for some years past has rendered most efficient assistance as one of the secretaries of Section G, to the office of secretary, vacated by Professor Bonney.

Reference was made in the report to the successful meeting at Montreal, and the stimulus it gave to the energy and life of the Association. Certain resolutions referred by the General Committee to the Council for consideration, and action if desirable, were mentioned. That concerning the tides of the Gulf of St. Lawrence and adjoining coast, their systematic observation and tabulation, and the establishment of observing stations had formed the subject of a communication from the Council to the Canadian Government. Another communication to the Canadian Government related to the urgent necessity of encouraging investigation with respect to the physical characters, languages, social industries, and artistic condition of the native tribes. The time was not thought opportune for action relating to the resolution urging the importance of the employment of the harmonic analysis in the reduction of Admiralty tidal observations.

The most interesting paragraph in the report was probably that relating to the feasibility of instituting a scheme for promoting an International Scientific Congress, to meet at intervals in different countries. This subject is to come on for discussion at the general meeting on Monday. With the report some informal correspondence between Professor Bonney on the one side and Dr. C. S. Minot on the other side was distributed. Professor Bonney pointed out the difficulties in the way of such a general congress, while Dr. Minot examined and commented upon these difficulties, giving also a clear and succinct summary of the opinion in America. It may be well to give an extract from Dr. C. S. Minot's original letter. He says :—

As regards four points there is, as far as ascertained, a general unanimity of opinion in this country :—

1. That it is desirable that the organisation should be initiated through the co-operation of Great Britain and North America, and that other countries be invited to join when the plans are somewhat advanced.
2. That London is the most desirable place for the first meeting.
3. Only persons of acknowledged scientific standing to be admitted to membership.
4. The meetings to be held not oftener than once in three years.

From the consultations held, I have derived the following suggestions as to the plan of organisation :—

1. To have a committee in each country, to whom shall be confided the duty of selecting scientific men of their country to be delegates to the Congress ; these committees to have considerable discretion. Where there is a National Association, that body might be invited to appoint the committee for its own nation. (Our American committee has already, under the general powers given it, authority to do this.)
2. These committees (but after the organisation of the Congress, the delegates) to elect an allotted number of representatives who shall form the permanent governing council of the Congress and administer its affairs. The members of the council to hold office from the time of their election until the next meeting of the Congress.
3. The council to appoint a committee for each meeting, with full powers to make all arrangements for that meeting. This committee to include the members of the council who are representatives of the country in which the meeting is to be held ; to have power to add to its numbers, and to nominate officers for the meeting.
4. Each delegate to pay an assessment towards meeting the expenses of the Association, and not to be admitted to the meeting until the payment has been made.
5. The Congress to divide into sections to meet separately. The committee on the meeting to have discretionary power to invite distinguished persons to deliver addresses before the sections, or to participate in the meeting.
6. Investigating committees shall be appointed by the council, either upon their own initiative or upon the approval of a recommendation from a section. It shall be the policy to encourage such work as requires international co-operation, and to induce Governments to join in and support such work under the general supervision of the Congress.
7. The place of meeting to be fixed by the Council ; but two successive meetings shall not be held in the same country.
8. French, German, and English to be the official languages.

In place of the retiring members of the Council, the following gentlemen are recommended for election :—W. T. Blandford, Esq., F.R.S. ; W. Crookes, Esq., F.R.S. ; J. B. Martin, Esq., F.S.S. ; Prof. H. M'Leva, F.R.S. ; and W. T. Thiselton-Dyer, Esq., C.M.G., F.R.S.

The report of the treasurer was adopted.

What may be called the real business of the meeting commenced with the delivery of the Presidential Address in the evening, at the Music Hall. This address, which is given elsewhere, deals with general questions rather than with special technical subjects, and will perhaps for that reason commend itself all the more to the general body politic.

(BY TELEGRAPH.)

ABERDEEN, Thursday Evening.

To-day, in the Mathematical Section, Prof. Crystal's address was devoted to advocating the greater diffusion of scientific teaching throughout the whole kingdom. He maintained that under the system which had grown up in recent years there was an excess of examining over teaching-power, and that, in fact, we were overrun with examinations ; trying to reap before we have sown. As a practical remedy he suggested, for one thing, the opening up of existing scientific societies to every comer, with, if necessary, an inner court of the Temple of Learning as a place for titular immortals. For example, the British Association itself might continue and extend its work of reporting the progress of special branches of science ; and he thought good would arise if the prophets of the science world deliver courses of lectures at intervals at different places, so that teachers and others might hear and gain knowledge at first hand.

Several papers interesting to electricians were afterwards read in the section, viz :—Lord Rayleigh, "On the Thermodynamic Efficiency of Thermopiles" ; Mr. T. Gray, "On the Measurement of the Intensity of the Horizontal Component of the Earth's Magnetic Field" ; Prof. Smith, "On Atmospheric Electricity ;" Prof. Parmor, "On Molecular Distances in Galvanic Polarisation ;" Dr. Home, "On the Employment of Mance's Method of Eliminating Polarisation for Testing the Resistance of the Human Body." Mr. Bottomley read three papers, viz., "New Experiments in Contact Electricity ;" "A Specimen of Almost Unmagnetisable Steel ;" and "Cooling of Wires in Air and Vacuum."

In the Chemical Section Prof. Ramsay read a paper, entitled "Observations on the Action of a Grove's Gas Battery."

On Tuesday next there will be a special discussion in this section on Electrolysis. Monday will be devoted to electrical papers, when Mr. Preece will read one on "Experiments as to the Strength of Round Timber," and Mr. Shoolbred another on "The Lighting of the Forth Bridge."

Prof. Adams's evening lecture on "Electric Light and Atmospheric Absorption" will be delivered to morrow (Friday) evening.

Up to last night 2,031 tickets had been sold, thus securing the success of the Aberdeen meeting.

ARCS IN AN INCANDESCENT LAMP CIRCUIT.—At a recent meeting of the National Electric Light Association in New York, Dr. Moses expressed his opinion on the subject of working arc lamps on incandescent circuits. He thought the usual kind of differential arc lamp to be unfit for a system that required, in order to be efficient, a lamp whose regulation was a direct function of the current. The lamp should respond with great rapidity to every variation in its condition, and for such purpose an electro-magnet at the point of saturation was most useful on account of its great sensibility.

HISTORY OF THE INCANDESCENT LAMP.—II.

Almost contemporaneously with the labours of De Changy in Europe towards the construction of a serviceable incandescent lamp, vigorous efforts were being made in the New World towards the development of the same idea. J. W. Starr, from Cincinnati, applied himself thoroughly to the study of incandescent lamps, and had made experiments in platinum as well as in carbon. Starr, being a man of very limited means, would hardly have been in a position to carry through satisfactory experiments entailing so much time and expense had he not found in Peabody a generous patron and an enthusiastic promoter of his plans.

Starr came to England with King to take up the business part of the combination, and it was King's first object to win over the scientific circles to Starr's idea, and to present to the public an effectual demonstration of it. To this end he had a magnificent chandelier coustructed with 26 arms, on which, by electric lights, were symbolically represented the existing 26 States of the North American Republic. The result was fully successful; an enormous throng witnessed with amazement the novel and magnificent display, Faraday being present at the interesting experiment, and in flattering terms acquainted his American *confrères* with his satisfaction at the results obtained.

After the death of Starr, King came into his property, and hastened to have Starr's invention patented under his own name. The patent was published on the 4th November, 1845, and described as *a piece of carbon heated to incandescence in an exhausted receiver*, or a platinum wire similarly heated in the open air. This patent (No. 10,919) already contained all the essential principles of the carbon incandescent lamps now in use, viz.:—(1) The incandescent carbon must be as thin as possible, this being an anticipation of the carbon thread employed in most of the incandescent lamp systems of the present day. Here, too, may be found the fundamental principles of all carbon incandescent lamps ever patented, and an indication of the acumen shown by Starr in the definition of the principle of construction of an incandescent lamp. (2) The carbon must be attached to a platinum wire sealed into the glass. (3) The length and resistance of this carbon conductor must be made proportionate to the electromotive force employed. (4) The carbon must be heated to incandescence in a vacuum as perfect as possible. A sketch of King's carbon incandescent lamp can be seen in Fig. 1.

In a recent number of *Nature** may be read the following interesting letter, relating to the discoveries of De Changy and Starr and King, from Mr. Mattieu Williams, a contemporary of Starr:—

"In the 'Notes.' of *Nature*, in Vol. XXVII., p. 209, M. de Changy is described as 'the first electrician who attempted to manufacture incandescent lamps *in vacuo* about twenty years ago.' This invention and its successful practical application (irrespective of cost) was made by a young American, Mr. Starr, and patented by King in 1845. A short stick of gas retort carbon was used, and the vacuum obtained by connecting one end of this with a wire sealed through the top of a barometer tube blown out at the upper part, and the other end with a wire dipping into the mercury. The tube was about 36in. long, and thus the enlarged upper portion became a torrecellian vacuum when the tube was filled and inverted. I had a share of one-eighth in the venture, assisted in making the apparatus and some of the experiments, and after the death of Mr. Starr all the apparatus was assigned to me. I showed this light (in the original lamp) publicly many times at the Midland Institute, Birmingham, and on two occasions in the town hall, all of them more than twenty years ago. The light was far more brilliant and the carbon stick more durable than the flimsy threads of the incandescent lamps now in use. It was abandoned solely on account of the cost of supplying the power. As a steady, reliable, and beautiful light its success was complete. In a contribution to the 'History of Electric Lighting,' published in the *Jonrnal of Science*, November 5, 1879, and reprinted lately in my 'Science in Short Chapters,' may be found further particulars concerning this invention and its inventor."

Without wishing in the smallest degree to depreciate the services of Williams or Starr, we still hope that we have satisfactorily established by the above-mentioned authenticated dates the fact that De Changy was already at work at the construction of incandescent lamps before the appearance of Starr and his invention. As to the credit of the discovery of the incandescent lamp, if this be the place for the discussion of a pure invention, neither Starr nor De Changy can lay claim to it, for the conception of the principle of the incandescent lamp, as well as the first impulse towards its practical application, is due to Professor Jobard as long ago as 1838.

In 1845 the first platinum lamp also made its appearance, when Mr. E. Staite, on the occasion of a lecture in the Sunderland Athenæum, showed in operation the incandescent lamp represented in Fig. 2. The incandescent material was a platinum-iridium wire, held in position by two small upright brass pillars in a wooden stand.

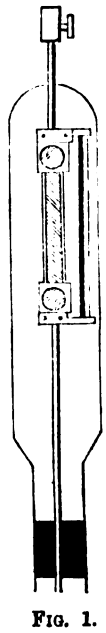

FIG. 1.

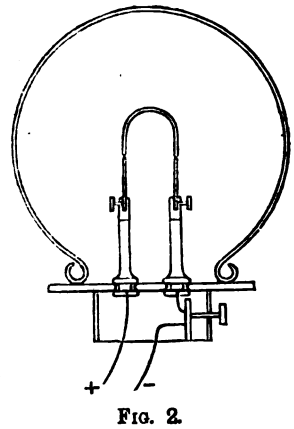

FIG. 2.

A year later Staite, in partnership with Greener, patented a lamp strikingly resembling King's, in which the carbon had been purified with nitric acid.

Three years after the patent of Greener and Staite the employment of iridium as incandescent substance was suggested in a patent taken out by Petrie. This idea so far commended itself as to be entertained by other electricians after him, but the high price of iridium, owing to its excessive rarity, precluded any practical application of it on economical grounds.

Ten years after the patenting of King's lamp in 1855 De Changy resumed, after a long interval, his investigations and experiments, pursuing them with redoubled energy. He made his researches at the same time in two directions. Without abandoning the carbon principle he applied himself to the construction of a system in which platinum appeared as incandescent substance, hoping with this metal to obtain much sooner a result which, if less perfect, would still be reasonably successful. But when he saw that in order to prevent fusion of the platinum wire the electrical current must be allowed to vary only between very narrow limits, he recognised the paramount necessity of constructing a current-regulator, which he patented in 1858.

It was intended that lamps provided with such a current-regulator should be applied to various purposes, some of them of considerable interest, as, for example, the lighting of mines, submarine lamps for fishing, small floating lights, and finally for nautical telegraphs,* in which, by means of a variety of

*This letter is a correct copy of Mr. Williams's communication to *Nature* of Jan. 11th, 1883.—[Ed. *E.*]

* This idea has been recently developed by an Austrian naval officer, named Sellner, who had his apparatus for the purpose constructed by Czeija and Nissl in Vienna, and by the firm of Saulter, Lemmonnier, and Co., in Paris.

Digitized by Google

combinations produced by a keyboard, illuminated signals were to be sent from the masthead of a ship. The platinum employed in these incandescent lamps was subjected to a special process. De Changy first raised the metal to a moderate red heat, and then allowed it to rise gradually to the temperature which it had afterwards to stand continuously—a process the practical importance of which was some twenty years later recognised and acted on by Edison.

It may not prove uninteresting to the reader to learn what prejudice was still entertained at that time by the Brussels Academy of Sciences against all commercial industries, and what an illiberal and one-sided view was then taken in learned circles of the profession of scientific investigators. Thus, when De Changy, a short time after obtaining his patent, submitted the results of his investigations to the Academy of Sciences, the latter sent a commission to institute an examination of the subject.

Deprez, who was a member of this commission, asked Herr Jobard by letter for a detailed description of the apparatus connected with De Changy's invention, and of all the technical preliminaries. Herr Jobard was naturally compelled to reply that it was impossible for him to give so full an explanation, for such a publication might have a prejudicial effect on the patent just obtained. On receiving this reply, M. Deprez announced that since M. De Changy wished to make his invention the basis of a remunerative industry, he had no claim to the title of a scientific man, and the Academy must therefore decline any further concern with his work.

This answer was naturally not calculated to encourage De Changy towards further researches. The result was that he abandoned his investigations in connection with incandescent lamps.

During the next fifteen years little worth mentioning occurred. Now and then there was another appearance of a "latest and most perfect" discovery, destined, as a rule, to vanish without leaving any lasting trace of its existence. It was in 1873 that the development of this lamp took a turn for the better, when a Russian *savant*, M. Lodyguine, succeeded in inventing an incandescent lamp, for which the St. Petersburg Academy of Science awarded him the first prize. The chief principles of his lamp may be thus summarised.

In an exhausted receiver are fitted small sticks of carbon, fitted at their extremities into two cubes of the same material. But since the lamp was badly sealed and the exhaustion was therefore deceptive, Lodyguine thought it sufficient after a single exhaustion of his receiver merely to close it hermetically, and so prevent any renewal of the oxygen when it had once been consumed. But this lamp, in spite of the improvements of M. Rosloff, of St. Petersburg, could not vindicate its existence in a practical sphere, and so shared the fate of its predecessors. The same may be said of Roun's and Bouligine's carbon incandescent lamps, the first of which was patented in the year 1875, the second in the year 1876. All these lamps suffered from the same drawback, that the carbon in process of time crumbled and finally broke in the middle, while the renewal of the useless carbon was rendered very troublesome by the fact that the lamp was sealed up.

After all these fruitless essays, a man at last appeared who had already won a name in the different branches of practical electricity, and who now was driven by his restless zeal after new triumphs to seek for fresh laurels in the sphere of incandescent lamps. This man was Edison.

In 1878 Edison made an extended tour to the Rocky Mountains in the company of a distinguished American phycisist, who matured his resolution to attack the question of electrical illumination.

He provided his laboratory with the necessary apparatus for the study of the problem. Edison began his experiments with arc lamps, but soon renounced them to try his fortune in the path trodden by so many predecessors.

Like De Changy, Edison imagined that he could construct a lamp more easily and quickly with metal than with carbon, and it remained to definitely ascertain what metal was most suitable for the end in view.

Most of the experimenters in electricity suffered from lack of sufficient pecuniary means, which tended to paralyse them and prevent them from following out their expensive experiments, for the majority of these scientific men lived in very limited financial circumstances, and had not all the good fortune to obtain the assistance of a Peabody in their undertakings. Edison's case was quite different; his industry had enriched him with several remunerative inventions, and we cannot, therefore, be surprised that the Electric Light Company called into being by him placed unlimited confidence in his inventive genius, and grudged no expense necessary to enable their manager to obtain the end he had set before him.

The following anecdote is interesting as bearing eloquent testimony to Edison's strength of will, often rising to actual stubbornness, and giving an instance of the colossal wealth at his disposal:—When Edison, in the search for a suitable material for his incandescent lamps, sent his assistants to all parts of the compass, his attention was drawn by one of them to the properties of the metal thorium as having a very high temperature of fusion. Edison immediately applied by letter to one of the most eminent mineralogists of the United States requesting him to send him a small quantity of this exceedingly rare metal. The *savant* replied with some Yankee sarcasm that it would afford him infinite pleasure to be able to put a few hundredweights of the required metal at the disposal of the eminent electrician, but this would be attended with great difficulty, as it would be impossible to obtain even half an ounce of it in the whole territory of the United States.

What was Edison's next move? He sent for one of his cleverest assistants, and informed him that in a gold mine of the Northern States, beneath a mass of valueless flint, some monarite crystals, from which thorium is obtained, had been unexpectedly discovered. Then he gave him a letter of credit to a very large amount, and said to him "Start at once, and bring me in as short a time as possible one hundred pounds of monarite." Three days later twenty miners were at work in the mine in question under the direction of the young assistant, who paid his workmen liberally, and allowed them besides all the gold brought to light, seeking only for the monarite himself. A few weeks later he returned to Menlo Park with the hundred pounds of monarite required. Edison began his experiments on the same day, and pursued them uninterruptedly till he was able to send the cynical *savant* several pounds of that metal, of which the latter had asserted that not half an ounce could be found in all America. This interesting account sufficiently proves with what a command of resources, and on what an extensive scale, the eminent American inventor pursued his investigations and experiments. The thorium so adventurously obtained did not fulfil Edison's expectations, and he found himself, therefore, compelled to return at last to De Changy's idea, and to fall back on platinum as the incandescent material for his lamps. He soon succeeded in constructing a platinum incandescent lamp which, as before mentioned, more nearly fulfilled the requirements of practical use than any produced by his numerous predecessors. Scarcely had the news of this so far satisfactory result reached the shareholders of the Electric Light Company, when they put in motion all the machinery of American assertion to sing the praises of the new lamp as an epoch making event.

The fickle spirit of speculation grasped eagerly at the opportunity offered, and capital coming down at the universal cry that the days of gas-lighting were numbered, the prices of electric light shares rose to the highest point, while a regular panic attacked the holders of gas stock.

But the heyday of the electric light shareholders was but short-lived. When it came to bringing the incandescent lamps so elaborately inaugurated to the crucial test of practical employment, it soon appeared how fast and loose the American press had been playing with the too credulous public. Though Edison's lamp was comparatively the most successful hitherto produced in that line, no idea could be entertained of any general adoption of it for practical purposes, and the new industry declined before it could be truly said to have made a regular stand.

For several years, even long before Edison's labours on the construction of an incandescent lamp, an English electrician, J. W. Swan, had been working hard to produce a lamp in which his constant aim was to obtain his object with carbon.

Digitized by Google

In 1845, when Mr. Staite delivered his lecture in the Sunderland Athenæum, among his audience was Mr. J. W. Swan, whose attention was then first directed to the electric light. Soon after Swan began to experiment with the object of developing to a more perfect degree the principle previously established by King, that the incandescent carbon in the electric lamp must be as thin as possible.

CORRESPONDENCE.

TREATMENT OF SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I must ask your permission to say a few words more on the subject on which I addressed you last week, after reading Mr. Bernard Drake's letter, in order to show that I do not advise any course adverse to the experience of the E.P.S. Company.

My method of charging the cells is as scientific as it is possible to make it with practical considerations. Every ampere-hour which goes to the house is checked on a Ferranti meter.

The charging is done at the rate of 30 amperes, and if it becomes more or less, the means exist of making the current return to the normal. The readings are checked every half hour; or more often I chalked down on a suitably ruled black board. When the charging ampere hours equal the meter readings the process is stopped, and in general the the usual phenomena which are taken to indicate "fully charged" are observable in the cells. It will thus be seen that the cells are always kept up to the mark.

At this time of year an evening takes out approximately 80 ampere hours, and in two nights about 160 ampere hours; hence, say a 5½ hours' charge every other day puts back what is taken out. My cells are supposed to hold 530 ampere hours available, but I have never run them so low, and therefore cannot speak on this point.

I find by this process the positive plates whiten as the complete charge approaches, and they regain their colour later, as described in my letter.

I regard the disconnecting of cells containing liquid a most dangerous process, and I have seen many accidents arise from this cause, but fortunately no harm was ever done to any one, more by good luck than otherwise. The waste which arises at any time from short-circuiting a cell through a resistance is not worth talking of. Say every cell requires the process once each year (this is a fair average) for two hours each. This is equivalent to a two hours' run of 30 amperes (the general charging rate), or in coal, say a waste of ½cwt., worth 6d. per annum, to secure the good condition of the accumulator. This is even a high value.

However, the main point is, do the positive plates whiten (or sulphate (?)) or not by overcharging? Chemically speaking, I think they ought to do so, and practically I find that there is the tendency.

I further believe that this state of things would not exist if the plates could be sent out wet from the factory directly after "forming," instead of allowing them to dry; and many may not know that when the E.P.S. plates are removed from the acid they dry very rapidly, becoming so hot that one can scarcely touch them. I fully believe that many experiments conducted away from the factory would probably differ from these causes.

In conclusion, I must beg my readers not to suppose that I am against the use of E.P.S. cells, for my results have been very favourable. But to find out the truth in science has always been my aim, and for this end we must experiment for good or for bad.

If my results and suggestions are bad, prove them so under like conditions, and I shall be the first to renew the experiments to find where the fault existed.—Yours, &c.,

Sept. 7, 1885. DAVID SALOMONS.

A NEW TESTING INSTRUMENT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Notwithstanding your note annexed to Mr. M. Volk's letter in your last issue, I imagine that his little instrument would prove useful. I made a similar contrivance three years ago, and have used it ever since. Before using I had only to allow the card to swing freely, and if it pointed to the north the magnetism was not reversed. I invariably found it correct. As wires were often fixed to roofs, I lettered both sides of the compass card, so that it could be used either above or below wire. It was often not easy to twist heavy or fixed-down wires into the magnetic meridian, so I added a little directing magnet, which could be slipped out when necessary. A narrow U-shaped copper strip slipped on the spring tight over the glass front and back, and as the ends projected I could use the whole as a galvanometer on an emergency. It was the most useful little tool I had, and might be made from 1s. to 2s. 6d. according to finish.—Yours, &c.,

JNO. M. M. MUNRO.

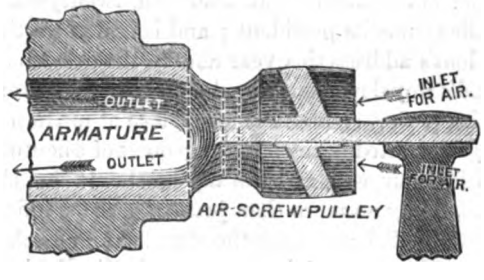
136, Bothwell-street, Glasgow, 5th September, 1885.

NEW PULLEY FOR DRIVING DYNAMO MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Perhaps the following may be interesting to your readers:—

I propose the use of a new pulley for driving dynamo machines, which at the same time serves to ventilate the armature, as follows:



The screw inside the pulley must be of such a shape as to give the best results for ventilation.

Can you kindly give me some information relating to the manufacture of carbon rods for electric light; as to the addresses of makers of the hydraulic and milling machinery; and about the process of manufacture?—Yours, &c.,

Slikkerveer, 8th Sept., 1885. WILLEM SMIT.

[We have no doubt that some of our readers will supply the required information.—ED. *E.*]

THE LIFE OF INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your article on the Law Courts installation there is a slight error in line 6 from bottom. Instead of "Grundy and Ready's holder" (*vide The Electrician*, p. 182, July 17), it should be, "Grundy's holder" (*vide The Electrician*, March 28th, 1885).—Yours, &c.,

A. GRUNDY,

Hazells, Gravesend, Sept. 8, 1885. Electrician R.C.J.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I beg to draw your attention to a slight error in your last week's issue, page 315. I am in conjunction with Mr. Grundy in the patent telescopic pendant only, and not in the holder, as stated.—Yours, &c., J. W. READY.

Law Courts, Strand, 7th Sept.

Answer to Correspondent.—Volt: The word "pressure" is very frequently used to denote E.M.F. or potential.

THE BRITISH ASSOCIATION AT ABERDEEN.

The visit which members of the British Association will pay to Balmoral to-morrow, by invitation of the Queen, is a fitting though perhaps an unpremeditated tribute to the memory of Her Majesty's illustrious consort. On the occasion of the Association's last gathering at Aberdeen, twenty-six years ago, Prince Albert was its president; and it is natural that both in the president's address this year and in the gracious invitation to Scotland's Royal residence we should detect some reminiscence of him who, perhaps more than any prince of modern times, was genuinely interested in the encouragement of scientific pursuits. Sir Lyon Playfair was, as naturally he should be, eloquent on this theme, doing no more than justice, perhaps indeed less, to the debt which Science owes the statesman and scholar whose influence on the cause of higher education in England did not cease with his life, and whose hopes and practical schemes are being realised within a comparatively short time after his death.

It is, of course, to be expected that the president for the present year should be dissatisfied; there would be an end of presidents and presidential addresses if we had achieved all that we anticipate, and had satisfied all our desires. But we have only to look at the programme of the British Association's meeting in 1859 and compare it with that for 1885 to see not only the wonderful progress that has been made in adding to our store of exact knowledge, but also in widely extending the means for diffusing this knowledge. The subjects are not merely startlingly novel as compared with those of a generation ago, but it is plain that they appeal to a wider audience; that, whether abstruse or simple, they are so treated as to reach the world outside the charmed circle of the Association; and that, moreover, the lay press treats them with a respectful attention which would have been thought impossible, and by most scientists of that day even undesirable. The late Prince Consort, however, held opinions which, though common enough now, were unfamiliar then, expressing the conviction "that the State will recognise in science one of its elements of strength and prosperity, to foster which the clearest dictates of self-interest demand."

With this pregnant text the presidential address on Wednesday was chiefly occupied, the subject being the relations of science to the public weal. Such, at least, was Dr. Playfair's own account of the address. We should rather describe it as an appeal of science for State encouragement. In this he was no doubt following in the Prince's footsteps; but it may be questioned whether the Royal Patron would have pursued them in the same direction as far as his follower would seem to recommend. It is one thing for the State to foster and encourage science; it may be quite another thing to convert science into a State Establishment, which is apparently what the president is driving at. The fate of Establishments generally is not encouraging, certainly not north of the Tweed; and neither in the interests of science nor in those of its votaries will thoughtful men confidently recommend the reversion of the theological mantle to the shoulders of science.

The inevitable tendency of State departments is to run in a specified groove, and to treat as heretical and schismatic any independent departure from the track in which its subsidy is earned. For science to voluntarily bind itself in this fashion, or anything akin to it, seems to us incredible, and altogether inexpedient. The endowment of science by certain States, if the examples cited by Dr. Playfair are cases of that kind, have been of too recent date to afford proof of their wisdom. The magnificent expenditure on the University of Strasburg by Germany is as much a political act as an educational project. The reservation by the United States of 150,000,000 acres of national lands for the promotion of scientific education only awakens the reflection that the science of the States is fortunate in belonging to a country that has millions of acres to reserve for any useful purpose whatever. We decline to look upon these or any other examples of the kind as telling to England's discredit. They are the outcome of local circumstances or national peculiarities. We are second to no country in the thoroughness and soundness of our scientific reputation, and we very much doubt whether an endowment of fabulous acres would better us, or will enable any other nation to beat us.

But as regards the diffusion of scientific knowledge Dr. Playfair is on safer ground, though even here he fails to give a sufficient reason for artificially forcing the operation. The State can do only what the people desire it shall do, or at all events consent to its doing. Too frequently the State is spoken of as something distinct from and independent of the people. Dr. Playfair even talks of the people of this country being anxious for scientific or technical knowledge. The statistics furnished by the science classes are evidence of diffusion, but not of a general craving for it. The fact that popular constituencies elect scientific professors would count for something if we were sure that the science counted for anything with the electors. Twelve working class constituencies, it appears, have invited Sir Lyon Playfair himself to sit for them in Parliament. The scientific significance of that interesting fact would be plainer if this "humble representative of science," to use his own words, were not a very ardent and far from humble representative of politics. If scientists are wanted, there ought to be no lack of candidates. It is no disparagement of Dr. Playfair to say that eleven other men not less eminent in science can be found if these working class constituents will have them. But we suspect that, unless the scientist has countless acres to dispose of, as they have in America, the answer of the populace will be, as it assuredly would be in the States if endowment of science meant taxation, like the cry of the French revolutionists, "The Republic has no need of *savants*." In popular estimation "the value of science is measured by its application to the useful purposes of life." Dr. Playfair deprecates this low estimate of its value; but it must be confessed he does little to alter that impression, for the whole address is one long assertion of the material advantages accruing to the nation that will give itself up to the study and application of science.

Of course, Dr. Playfair has a higher conception of the province of science than this. He betrays it in many passages devoted to the science of the ancients, and in the enthusiasm with

Digitized by Google

which he speaks of the famous dead who have devoted their lives to the study for its own sake. But in seeking to obtain a recognised position for modern scientists, which formerly they did not seek, and a State subsistence which they never asked for and rarely accepted, he is addressing unconsciously, and with the instincts of a politician, the populace who look only for the useful, and who see it only in the tangible. The relation of science to the public weal, or, in other words, the material advantages of a closer relationship between science and the State, is therefore necessarily the shape which the president's address has assumed. It is a confession that to appeal to higher motives would have been in vain; and it is also a plain indication of what we said at the outset, namely, that an association of scientists nowadays addresses itself to the non-scientific world hardly less than to its own members. We shall rejoice if this year's meeting in any way helps to convince the English public of the advantages to be derived from a diffusion of scientific knowledge; but it is not to be expected that the habits and genius of a nation will be suddenly transformed by State patronage. Dr. Playfair laments that Scotland is singularly deficient in respect to scientific instruction. Yet the Scotch, with the poorest endowments, are the best educated people of the three kingdoms. That they have always preferred the speculative to the exact sciences is easily explained, but not easily to be altered.

THE EFFICIENCY & DURATION OF INCANDESCENT ELECTRIC LAMPS.

The report of a special committee appointed by the President of the Franklin Institute to determine the efficiency and duration of certain kinds of incandescent electric lamps has just been issued. A test of this description upon a large scale, and including every kind of known lamp, might have been of the utmost value; as it is, we think it would be unfair to certain firms whose lamps have been tried to consider the report as anything else than the result of a competition between the United States Electric Lighting Company, represented by Mr. Weston, and the Edison Company. The results, however, even so far as they concern the Edison and Weston lamps, are very interesting, as showing the behaviour of the lamps at different periods of their existence. The Tamadine carbon of the Weston lamps will be found to present some curious variations in resistance, and intensity of light, while on the other hand the Edison lamp is remarkably constant in its obedience to known laws. By the report we notice that a code had been prepared by Mr. Upton, representing the interest of the United States and the Edison Companies, specifying how the test should be conducted. The Brush-Swan and the Bernstein companies declined to enter their lamps, while a number of Woodhouse and Rawson lamps, obtained from the Van de Poele Company, and two grades of the Stanley-Thompson lamp, made by the Union Switch and Signal Company, of Pittsburg, were entered, not by the makers but by the Franklin Institute. The president of the Franklin Institute subsequently entered, for efficiency measurement and for such a test of duration as circumstances would permit, a lot of Weston lamps, furnished by Mr. Weston; a lot of Woodhouse and Rawson lamps, received from the Edison Lamp Company; and a lot of White lamps from the Electrical Supply Company. The examiners were Lieut. J. B. Murdock, U.S.N.; Ensign L. Duncan, of the same service; Professor William D. Marks, and Dr. G. M. Ward. Comprehensive arrangements were made, we are informed, to ensure the best conditions being obtained in each case, and precautions of a somewhat extraordinary nature were taken in order to prevent any possibility of the lamps being tampered with. The tests began with the following lamps entered:—20 Weston, 110·5 volts, Tamadine carbon; 20 Edison 94—100 volts; 10 Woodhouse and Rawson 55 volts; 10 Stanley-Thompson, 96 volts, and 10 Stanley-Thompson, 44 volts. The Tamadine carbon of the Weston lamps had been prepared by chemically treating guncotton in the form of flat sheets to separate the nitryl from the cellulose. The resulting cellulose product is a tough, firm translucent substance, from which the strips are cut in a sinuous form, and carbonised. The carbon is rectangular in cross section, but is placed in the lamps so that at the shanks the longer side of the rectangle is in the line of the shanks instead of at right angles, as in most other lamps. The connections are made at the terminals, with minute steel screw bolts and nuts, setting up with platinum washers. The bending of the carbon turns the long side of the rectangle, so that it lies in different directions at different points. The Edison and Woodhouse and Rawson lamps are too well known to need description. The Stanley-Thompson lamps had carbons apparently made from thread.

The method adopted in taking photometric measurements presents some points of novelty, no doubt due to the presence of two naval officers upon the committee. Quoting from the report we learn that the measurements of the spherical illuminating power of the lamps were made with the object of obtaining the average candle-power of the lamps, and of avoiding the doubt as to the total amount of light which might arise from the various forms of carbon (many of them distorted in manufacture) used by different makers. Sixty-five measurements or more were made on each lamp. The method pursued may be more easily understood by a comparison with the parallels and meridians of the earth, referring to points by their latitude and longitude. The lamp was placed in a vertical position with the plane of the shanks of the carbon at right angles to the photometer bar. The side nearest the bar was marked for future reference. The top and bottom of the lamp were assumed as the north and south poles respectively, and the vertical circle at right angles to the plane of the shanks of the carbon as the prime meridian. The lamp, after adjustment as above, was first rotated horizontally, and thirteen measurements were made in the equator at equal angles of thirty degrees, the last checking on the first. The mean of these measurements gave the "mean horizontal intensity." Starting again from the first position, the lamp was rotated in the plane of the prime meridian, and thirteen measurements were made at equal intervals at thirty degrees, the last checking the first, and making four measurements of the point 0° latitude, 0° longitude. The mean of these four was called the "standard reading." If any noticeable discrepancy was seen the measurements at this point were repeated. As this point was that on which the calculations for the duration test were based, its careful determination was essential. The lamp was then moved 45° horizontally, so that 0° latitude, 45° longitude E. was towards the photometer. It was then rotated in the vertical plane passing through that point, and thirteen measurements made as before, at intervals of 30°, the last checking the first. The lamp was next moved 45° horizontally, so that 0° latitude, and 90° longitude E. was towards the photometer, and 13 measurements made in that meridian as before. Lastly, the lamp was rotated till 0° latitude, 135° longitude E. was towards the photometer and twelve thirty degree measurements made in that meridian, checking with a thirteenth. This makes a total of 65 measurements on each lamp. As the sockets in use with all the lamps prevented the exit of any light from the bottom or south pole of the lamp, the reading at that point was always taken as zero. The measurements were combined as follows:—

The mean of four readings at the north pole of lamp	1
Four measurements on each of the parallels of 60° N. and 60° S. on the prime meridian and 90° meridian circle	8
Eight measurements on each of the parallels of 30° N. and 30° S. at the intersection of the meridian circles of 0°, 45°, 90°, and 135°	16
Twelve measurements, 30° apart, on the equator	12
One zero reading for south pole (base of lamp)	1
Making a total of	38

By laying down the points on a sphere it will be found that they are nearer at the equator than at the poles. The average of the illuminating power at these 38 points is taken at the mean spherical intensity of illuminating power. Fig. 1 shows the location of the thirty-eight points. It is a photograph of a

Digitized by Google

Mueller lamp of nearly spherical shape, around which four rubber bands are stretched to show the four meridian circles, and one rubber band to represent the equator. The small black patches show the thirty-eight points. In order to determine whether the arithmetical mean of these observations gives a close approximation to the mean spherical intensity, calculable from the observations taken, the sphere may be divided into zones, each extending 15° on either side of the equator and the parallels of 30° and 60°, and the spherical intensity be calculated from the area of these zones and the mean candle-power in each. (See Fig. 2.)

The surface of the sphere is developed at the equator by means of a tangent cylinder, at 30° and 60° latitude, by means of a tangent conical frustra, and at the poles by tangent discs.

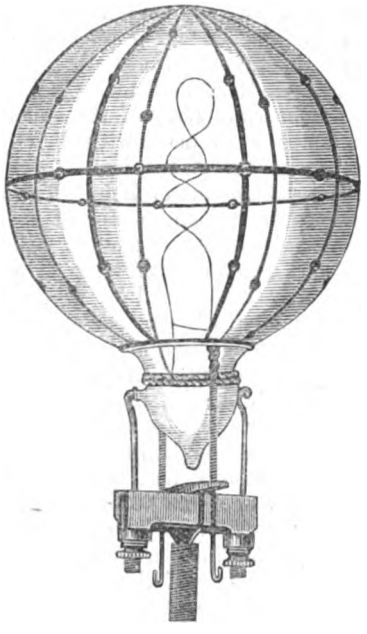

Fig 1.

If now we multiply the mean intensity of illumination of each zone by its area, and divide the sum of these products by the whole area of the sphere, we obtain with very close accuracy the mean spherical intensity of illumination. The following formula gives the method :—

$$\frac{\text{Mean eq.} + \text{mean } 60° \text{ lat.} + 1{\cdot}73 \text{ mean } 30° \text{ lat.} + 0{\cdot}131 \text{ poles}}{3{\cdot}861} = \text{mean spherical candle-power.}$$

This method when compared with that in use gives

Stanley (large), No. 26...13·09 cndles. Method in use .....13·10 cndles.
Edison, No. 2..... ....14·30 ,, ,, ,, ...14·38 ,,

The method adopted yielded results giving slight preponderance to the illumination at the equator, but the difference was small, and this method lent itself readily to the mechanical conditions of the lamp-holder.

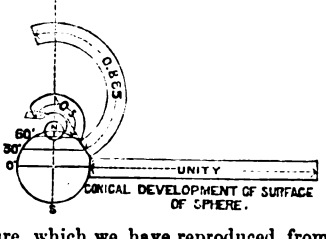

Fig. 2.—This figure, which we have reproduced from the *Journal* of the Franklin Institute, should show the tangents.

The standard Letheby-Bunsen photometer, with a 60in. bar, was used in the efficiency tests, and the Methven standard two-candle slit in all the photometric measurements. Although only twenty-three Edison lamps were required to be measured by the duration test, a larger number were examined. The first twenty of the lamps were tested for duration, and curves were calculated from them ; but few peculiarities were observed. One of these lamps, through a peculiar distortion of the carbon, gave an almost circular curve of horizontal distribution ; the curves of the others were essentially the same. We are further informed that the lamps were taken at random from 400 furnished by the company.

Fourteen of the Stanley-Thompson 96 volt lamps were tested for efficiency, four of the original lot having been broken in fitting them to sockets preparatory to the test of duration, and four others tested in their places. The high potential of the 44 volt lamps 37, 41, and 51 was due to an error of calculation which, corrected after the efficiency test, gave the high figures recorded. These lamps gave the highest average of efficiency of any lot under test, but varied considerably from each other. The curves were essentially the same as those of the 96 volt lamps, except in giving less light at the top of the lamp. They were also taken at random from a lot of 50. Of the Woodhouse and Rawson lamps two lots were tested, the results obtained being generally the same. The first lot were marked 55 volts, and were taken from 25 lamps furnished. There were slight irregularities in the curves obtained from them, due to the fact of the lamp being mounted on a Swan spring socket. In the efficiency measurements, the motion and vibration of this socket in moving it through the various positions occupied, prevented as accurate a measurement as in other cases where the lamp was held rigidly. The second set of this firm's lamps, selected from 50 furnished, were marked 50 volts, and a paper accompanied them from the makers, we are informed, invoicing them as "20 candle-power 50 volt lamps." They were tested by the committee, as the duration test on the former lot was unsatisfactory by reason of many of the lamps being connected two in series. On setting the new lot up at 50 volts they were found to give only 12 spherical candles and to have an efficiency of about 5 watts of candle. A duration test of 300 hours, says the report, was all that could be allotted to these lamps, and would determine nothing if the lamps were tested at so low a candle-power. As the resistance of the lamps cold was the same as some of the first lot of 55 volts, the committee determined to test the second lot at that potential also.

The White lamps were taken from a lot of 24. The carbons, which, as we have mentioned, appeared to be made of thread, had a circular cross section and were heavily treated. The curves of the whole of these lamps were almost identical. The lamps decreased in resistance during the duration test. The average cold resistance before use of several lamps of the same lot was found to be 102 ohms, and those under test probably averaged about the same. On the subject of the Weston lamps some controversy took place between Mr. Weston and the members of the committee ; Mr. Weston having had, it would appear, very much his own way in the matter. His lamps were of 110·5 volts for the first lot, and the light curves obtained from them were very similar in form. In one the major axis of the curve of horizontal illumination laid in the direction of 30°—210°, and in making up the average of 20 another lamp was substituted for this one. The 70 volt paper carbon lamps of the same company were 10 in number, selected from a lot of 33 received from Mr. Weston, and were tested for efficiency, and afterwards subjected to a duration test of 523 hours. In reviewing the results of the tests the committee, and doubtless many other people, have noticed discrepancies in the candle-power. This was unavoidably the case ; from the continuous nature of the test no repetition of the work was possible, and the discrepancies referred to were shown to be such only by observation on subsequent days.

Some general remarks on the subject of the tests of each lot of lamps are given. The Edison lamps behaved with great uniformity, there being in all a gradual increase of resistance throughout the test. One volt was assumed to cause a difference of mean horizontal intensity of one candle. The same allowance for candle-power per volt was made with the 96 volt Stanley-Thompson lamps as with the Edison. In correcting the 44 volt lamps an allowance of 1·5 spherical candle was made for one volt.

The allowance for the Woodhouse and Rawson lamps was 1·5 spherical candle-power per volt. The resistance of the second lot gradually decreased for three days, the candle-power rising and then falling as the resistance increased. All

Digitized by Google

these lamps were much discoloured, and, as a bare possibility, received more than their proper potential.

The White lamps decreased in resistance, the average decrease being 2·5 ohms in 100 hours; the candle-power increasing greatly. The resistance then began to decrease and the candle-power to fall off, but after 250 hours the candle-power was still higher than in the preliminary efficiency test. The correction was 1·5 spherical candle per volt.

The Weston 110·5 volt lamps increased rapidly in resistance at first, the candle-power falling greatly; a correction of one spherical candle per volt was assumed. Great difficulty, we are informed, was experienced with all the Weston lamps in getting the point of 0° latitude 0° longitude exactly towards the photometer. Owing to the peculiar oblique position of the major axis of the curve of horizontal illumination in relation to the plane of the carbon shanks, a slight rotation of the lamp was noticed; the socket materially affecting the photometer reading. A fall of candle-power which took place in lamp No. 62 may have been partially due to this. The resistance, however, showed a deterioration in the lamp as well. The resistance of the 70 volt lamps, as a whole, remained fairly constant, the changes being but slight in either direction. The correction allowed was one and three-tenth spherical candle-power per volt. Very great care was evidently taken to do full justice to Mr. Weston.

The following table shows the mean preliminary readings taken of the various lots of lamps:—

Name.	No. of Lamps.	Volts.		Amps. mean.	Watts mean.	Candles.		Watts per sphrical. candle	Resist. cold.	Candles per elec. h.-p.	
		Marked	Observed.			Mean Spherical.	Mean Horizontal			Spherical.	Horizontal

* 1st lot. † 2nd lot.

Referring to the tables, in which we have endeavoured to include the whole of the information contained in the very many tables in the report, we may mention that of the Edison lamps the readings of Nos. 4, 7 and 9 were very similar to those of No. 3, No. 12 approximated to No. 2, but gave a slight excess of light, while No. 14 approximated to No. 13, taking however ·659 ampere at the finish of test. The carbon of No. 15 broke at the side of the loop at the 265th hour, this being the only loss. No. 17 was similar to No. 11, No. 18 to No. 10, and No. 19 to No. 6. The first four of the Stanley-Thompson lamps broke down at the times specified upon the table, the fault being the breaking of the carbon at the side of the loop in the first three cases, and at the middle of the loop in the fourth. Nos. 6 and 7 of these lamps lasted but 288 and 303 hours, while No. 9 broke at the side of the loop at the 39th hour. No. 12 was destroyed by too high a potential, whilst of the others we have omitted from the table, No. 28 lasted 233 hours; No. 29, 176 hours; No. 33, 256 hours; Nos. 35 and 99, 3 and 36 hours; 300, 4 hours; No. 41, 682 hours. The failure of all these was due to the breaking of the carbon. The Woodhouse and Rawson lamps not given in the table are Nos. 4, 5, 6, 7, 8, 10, 18, 31, 32, and 33. These broke at periods ranging from 117 to 422 hours. The remaining four lasted 330, 176, 223, and 212 hours respectively. Nos. 2 and 3 of the White lamps both lasted 211 hours, whilst Nos. 5, 6, 8, 9, and 10, endured 310, 228, 309, 165, and 309 hours in each case. The first two of the Weston 110·5 volt lamps gave out after 227 and 46 hours. Those omitted from the table are Nos. 4, 5, 7, 51, 54, and 59, which lived 106, 320, 40, 259, 524, and 222 hours; Nos. 61 and 63 reached the 523rd hour. The failures, as in other cases, were caused by the breaking of the carbon. In glancing over the table some curious discrepancies in the candle-power and resistance given by these latter lamps at different periods of their lives will be noticed; but we refrain from comment, preferring to leave our readers to form their own conclusions as to the respective merits of at least the two most prominent representatives of electric lighting in America.

BRITISH ASSOCIATION MEETING AT ABERDEEN.

PRESIDENTIAL ADDRESS BY THE RIGHT HON. SIR LYON PLAYFAIR, K.C.B., M.P., F.R.S.

I. *Visit to Canada.*

LADIES AND GENTLEMEN:

Our last meeting at Montreal was a notable event in the life of the British Association, and even marked a distinct epoch in the history of civilisation. It was by no mere accident that the constitution of the Association enabled it to embrace all parts of the British Empire. Science is truly catholic, and is bounded only by the universe. In relation to our vast empire, science, as well as literature and art, are the common possession of all its varying people. The United Kingdom is limited to 120,800 square miles, inhabited by 35 millions of people; but the empire as a whole has 8½ millions of square miles, with a population of 305 millions. To federate such vast possessions and so teeming a population into a political unit is a work only to be accomplished by the labours and persistent efforts of perhaps several generations of statesmen. The federation of its science is a subject of less dimensions well within the range of experiment. No part of the British Empire was more suited than Canada to try whether her science could be federated with our science. Canada has lately federated distinct provinces, with conflicting interests arising from difference of races, nationalities, and religions. Political federation is not new in the history of the world, though it generally arises as a consequence of war. It was war that taught the Netherlands to federate in 1619. It was war which united the States in America; federated Switzerland, Germany, and Austria, and unified Italy. But Canada formed a great national life out of petty provincial existences in a time of profound peace. This evolution gave an immense impulse to her national resources. The Dominion still requires consolidation in its vast extent, and applied science is rapidly effecting it. Canada, with its great expanse of territory, nearly as large as the United States, is being knit together by the iron bands of railways from the Gulf of St. Lawrence to the Pacific Ocean, so that the fertile lands of Ontario, Manitoba, Columbia, and the North-Western territories will soon be available to the world. Still, practical science has much to accomplish. England and France, with only one-fifth the fertile area of Canada, support 80 millions of people, while Canada has a population not exceeding 5 millions.

A less far-seeing people than the Canadians might have invited the applied science which they so much require. But they knew that without science there are no applications. They no doubt felt with Emerson—

> "And what if Trade sow cities
> Like shells along the shore,
> And thatch with towns the prairie broad
> With railways ironed o'er;
> They are but sailing foam-bells
> Along Thought's causing stream,
> And take their shape and sun-colour
> From him that sends the dream."

So it was with a far-reaching foresight that the Canadian Government invited the British Association for the Advancement of Science to meet in Montreal. The inhabitants of Canada received us with open arms, and the science of the Dominion and that of the United Kingdom were welded. We found in Canada, as we had every reason to expect, men of manly and self-reliant character, who loved not less than we did the old home from which they had come. Among them is the same healthiness of political and moral life, with the same love of truth which distinguishes the English people. Our great men are their great men; our Shakspeare, Milton, and Burns belong to them as much as to ourselves; our Newton, Dalton, Faraday, and Darwin are their men of science as much as they are ours. Thus a common possession and mutual sympathy made the meeting in Canada a successful effort to stimulate the progress of science, while it established, at the same time, the principle that all people of British origin—and I would fain include our cousins in the United States—possess a common interest in the intellectual glories of their race, and ought, in science at least, to constitute part and parcel of a common empire, whose heart may beat in the small islands of the Northern seas, but whose blood circulates in all her limbs, carrying warmth to them and bringing back vigour to us. Nothing can be more cheering to our Association than to know that many of the young communities of English-speaking people all over the globe—in India, China, Japan, the Straits, Ceylon, Australia, New Zealand, the Cape—have founded scientific societies in order to promote the growth of scientific research. No doubt science, which is only a form of truth, is one in all lands, but still its unity of purpose and fulfilment received an important practical expression by our visit to Canada. This community of science will be continued by the fact that we have invited Sir William Dawson, of Montreal, to be our next President at Birmingham.

II. *Science and the State.*

I cannot address you in Aberdeen without recollecting that when we last met in this city our president was a great prince. The just verdict of time is that, high as was his royal rank, he has a far nobler claim to our regard as a lover of humanity in its widest sense, and especially as a lover of those arts and sciences which do so much to adorn it. On September 14, 1859, I sat on this platform and listened to the eloquent address and wise counsel of the Prince Consort. At one time a member of his household, it was my privilege to co-operate with this illustrious prince in many questions relating to the advancement of science. I naturally, therefore,

Digitized by Google

turned to his presidential address to see whether I might not now continue those counsels which he then gave with all the breadth and comprehensiveness of his masterly speeches. I found, as I expected, a text for my own discourse in some pregnant remarks which he made upon the relation of Science to the State. They are as follows:—"We may be justified in hoping . . . that the Legislature and the State will more and more recognise the claims of science to their attention, so that it may no longer require the begging-box, but speak to the State like a favoured child to its parent, sure of his paternal solicitude for its welfare; that the State will recognise in science one of its elements of strength and prosperity to foster which the clearest dictates of self-interest demand."

This opinion, in its broadest sense, means that the relations of science to the State should be made more intimate because the advance of science is needful to the public weal.

The importance of promoting science as a duty of statecraft was well enough known to the ancients, especially to the Greeks and Arabs, but it ceased to be recognised in the dark ages, and was lost to sight during the revival of letters in the fifteenth and sixteenth centuries. Germany and France, which are now in such active competition in promoting science, have only publicly acknowledged its national importance in recent times. Even in the last century, though France had its Lavoisier and Germany its Leibnitz, their Governments did not know the value of science. When the former was condemned to death in the Reign of Terror, a petition was presented to the rulers that his life might be spared for a few weeks in order that he might complete some important experiments, but the reply was, "The Republic has no need of savants." Earlier in the century the much-praised Frederick William of Prussia shouted with a loud voice, during a graduation ceremony in the University of Frankfort, "An ounce of mother-wit is worth a ton of university wisdom." Both France and Germany are now ashamed of these utterances of their rulers, and make energetic efforts to advance science with the aid of their national resources. More remarkable is it to see a young nation like the United States reserving 150,000,000 acres of national lands for the promotion of scientific education. In some respects this young country is in advance of all European nations in joining science to its administrative offices. Its scientific publications, like the great paleontological work embodying the researches of Professor Marsh and his associates in the Geological Survey, are an example to other Governments. The Minister of Agriculture is surrounded with a staff of botanists and chemists. The Home Secretary is aided by a special Scientific Commission to investigate the habits, migrations, and food of fishes, and the latter has at its disposal two specially constructed steamers of large tonnage. The United States and Great Britain promote fisheries on distinct systems. In this country we are perpetually issuing expensive Commissions to visit the coasts in order to ascertain the experiences of fishermen. I have acted as chairman of one of these Royal Commissions, and found that the fishermen, having only a knowledge of a small area, gave the most contradictory and unsatisfactory evidence. In America the questions are put to Nature, and not to fishermen. Exact and searching investigations are made into the life-history of the fishes, into the temperature of the sea in which they live and spawn, into the nature of their food, and into the habits of their natural enemies. For this purpose the Government give the co-operation of the navy, and provide the Commission with a special corps of skilled naturalists, some of whom go out with the steamships and others work in the biological laboratories at Wood's Hall, Massachusetts, or at Washington. The different universities send their best naturalists to aid in these investigations, which are under the direction of Mr. Baird, of the Smithsonian Institution. The annual cost of the Federal Commission is about £40,000, while the separate States spend about £20,000 in local efforts. The practical results flowing from these scientific investigations have been important. The inland waters and rivers have been stocked with fish of the best and most suitable kinds. Even the great ocean which washes the coasts of the United States is beginning to be affected by the knowledge thus acquired, and a sensible result is already produced upon the most important of its fisheries. The United Kingdom largely depends upon its fisheries, but as yet our Government have scarcely realised the value of such scientific investigations as those pursued with success by the United States. Less systematically, but with great benefit to science, our own Government has used the surveying expeditions, and sometimes has equipped special expeditions to promote natural history and solar physics. Some of the latter, like the voyage of the "Challenger," have added largely to the store of knowledge; while the former, though not primarily intended for scientific research, have had an indirect result of infinite value by becoming training schools for such investigators as Edward Forbes, Darwin, Hooker, Huxley, Wyville Thomson, and others.

In the United Kingdom we are just beginning to understand the wisdom of Washington's farewell address to his countrymen, when he said: "Promote as an object of primary importance institutions for the general diffusion of knowledge. In proportion as the structure of a government gives force to public opinion, it is essential that public opinion should be enlightened." It was only in 1870 that our Parliament established a system of national primary education. Secondary education is chaotic, and remains unconnected with the State, while the higher education of the universities is only brought at distant intervals under the view of the State. All great countries except England have Ministers of Education; but this country has only ministers who are the managers of primary schools. We are inferior even to smaller countries in the absence of organised State supervision of education. Greece, Portugal, Egypt, and Japan have distinct Ministers of Education, and so also among our colonies have Victoria and New Zealand. Gradually England is gathering materials for the establishment of an efficient Education Minister. The Department of Science and Art is doing excellent work in diffusing a taste for elementary science among the working classes. There are now about 78,000 persons who annually come under the influence of its science classes, while a small number of about two hundred, many of them teachers, receive thorough instruction in science at the excellent school in South Kensington, of which Professor Huxley is the dean. I do not dwell on the work of this Government department, because my object is chiefly to point out how it is that science lags in its progress in the United Kingdom owing to the deficient interest taken in it by the middle and upper classes. The working classes are being roused from their indifference. They show this by their selection of scientific men as candidates at the next election. Among these are Professors Stuart, Roscoe, Maskelyne, and Rücker. It has its significance that such a humble representative of science as myself received invitations from working-class constituencies in more than a dozen of the leading manufacturing towns. In the next Parliament I do not doubt that a Minister of Education will be created as a nucleus round which the various educational materials may crystallise in a definite form.

III. *Science and Secondary Education.*

Various Royal Commissions have made inquiries and issued recommendations in regard to our public and endowed schools. The Commissions of 1861, 1864, 1868, and 1873 have expressed the strongest disapproval of the condition of our schools, and, so far as science is concerned, their state is much the same as when the Duke of Devonshire's Commission in 1873 reported in the following words:—"Considering the increasing importance of science to the material interests of the country, we cannot but regard its almost total exclusion from the training of the upper and middle classes as little less than a national misfortune." No doubt there are exceptional cases and some brilliant examples of improvement since these words were written, but generally throughout the country teaching in science is a name rather than a reality. The Technical Commission which reported last year can only point to three schools in Great Britain in which science is fully and adequately taught. While the Commission gives us the consolation that England is still in advance as an industrial nation, it warns us that foreign nations, which were not long ago far behind, are now making more rapid progress than this country, and will soon pass it in the race of competition unless we give increased attention to science in public education. A few of the large towns, notably Manchester, Bradford, Huddersfield, and Birmingham, are doing so. The working classes are now receiving better instruction in science than the middle classes. The competition of actual life asserts its own conditions, for the children of the latter find increasing difficulty in obtaining employment. The cause of this lies in the fact that the schools for the middle classes have not yet adapted themselves to the needs of modern life. It is true that many of the endowed schools have been put under new schemes, but as there is no public supervision or inspection of them, we have no knowledge as to whether they have prospered or slipped back. Many corporate schools have arisen, some of them, like Clifton, Cheltenham, and Marlborough Colleges, doing excellent educational work, though as regards all of them the public have no rights and cannot enforce guarantees for efficiency. A Return just issued, on the motion of Sir John Lubbock, shows a lamentable deficiency in science teaching in a great proportion of the endowed schools. While twelve to sixteen hours per week are devoted to classics, two or three hours are considered ample for science in a large proportion of the schools. In Scotland there are only six schools in the Return which give more than two hours to science weekly, while in many schools its teaching is wholly omitted. Every other part of the kingdom stands in a better position than Scotland in relation to the science of its endowed schools. The old traditions of education stick as firmly to schools as a limpet does to a rock; though I do the limpet injustice, for it does make excursions to seek pastures new. Are we to give up in despair because an exclusive system of classical education has resisted the assaults of such cultivated authors as Milton, Montaigne, Cowley, and Locke? There was once an enlightened Emperor of China, Chi Hwangti, who knew that his country was kept back by its exclusive devotion to the classics of Confucius and Mencius. He invited 500 of the teachers to bring their copies of these authors to Pekin, and after giving a great banquet in their honour, he buried alive the professors along with their manuscripts in a deep pit. But Confucius and Mencius still reign supreme. I advocate milder measures, and depend for their adoption on the force of public opinion. The needs of modern life will force schools to adapt themselves to a scientific age. Grammar schools believe themselves to be immortal. Those curious immortals—the Struldbrugs—described by Swift, ultimately regretted their immortality, because they found themselves out of touch, sympathy, and fitness with the centuries in which they lived.

As there is no use clamouring for an instrument of more compass and power until we have made up our mind as to the tune, Professor Huxley, in his evidence before a Parliamentary Committee in 1884, has given a time-table for grammar schools. He demands that out of their forty hours for public and private study, ten should be given to modern languages and history, eight to arithmetic and mathematics, six to science, and two to geography, thus leaving fourteen hours to dead languages. No time table would, however, be suitable to all schools. The great public schools of England will continue to be the gymnasia for the upper classes, and should devote much of their time to classical and literary culture. Even now they introduce into their curriculum subjects unknown to them when the Royal Commission of 1868 reported, though they still accept science with timidity. Unfortunately, the other grammar schools which educate the middle classes look to the higher public schools as a type to which they should conform, although their functions are so different. It is in the interest of the higher public schools that this difference should be recognised, so that while they give an all-round education and expand their curriculum by a freer recognition of the value of science as an educational power in developing the faculties of the upper classes, the schools for the middle classes should adapt themselves to the needs of their exist-

Digitized by Google

ence, and not keep up a slavish imitation of schools with a different function. The old classical grammar schools may view these remarks as a direct attack upon them, and so it is in one sense, but it is like the stroke of Ithuriel's spear, which heals while it wounds.

The stock argument against the introduction of modern subjects into grammar schools is that it is better to teach Latin and Greek thoroughly rather than various subjects less completely. But it is true that thoroughness in teaching dead languages is the result of an exclusive system? In 1868 the Royal Commission stated that even in the few great public schools thoroughness was only given to thirty per cent. of the scholars, at the sacrifice of seventy per cent. who got little benefit from the system. Since then the curriculum has been widened and the teaching has improved. I question the soundness of the principle that it is better to limit the attention of the pupils mainly to Latin and Greek, highly as I value their educational power to a certain order of minds. As in biology the bodily development of animals is from the general to the special, so is it in the mental development of man. In the school a boy should be aided to discover the class of knowledge that is best suited for his mental capacities, so that, in the upper forms of the school and in the university, knowledge may be specialised in order to cultivate the powers of the man to their fullest extent. Shakspeare's educational formula may not be altogether true, but it contains a broad basis of truth—

"No profit goes, where is no pleasure ta'en;
In brief, sir, study what you most affect."

The comparative failure of the modern side of school education arises from constituting it out of the boys who are looked upon as classical asses. Milton pointed out that in all schools there are boys to whom the dead languages are "like thorns and thistles," which form a poor nourishment even for asses. If teachers looked upon these classical asses as beings who might receive mental nurture according to their nature, much higher results would follow the bifurcation of our schools. Saul went out to look for asses and he found a kingdom. Surely this fact is more encouraging than the example of Gideon, who "took thorns of the wilderness and briars, and with these he *taught* the men of Succoth."* The adaptation of public schools to a scientific age does not involve a contest as to whether science or classics shall prevail, for both are indispensable to true education. The real question is whether schools will undertake the duty of moulding the minds of boys according to their mental varieties. Classics, from their structural perfection and power of awakening dormant faculties, have claims to precedence in education, but they have none to a practical monopoly. It is by claiming the latter that teachers sacrifice mental receptivity to a Procrustean uniformity.

The universities are changing their traditions more rapidly than the schools. The *via antiqua* which leads to them is still broad, though a *via moderna*, with branching avenues, is also open to their honours and emoluments. Physical science, which was once neglected, is now encouraged at the universities. As to the seventy per cent. of boys who leave schools for life work without going through the universities, are there no growing signs of discontent which must force a change? The Civil Service, the learned professions, as well as the army and navy, are now barred by examinations. Do the boys of our public schools easily leap over the bars, although some of them have lately been lowered so as to suit the schools? So difficult are these bars to scholars that crammers take them in hand before they attempt the leap; and this occurs in spite of the large value attached to the dead languages and the small value placed on modern subjects. Thus, in the Indian Civil Service examinations, 800 marks as a maximum are assigned to Latin, 600 to Greek, 500 to chemistry, and 300 to each of the other physical sciences. But if we take the average working of the system for the last four years, we find that while sixty-eight per cent. of the maximum were given to candidates in Greek and Latin, only forty-five per cent. were accorded to candidates in chemistry, and but thirty per cent. to the other physical sciences. Schools sending up boys for competition naturally shun subjects which are dealt with so hardly and so heavily handicapped by the State.

Passing from learned or public professions to commerce, how is it that in our great commercial centres, foreigners—German, Swiss, Dutch, and even Greeks—push aside our English youth and take the places of profit which belong to them by national inheritance? How is it that in our colonies, like those in South Africa, German enterprise is pushing aside English incapacity? How is it that we find whole branches of manufactures, when they depend on scientific knowledge, passing away from this country, in which they originated, in order to engraft themselves abroad, although their decaying roots remain at home?† The answer to these questions is that our systems of education are still too narrow for the increasing struggle of life.

Faraday, who had no narrow views in regard to education, deplored the future of our youth in the competition of the world, because, as he said with sadness, "our schoolboys, when they come out of school, are ignorant of their ignorance at the end of all that education."

The opponents of science education allege that it is not adapted for mental development, because scientific facts are often disjointed, and exercise only the memory. Those who argue thus do not know what science is. No doubt an ignorant or half-informed teacher may present science as an accumulation of unconnected facts. At all times and in all subjects there are teachers without æsthetical or philosophical capacity—men who can only see carbonate of lime in a statue by Phidias or Praxiteles; who cannot survey zoology on account of its millions of species, or botany because of its 130,000 distinct plants; men who can look at trees without getting a conception of a forest, and cannot distinguish a stately edifice from its bricks. To teach in that fashion is like going to the tree of science with its glorious fruit in order to pick up a handful of the dry fallen leaves from the ground. It is, however, true that as science teaching has had less lengthened experience than that of literature, its methods of instruction are not so matured. Scientific and literary teaching have different methods; for while the teacher of literature rests on authority and on books for his guidance, the teacher of science discards authority and depends on facts at first hand, and on the book of Nature for their interpretation. Natural science more and more resolves itself into the teaching of the laboratory. In this way it can be used as a powerful means of quickening observation, and of creating a faculty of induction after the manner of Zadig, the Babylonian described by Voltaire. Thus facts become surrounded by scientific conceptions, and are subordinated to order and law.

It is not those who desire to unite literature with science who degrade education; the degradation is the consequence of the refusal. A violent reaction—too violent to be wise—has lately taken place against classical education in France, where their own vernacular occupies the position of dead languages, while Latin and science are given the same time in the curriculum. In England manufacturers cry out for technical education, in which classical culture shall be excluded. In the schools of the middle classes science rather than technics is needed, because, when the seeds of science are sown, technics as its fruit will appear at the appointed time. Epictetus was wise when he told us to observe that though sheep eat grass, it is not grass but wool that grows on their backs. Should, however, our grammar schools persist in their refusal to adapt themselves to the needs of a scientific age, England must follow the example of other European nations and found new modern schools in competition with them. For, as Huxley has put it, we cannot continue in this age "of full modern artillery to turn out our boys to do battle in it equipped only with the sword and shield of an ancient gladiator." In a scientific and keenly competitive age an exclusive education in the dead languages is a perplexing anomaly. The flowers of literature should be cultivated and gathered, though it is not wise to send men into our fields of industry to gather the harvest when they have been taught only to cull the poppies and to push aside the wheat.

IV. *Science and the Universities.*

The State has always felt bound to alter and improve universities, even when their endowments are so large as to render it unnecessary to support them by public funds. When universities are poor, Parliament gives aid to them from imperial taxation. In this country that aid has been given with a very sparing hand. Thus the universities and colleges of Ireland have received about £30,000 annually, and the same sum has been granted to the four universities of Scotland. Compared with imperial aid to foreign universities such sums are small. A single German university, like Strasburg or Leipsic, receives above £40,000 annually, or £10,000 more than the whole colleges of Ireland or of Scotland. Strasburg, for instance, has had her university and its library rebuilt at a cost of £711,000, and receives an annual subscription of £43,000. In rebuilding the university of Strasburg eight laboratories have been provided, so as to equip it fully with the modern requirements for teaching and research.* Prussia, the most economical nation in the world, spends £391,000 yearly out of taxation on her universities.

The recent action of France is still more remarkable. After the Franco-German War the Institute of France discussed the important question:—"Pourquoi la France n'a pas trouvé d'hommes supérieurs au moment du péril?" The general answer was because France had allowed university education to sink to a low ebb. Before the great Revolution France had twenty-three autonomous universities in the provinces. Napoleon desired to found one great university at Paris, and he crushed out the others with the hand of a despot, and remodelled the last with the instincts of a drill sergeant. The central university sank so low that in 1868 it is said that only £8,000 were spent for true academic purposes. Startled by the intellectual sterility shown in the war, France has made gigantic efforts to retrieve her position, and has rebuilt the provincial colleges at a cost of £3,280,000, while her annual budget for their support now reaches half a million of pounds. In order to open these provincial colleges to the best talent of France, more than 500 scholarships have been founded at an annual cost of £30,000. France now recognises that it is not by the number of men under arms that she can compete with her great neighbour Germany, so she has determined to equal her in intellect. You will understand why it is that Germany was obliged, even if she had not been willing, to spend such large sums in order to equip the university of her conquered provinces, Alsace-Lorraine. France and Germany are fully aware that science is the source of wealth and power, and that the only way of advancing it is to encourage universities to make researches and to spread existing knowledge through the community. Other European nations are advancing on the same lines. Switzerland is a remarkable illustration of how a country can compensate itself for its natural disadvantages by a scientific education of its people. Switzerland contains neither coal nor the ordinary raw materials of industry, and is separated from other countries which might supply them by mountain barriers. Yet, by a singularly good system of graded schools, and by the great technical college of Zurich, she has become a prosperous manufacturing country. In Great Britain, we have nothing comparable to this technical college, either in magnitude or efficiency. Belgium is reorganising its universities, and the State has freed the localities from the charge of buildings, and it will in future equip the universities with efficient teaching resources out of public taxation. Holland, with a population of 4,000,000 and a small revenue of £9,000,000, spends £136,000 on her four universities. Contrast this liberality of foreign countries in the

* Judges viii. 16.

† See Dr. Perkins' address to the Soc. Chem. Industry. *Nature*, Aug. 6, 1855, p. 333.

* The cost of these laboratories has been as follows:—Chemical Institute, £35,000; Physical Institute, £28,000; Botanical Institute, £26,000; Observatory, £25,000; Anatomy, £42,000; Clinical Surgery, £26,000; Physiological Chemistry, £16,000; Physiological Institute, £13,900.

Digitized by Google

promotion of higher instruction with the action of our own country. Scotland, like Holland, has four universities, and is not very different from it in population, but it only receives £30,000 from the State. By a special clause in the Scotch Universities Bill the Government asked Parliament to declare that under no circumstances should the Parliamentary grant be ever increased above £40,000. According to the views of the British Treasury there is a finality in science and in expanding knowledge.

The wealthy Universities of Oxford and Cambridge are gradually constructing laboratories for science. The merchant princes of Manchester have equipped their new Victoria University with similar laboratories. Edinburgh and Glasgow Universities have also done so, partly at the cost of Government and largely by private subscriptions. The poorer Universities of Aberdeen and St. Andrews are still inefficiently provided with the modern appliances for teaching science.

London has one small Government college and two chartered colleges, but is wholly destitute of a teaching university. It would excite great astonishment at the Treasury if we were to make the modest request that the great metropolis, with a population of four millions, should be put into as efficient academical position as the town of Strasburg, with 104,000 inhabitants, by receiving, as that town does, £43,000 annually for academic instruction, and £700,000 for University buildings. Still, the amazing anomaly that London has no teaching university must ere long cease.

It is a comforting fact that, in spite of the indifference of Parliament, the large towns of the kingdom are showing their sense of the need of higher education. Manchester has already its university. Nottingham, Birmingham, Leeds, and Bristol have colleges more or less complete. Liverpool converts a disused lunatic asylum into a college for sane people. Cardiff rents an infirmary for a collegiate building. Dundee, by private benefaction, rears a Baxter College with larger ambitions. All these are healthy signs that the public are determined to have advanced science teaching, but the resources of the institutions are altogether inadequate to the end in view. Even in the few cases where the laboratories are efficient for teaching purposes, they are inefficient as laboratories for research. Under these circumstances the Royal Commission on Science advocates special Government laboratories for research. Such laboratories, supported by public money, are as legitimate subjects for expenditure as galleries for pictures or sculpture; but I think that they would not be successful, and would injure science if they failed. It would be safer in the meantime if the State assisted universities or well-established colleges to found laboratories of research under their own care. Even such a proposal shocks our Chancellor of the Exchequer, who tells us that this country is burdened with public debt, and has ironclads to build and arsenals to provide. Nevertheless our wealth is proportionally much greater than that of foreign States, which are competing with so much vigour in the promotion of higher education. They deem such expenditure to be true economy, and do not allow their huge standing armies to be an apology for keeping their people backwards in the march of knowledge. France, which in the last ten years has been spending a million annually on university education, had a war indemnity to pay, and competes successfully with this country in ironclads. Either all foreign States are strangely deceived in their belief that the competition of the world has become a competition of intellect, or we are marvellously unobservent of the change which is passing over Europe in the higher education of the people. Preparations for war will not ensure to us the blessings and security of an enlightened peace. Protective expenditure may be wise, though productive expenditure is wiser.

"Were half the powers which fill the world with terror,
Were half the wealth bestowed on camps and courts,
Given to redeem the human mind from error—
There were no need of arsenals and forts."

Universities are not mere storehouses of knowledge; they are also conservatories for its cultivation. In Mexico there is a species of ant which sets apart some of its individuals to act as honey-jars by monstrously extending their abdomens to store the precious fluid till it is wanted by the community. Professors in a university have a higher function, because they ought to make new honey as well as to store it. The widening of the bounds of knowledge, literary or scientific, is the crowning glory of university life. Germany unites the functions of teaching and research in the universities, while France keeps them in separate institutions. The former system is best adapted to our habits, but its condition for success is that our science chairs should be greatly increased so that teachers should not be wholly absorbed in the duties of instruction. Germany subdivides the sciences into various chairs, and gives to the professors special laboratories. It also makes it a condition for the higher honours of a university that the candidates shall give proofs of their ability to make original researches. Under such a system, teaching and investigation are not incompatible. In the evidence before the Science Commission many opinions were given that scientific men engaged in research should not be burdened with the duties of education, and there is much to be said in support of this view when a single professor for the whole range of a physical science is its only representative in a university. But I hope that such a system will not long continue, for if it do we must occupy a very inferior position as a nation in the intellectual competition of Europe. Research and education in limited branches of higher knowledge are not incompatible. It is true that Galileo complained of the burden imposed upon him by his numerous astronomical pupils, though few other philosophers have echoed this complaint. Newton, who produced order in worlds, and Dalton, who brought atoms under the reign of order and number, rejoiced in their pupils. Lalande spread astronomers, as Liebig spread chemists and Johannes Müller biologists, all over the world. Laplace, La Grange, Dulong, Gay Lussac, Berthollet, and Dumas were professors as well as discoverers in France. In England our discoverers have generally been teachers. In fact I recollect only three notable examples of men who were not—Boyle, Cavendish, and Joule. It was so in ancient as well as in modern times, for Plato and Aristotle taught and philosophised. If you do not make the investigator a schoolmaster, as Dalton was, and as practically our professors are at the present time, with the duty of teaching all branches of their sciences, the mere elementary truths as well as the highest generalisations being compressed into a course, it is well that they should be brought into contact with the world in which they live, so as to know its wants and aspirations. They could then quicken the pregnant minds around them, and extend to others their own power and love of research. Goethe had a fine perception of this when he wrote—

Wer in der Weltgeschichte lebt,
Wer in die Zeiten schaut, und strebt,
Nur der ist werth, zu sprechen und zu dichten.

Our universities are still far from the attainment of a proper combination of their resources between teaching and research. Even Oxford and Cambridge, which have done so much in recent years in the equipment of laboratories and in adding to their scientific staff, are still far behind a second-class German university. The professional faculties of the English universities are growing, and will diffuse a greater taste for science among their students, though they may absorb the time of the limited professoriate so as to prevent it advancing the boundaries of knowledge. Professional faculties are absolutely essential to the existence of universities in poor countries like Scotland and Ireland. This has been the case from the early days of the Bologna University up to the present time. Originally universities arose not by mere bulls of popes, but as a response to the strong desire of the professional classes to dignify their crafts by real knowledge. If their education had been limited to mere technical schools like the Medical School of Salerno which flourished in the eleventh century, length but not breadth would have been given to education. So the universities wisely joined culture to the professional sciences. Poor countries like Scotland and Ireland must have their academic systems based on the professional faculties, although wealthy universities like Oxford and Cambridge may continue to have them as mere supplements to a more general education. A greater liberality of support on the part of the State in the establishment of chairs of science, for the sake of science and not merely for the teaching of the professions, would enable the poorer universities to take their part in the advancement of knowledge.

I have already alluded to the foundation of new colleges in different parts of the kingdom. Owens College has worthily developed into the Victoria University. Formerly she depended for degrees on the University of London. No longer will she be like a moon reflecting cold and sickly rays from a distant luminary, for in future she will be a sun, a centre of intelligence, warming and illuminating the regions around her. The other colleges which have formed themselves in large manufacturing districts are remarkable expressions from them that science must be promoted. Including the colleges of a high class, such as University College and King's College in London, and the three Queen's Colleges in Ireland, the aggregate attendance of students in colleges without university rank is between nine and ten thousand, whilst that of the universities is fifteen thousand. No doubt some of the provincial colleges require considerable improvement in their teaching methods; sometimes they unwisely aim at a full university curriculum when it would be better for them to act as faculties. Still they are all growing in the spirit of self-help, and some of them are destined, like Owens College, to develop into universities. This is not a subject of alarm to lovers of education, while it is one of hope and encouragement to the great centres of industry. There are too few autonomous universities in England in proportion to its population. While Scotland, with a population of 3¾ millions, has four universities with 6,500 students, England, with 26 millions of people, has only the same number of teaching universities with 6,000 students. Unless English colleges have such ambition, they may be turned into mere mills to grind out material for examinations and competitions. Higher colleges should always hold before students that knowledge, for its own sake, is the only object worthy of reverence. Beyond college life there is a land of research flowing with milk and honey for those who know how to cultivate it. Colleges should at least show a Pisgah view of this Land of Promise, which stretches far beyond the Jordan of examinations and competitions.

V. *Science and Industry.*

In the popular mind the value of science is measured by its applications to the useful purposes of life. It is no doubt true that science wears a beautiful aspect when she confers practical benefits upon man. But truer relations of science to industry are implied in Greek mythology. Vulcan, the god of industry, wooed science, in the form of Minerva, with a passionate love, but the chaste goddess never married, although she conferred upon mankind nearly as many arts as Prometheus, who, like other inventors, saw civilisation progressing by their use while he lay groaning in want on Mount Caucasus. The rapid development of industry in modern days depends on the applications of scientific knowledge, while its slower growth in former times was due to experiments being made by trial and error in order to gratify the needs of man. Then an experiment was less a questioning of Nature than an exercise on the mind of the experimentalist. For a true questioning of Nature only arises when intellectual conceptions of the causes of phenomena attach themselves to ascertained facts as well as to their natural environments. Much real science had at one time accumulated in Egypt, Greece, Rome, and Arabia, though it became obscured by the intellectual darkness which spread over Europe like a pall for many centuries. The mental results of Greek science, filtered through the Romans and Arabians, gradually fertilised the soil of Europe. Even in ages which are deemed to be dark and unprolific, substantial though slow progress was made. By the end of the fifteenth century the mathematics of the Alexandrian school had become

Digitized by Google

the possession of Western Europe; Arabic numerals, algebra, trigonometry, decimal reckoning, and an improved calendar having been added to its stock of knowledge. The old discoveries of Democritus and Archimedes in physics, and of Hipparchus and Ptolemy in astronomy, were producing their natural developments, though with great slowness. Many manufactures, growing chiefly by experience, and occasionally lightened up by glimmerings of science throughout the prevailing darkness, had arisen before the sixteenth century. A knowledge of the properties of bodies, though scarcely of their relations to each other, came through the labours of the alchemists, who had a mighty impulse to work, for by the philosopher's stone, often not larger than half a rape-seed, they hoped to attain the three sensuous conditions of human enjoyment, gold, health, and immortality. By the end of the fifteenth century many important manufactures were founded by empirical experiment, with only the uncertain guidance of science. Among these were the compass, printing, paper, gunpowder, guns, watches, forks, knitting-needles, horseshoes, bells, woodcutting and copper engraving, wire-drawing, steel, table glass, spectacles, microscopes, glass mirrors backed by amalgams of tin and lead, windmills, crushing and saw mills. These important manufactures arose from an increased knowlege of facts, around which scientific conceptions were slowly concreting. Aristotle defines this as science when he says, "Art begins when, from a great number of experiences, one general conception is formed which will embrace all similar cases." Such conceptions are formed only when culture develops the human mind and compels it to give a rational account of the world in which man lives, and of the objects in and around it, as well as of the phenomena which govern their action and evolution. Though the accumulation of facts is indispensable to the growth of science, a thousand facts are of less value to human progress than is a single one when it is scientifically comprehended, for it then becomes generalised in all similar cases. Isolated facts may be viewed as the dust of science. The dust which floats in the atmosphere is to the common observer mere incoherent matter in a wrong place, while to the man of science it is all-important when the rays of heat and light act upon its floating particles. It is by them that clouds and rains are influenced; it is by their selective influence on the solar waves that the blue of the heavens and the beauteous colours of the sky glorify all Nature. So, also, ascertained through isolated facts, forming the dust of science, become the reflecting media of the light of knowledge, and cause all Nature to assume a new aspect. It is with the light of knowledge that we are enabled to question Nature through direct experiment. The hypothesis or theory which induces us to put the experimental question may be right or wrong; still, *prudens questio dimidium scientiæ est*—it is half-way to knowledge when you know what you have to inquire. Davy described hypothesis as the mere scaffolding of science, useful to build up true knowledge, but capable of being put up or taken down at pleasure. Undoubtedly a theory is only temporary, and the reason is, as Bacon has said, that the man of science "loveth truth more than his theory." The changing theories which the world despises are the leaves of the tree of science drawing nutriment to the parent stems, and enabling it to put forth new branches and to produce fruit; and though the leaves fall and decay, the vary products of decay nourish the roots of the tree and reappear in the new leaves or theories which succeed.

When the questioning of Nature by intelligent experiment has raised a system of science, then those men who desire to apply it to industrial inventions proceed by the same methods to make rapid progress in the arts. They also must have means to compel Nature to reveal her secrets. Æneas succeeded in his great enterprise by plucking a golden branch from the tree of science. Armed with this even dread Charon dared not refuse a passage across the Styx; and the gate of the Elysian fields was unbarred when he hung the branch on its portal. Then new aspects of Nature were revealed—

"Another sun and stars they know
That shine like ours, but shine below."

It is by carrying such a golden branch from the tree of science that inventors are able to advance the arts. In illustration of how slowly at first and how rapidly afterwards science and its applications arise, I will take only two out of thousands of examples which lie ready to my hand. One of the most familiar instances is air, for that surely should have been soon understood if man's unaided senses are sufficient for knowledge. Air has been under the notice of mankind ever since the first man drew his first breath. It meets him at every turn; it fans him with gentle breezes, and it buffets him with storms. And yet it is certain that this familiar object—air—is very imperfectly understood up to the present time. We now know by recent researches that air can be liquified by pressure and cold; but as a child still looks upon air as nothing, so did man in his early state. A vessel with air was deemed to be empty. But man, as soon as he began to speculate, felt the importance of air, and deemed it to be a soul of the world upon which the respiration of man and the god-like quality of fire depended. Yet a really intelligent conception of these two essential conditions to man's existence—respiration and combustion—was not formed till about a century ago (1775). No doubt long before that time there had been abundant speculations regarding air. Anaximenes, 548 years before Christ, and Diogenes of Apollonia, a century later, studied the properties of air so far as their senses would allow them; so, in fact, did Aristotle. Actual scientific experiments were made on air about the year 1100 by a remarkable Saracen, Alhazen, who ascertained important truths which enabled Galileo, Torricelli, Otto de Guericke, and others at a later period to discover laws leading to important practical applications. Still there was no intelligent conception as to the composition of air until Priestley in 1774 repeated, with the light of science, an empirical observation which Eck de Sulbach had made three hundred years before upon the union of mercury with an ingredient of air and the decomposition of this compound by heat. This experiment now proved that the active element in air is oxygen. From that date our knowledge, derived from an intelligent questioning of air by direct experiments, has gone on by leaps and bounds. The air, which mainly consists of nitrogen and oxygen, is now known to contain carbonic acid, ammonia, nitric acid, ozone, besides hosts of living organisms which have a vast influence for good or evil in the economy of the world. These micro-organisms, the latest contribution to our knowledge of air, perform great analytical functions in organic nature, and are the means of converting much of its potential energy into actual energy. Through their action on dead matter the mutual dependence of plants and animals is secured, so that the air becomes at once the grave of organic death and the cradle of organic life. No doubt the ancients suspected this without being able to prove the dependence. Euripides seems to have seen it deductively when he describes the result of decay:—

"Then that which springs from earth, to earth returns,
And that which draws its being from the sky
Rises again up to the skyey height."

The consequences of the progressive discoveries have added largely to our knowledge of life, and have given a marvellous development to the industrial arts. Combustion and respiration govern a wide range of processes. The economical use of fuel, the growth of plants, the food of animals, the processes of husbandry, the maintenance of public health, the origin and cure of disease, the production of alcoholic drinks, the processes of making vinegar and saltpetre—all these and many other kinds of knowledge have been brought under the dominion of law. No doubt animals respired, fuel burned, plants grew, sugar fermented, before we knew how they depended upon air. But as the knowledge was empirical, it could not be intelligently directed. Now all these processes are ranged in order under a wise economy of Nature, and can be directed to the utilities of life; for it is true, as Swedenborg says, that human "ends always ascend as Nature descends." There is scarcely a large industry in the world which has not received a mighty impulse by the better knowledge of air acquired within a hundred years. If I had time I could show still more strikingly the industrial advantages which have followed from Cavendish's discovery of the composition of water. I wish that I could have done this, because it was Addison who foolishly said, and Paley who as unwisely approved the remark, "that mankind required to know no more about water than the temperature at which it froze and boiled, and the mode of making steam."

When we examine the order of progress in the arts, even before they are illumined by science, their improvements seem to be resultants of three conditions.

1. The substitution of natural forces for brute animal power, as when Hercules used the waters of the Alpheus to cleanse the Augean stables; or when a Kamchadal of Eastern Asia, who has been three years hollowing out a canoe, finds that he can do it in a few hours by fire.

2. The economy of time, as when a calendering machine produces the same gloss to miles of calico that an African savage gives to a few inches by rubbing it with the shell of the snail; or the economy of production, as when steel pens, sold when first introduced at one shilling a piece, are now sold at a penny per dozen; or when steel rails, lately costing £45 per ton, can now be sold at £5.

3. Methods of utilising waste products, or of endowing them with properties which render them of increased value to industry, as when waste-scrap iron and the galls on the oak are converted into ink; or the badly-smelling waste of gasworks is transformed into fragrant essences, brilliant dyes, and fertilising manure; or when the effete matter of animals or old bones is changed into lucifer matches.

All three results are often combined when a single end is obtained—at all events, economy of time and production invariably follows when natural forces substitute brute animal force. In industrial progress the sweat of the brow is lessened by the conceptions of the brain. How exultant is the old Greek poet, Antipator,* when women are relieved of the drudgery of turning the grindstones for the daily supply of corn. "Woman! you have hitherto had to grind corn, let your arms rest for the future. It is no longer for you that the birds announce by their songs the dawn of the morning. Ceres has ordered the *water-nymphs* to move the heavy millstones and perform your labour." Penelope had twelve slaves to grind corn for her small household. During the most prosperous time of Athens it was estimated that there were twenty slaves to each free citizen. Slaves are mere machines, and machines neither invent nor discover. The bondmen of the Jews, the helots of Sparta, the captive slaves of Rome, the serfs of Europe, and uneducated labourers of the present day who are the slaves of ignorance have added nothing to human progress. But as natural forces substitute and become cheaper than slave labour, liberty follows advancing civilisation. Machines require educated superintendence. One shoe factory in Boston by its machines does the work of thirty thousand shoemakers in Paris who have still to go through the weary drudgery of mechanical labour. The steam power of the world, during the last twenty years, has risen from 11½ million to 29 million horse-power, or 152 per cent.

Let me take a single example of how even a petty manufacture improved by the teachings of science affects the comforts and enlarges the resources of mankind. When I was a boy, the only way of obtaining a light was by the tinder box, with its quadruple materials, flint and steel, burnt rags or tinder, and a sulphur match. If everything went well, if the box could be found and the air was dry, a light could be obtained in two minutes; but very often the time occupied was much longer, and the process became a great trial to the serenity of temper. The consequence of this was that a fire or a burning lamp was kept alight through the day. Old Gerard, in his herbal, tells us how certain fungi were used to carry fire from one part of the country to the other. The tinder-box long held its position as a great discovery in the arts. The *Pyxidicula Igniaria* of the Romans appears to have been much the same implement.

* *Analecta Veterum Græcorum*, Epig. 39, Vol. II., p. 119.

Digitized by Google

though a little ruder, than the flint and steel which Philip the Good put into the collar of the Golden Fleece in 1429 as a representation of high knowledge in the progress of the arts. It continued to prevail till 1833, when phosphorous matches were introduced, though I have been amused to find that there are a few venerable ancients in London who still stick to the tinder box, and for whom a few shops keep a small supply. Phosphorous was no new discovery, for it had been obtained by an Arabian called Bechel in the eighth century. However, it was forgotten, and was rediscovered by Brandt, who made it out of very stinking materials in 1669. Other discoveries had, however, to be made before it could be used for lucifer matches. The science of combustion was only developed on the discovery of oxygen a century later. Time had to elapse before chemical analysis showed the kind of bodies which could be added to phosphorus so as to make it ignite readily. So it was not till 1833 that matches became a partial success. Intolerably bad they then were, dangerously inflammable, horribly poisonous to the makers and injurious to the lungs of the consumers. It required another discovery by Schrötter in 1845 to change poisonous waxy into innocuous red-brick phosphorous in order that these defects might be remedied, and to give us the safety match of the present day. Now what have these successive discoveries in science done for the nation, in this single manufacture, by an economy of time? If before 1833 we had made the same demands for light that we now do, when we daily consume eight matches per head of the population, the tinder box could have supplied the demand under the most favourable conditions by an expenditure of one quarter of an hour. The lucifer match supplies a light in fifteen seconds on each occasion, or in two minutes for the whole day. Putting these differences into a year, the venerable ancient who still sticks to his tinder box would require to spend ninety hours yearly in the production of light, while the user of lucifer matches spends twelve hours; so that the latter has an economy of seventy-eight hours yearly, or about ten working days. Measured by cost of production at one shilling and sixpence daily, the economy of time represented in money to our population is twenty-six millions of pounds annually. This is a curious instance of the manner in which science leads to economy of time and wealth even in a small manufacture. In larger industries the economy of time and labour produced by the application of scientific discoveries is beyond all measurement. Thus the discovery of latent heat by Black led to the inventions of Watt; while that of the mechanical equivalent of heat by Joule has been the basis of the progressive improvements in the steam engine which enables power to be obtained by a consumption of fuel less than one-fourth the amount used twenty years ago. It may be that the engines of Watt and Stephenson will yield in their turn to more economical motors; still they have already expanded the wealth, resources, and even the territories of England more than all the battles fought by her soldiers or all the treaties negotiated by her diplomatists.

The coal which has hitherto been the chief source of power probably represents the product of five or six million years during which the sun shone upon the plants of the carboniferous period, and stored up its energy in this convenient form. But we are using this conserved force wastefully and prodigally; for although horse-power in steam engines has so largely increased since 1864, two men only now produce what three men did at that date. It is only three hundred years since we became a manufacturing country. According to Professor Dewar, in less than two hundred years more the coal of this country will be wholly exhausted, and in half that time will be difficult to procure. Our not very distant descendants will have to face the problem, What will be the condition of England without coal? The answer to that question depends upon the intellectual development of the nation at that time. The value of the intellectual factor of production is continually increasing; while the values of raw material and fuel are lessening factors. It may be that when the dreaded time of exhausted fuel has arrived, its importation from other coal-fields, such as those of New South Wales, will be so easy and cheap that the increased technical education of our operatives may largely overbalance the disadvantages of increased cost in fuel. But this supposes that future Governments in England will have more enlightened views as to the value of science than past Governments have possessed.

Industrial applications are but the overflowing of science welling over from the fulness of its measure. Few would ask now, as was constantly done a few years ago, "What is the use of an abstract discovery in science?" Faraday once answered this question by another, "What is the use of a baby?" Yet round that baby centre all the hopes and sentiments of his parents, and even the interests of the State, which interferes in its upbringing, so as to insure it being a capable citizen. The processes of mind which produce a discovery or an invention are rarely associated in the same person, for while the discoverer seeks to explain causes and the relations of phenomena, the inventor aims at producing new effects, or at least of obtaining them in a novel and efficient way. In this the inventor may sometimes succeed without much knowledge of science, though his labours are infinitely more productive when he understands the causes of the effects which he desires to produce.

A nation in its industrial progress, when the competition of the world is keen, cannot stand still. Three conditions only are possible for it. It may go forward, retrograde, or perish. Its extinction as a great nation follows its neglect of higher education, for, as described in the proverb of Solomon, "They that hate instruction love death." In sociology, as in biology, there are three states. The first of balance, when things grow neither better nor worse; the second that of elaboration or evolution, as we see it when animals adapt themselves to their environments; and third, that of degeneration, when they rapidly lose the ground they have made. For a nation, a state of balance is only possible in the early stage of its existence, but it is impossible when its environments are constantly changing.

The possession of the raw materials of industry and the existence of a surplus population are important factors for the growth of manufactures in the early history of a nation, but afterwards they are bound up with another factor—the application of intellect to their development. England could not be called a manufacturing nation till the Elizabethan age. No doubt coal, iron, and wool were in abundance, though in the reign of the Plantagenets, they produced little prosperity. Wool was sent to Flanders to be manufactured, for England then stood to Holland as Australia now does to Yorkshire. The political crimes of Spain from the reign of Ferdinand and Isabella to that of Philip III. destroyed it as a great manufacturing nation, and indirectly led to England taking its position. Spain, through the activity and science of the Arabian intellect, had acquired many important industries. The Moors and the Moriscoes, who had been in Spain for a period as long as from the Norman Conquest of this country to the present date, were banished, and with them departed the intellect of Spain. Then the invasion of the Low Countries by Philip II. drove the Flemish manufacturers to England, while the French persecution of the Huguenots added new manufacturing experience, and with them came the industries of cotton, wool, and silk. Cotton mixed with linen and wool became freely used, but it was only from 1738 to the end of the the century that the inventions of Wyatt, Arkwright, Hargreaves, Crompton, and Cartwright started the wonderful modern development. The raw cotton was imported from India or America, but that fact as regards cost was a small factor in comparison with the intellect required to convert it into a utility. Science has in the last hundred years altered altogether the old conditions of industrial competition. She has taught the rigid metals to convey and record our thoughts even to the most distant lands, and, within less limits, to reproduce our speech. This marvellous application of electricity has diminished the cares and responsibilities of Governments, while it has at the same time altered the whole practice of commerce. To England steam and electricity have been of incalculable advantage. The ocean, which once made the country insular and isolated, is now the very life-blood of England and of the greater England beyond the seas. As in the human body the blood bathes all its parts, and through its travelling corpuscles carries force to all its members, so in the body politic of England and its pelasgic extensions, steam has become the circulatory and electricity the nervous system. The colonies, being young countries, value their raw materials as their chief source of wealth. When they become older they will discover it is not in these, but in the culture of scientific intellect, that their future prosperity depends. Older nations recognise this as the law of progress more than we do; or, as Jules Simon tersely puts it—"That nation which most educates her people will become the greatest nation, if not to-day, certainly to-morrow." Higher education is the condition of higher prosperity, and the nation which neglects to develop the intellectual factor of production must degenerate, for it cannot stand still. If we felt compelled to adopt the test of science given to Comte, that its value must be measured by fecundity, it might be prudent to claim industrial inventions as the immediate fruit of the tree of science, though only fruit which the prolific tree has shed. But the test is untrue in the sense indicated, or rather the fruit, according to the simile of Bacon, is like the golden apples which Aphrodite gave to the suitor of Atalanta, who lagged in her course by stooping to pick them up, and so lost the race. The true cultivators of the tree of science must seek their own reward by seeing it flourish, and let others devote their attention to the possible practical advantages which may result from their labours.

There is, however, one intimate connection between science and industry which I hope will be more intimate as scientific education becomes more prevalent in our schools and universities. Abstract science depends on the support of men of leisure, either themselves possessing or having provided for them the means of living without entering into the pursuits of active industry. The pursuit of science requires a superfluity of wealth in a community beyond the needs of ordinary life. Such superfluity is also necessary for art, though a picture or a statue is a saleable commodity, while an abstract discovery in science has no immediate or, as regards the discoverer, proximate commercial value. In Greece, when philosophical and scientific speculation was at its highest point, and when education was conducted in its own vernacular, and not through dead languages, science, industry, and commerce were actively prosperous. Corinth carried on the manufactures of Birmingham and Sheffield, while Athens combined those of Leeds, Staffordshire, and London, for it had woollen manufactures, potteries, gold and silver work, as well as shipbuilding. Their philosophers were the sons of burghers, and sometimes carried on the trades of their fathers. Thales was a travelling oil merchant, who brought back science as well as oil from Egypt. Solon and his great descendant Plato, as well as Zeno, were men of commerce. Socrates was a stone mason, Thucydides a gold miner, Aristotle kept a druggist's shop until Alexander endowed him with the wealth of Asia. All but Socrates had a superfluity of wealth, and he was supported by that of others. Now, if our universities and schools created that love of science which a broad education would surely inspire, our men of riches and leisure who advance the boundaries of scientific knowledge could not be counted on the fingers as they now are, when we think of Boyle, Cavendish, Napier, Lyell, Murchison, and Darwin, but would be as numerous as our statesmen and orators. Statesmen, without a following of the people who share their views and back their work, would be feeble indeed. But while England has never lacked leaders in science, they have too few followers to risk a rapid march. We might create an army to support our generals in science, as Germany has done, and as France is now doing, if education in this country would only mould itself to the needs of a scientific age. It is with this feeling that Horace Mann wrote:—"The action of the mind is like the action of fire; one billet of wood will hardly burn alone, though as dry as the sun and north west wind can make it, and though placed in a current of air; ten such billets will burn well together, but a hundred will create a heat fifty times as intense as ten—will make a current of air to fan their own flame, and consume even greenness itself."

VI.—*Abstract Science the Condition for Progress.*

The subject of my address has been the relations of science to the public weal. That is a very old subject to select for the year 1885. I began it by quoting the words of an illustrious prince, the consort of our Queen, who addressed us on the same subject from this platform twenty-six years ago. But he was not the first prince who saw how closely science is bound up with the welfare of States. Ali, the son-in-law of Mahomed, the fourth successor to the Caliphate, urged upon his followers that men of science and their disciples give security to human progress. Ali loved to say, "Eminence in science is the highest of honours," and "He dies not who gives life to learning." In addressing you upon texts such as these, my purpose was to show how unwise it is for England to lag in the onward march of science, when most other European Powers are using the resources of their States to promote higher education and to advance the boundaries of knowledge. English Governments alone fail to grasp the fact that the competition of the world has become a competition in intellect. Much of this indifference is due to our systems of education. I have ill fulfilled my purpose if, in claiming for science a larger share in public education, I have in any way depreciated literature, art, or philosophy, for every subject which adds to culture aids in human development. I only contend that in public education there should be a free play to the scientific faculty, so that the youths who possess it should learn the richness of their possession during the educative process. The same faculties which make a man great in any walk of life—strong love of truth, high imagination tempered by judgment, a vivid memory which can co-ordinate other facts with those under immediate consideration—all these are qualities which the poet, the philosopher, the man of literature, and the man of science equally require, and should cultivate through all parts of their education as well as in their future careers. My contention is that science should not be practically shut out from the view of a youth while his education is in progress, for the public weal requires that a large number of scientific men should belong to the community. This is necessary because science has impressed its character upon the age in which we live, and as science is not stationary but progressive, men are required to advance its boundaries, acting as pioneers in the onward march of States. Human progress is so identified with scientific thought, both in its conception and realisation, that it seems as if they were alternative terms in the history of civilisation. In literature, and even in art, a standard of excellence has been attained which we are content to imitate because we have been unable to surpass. But there is no such standard in science. Formerly, when the dark cloud was being dissipated which had obscured the learning of Greece and Rome, the diffusion of literature or the discovery of lost authors had a marked influence on advancing civilisation. Now, a Chrysoloras might teach Greek in the Italian universities without hastening sensibly the onward march of Italy; a Poggio might discover copies of Lucretius and Quintilian without exercising a tithe of the influence on modern life that an invention by Stephenson or Wheatstone would produce. Nevertheless, the divorce of culture and science, which the present state of education in this country tends to produce, is deeply to be deplored, because a cultured intelligence adds greatly to the development of the scientific faculty. My argument is that no amount of learning without science suffices in the present state of the world to put us in a position which will enable England to keep ahead or even on a level with foreign nations as regards knowledge and its applications to the utilities of life. Take the example of any man of learning, and see how soon the direct consequences resulting from it disappear in the life of a nation, while the discoveries of a man of science remain productive amid all the shocks of empire. As I am in Aberdeen I remember that the learned Dutchman Erasmus was introduced to England by the encouragement which he received from Hector Boece, the Principal of King's College in this University. Yet even in the case of Erasmus—who taught Greek at Cambridge and did so much for the revival of classical literature as well as in the promotion of spiritual freedom—how little has civilisation to ascribe to him in comparison with the discoveries of two other Cambridge men, Newton and Cavendish. The discoveries of Newton will influence the destinies of mankind to the end of the world. When he established the laws by which the motions of the great masses of matter in the universe are governed, he conferred an incalculable benefit upon the intellectual development of the human race. No great discovery flashes upon the world at once, and therefore Pope's lines on Newton are only a poetic fancy:—

"Nature and Nature's laws lay hid in night,
God said, 'Let Newton be,' and all was light."

No doubt the road upon which he travelled had been long in preparation by other men. The exact observations of Tycho Brahe, coupled with the discoveries of Copernicus, Kepler, and Galileo, had already broken down the authority of Aristotle and weakened that of the Church. But though the conceptions of the universe were thus broadened, mankind had not yet rid themselves of the idea that the powers of the universe were still regulated by spirits or special providences. Even Kepler moved the planets by spirits, and it took some time to knock these celestial steersmen on the head. Descartes, who really did so much by his writings to force the conclusion that the planetary movements should be dealt with as an ordinary problem in mechanics, looked upon the universe as a machine, the wheels of which were kept in motion by the unceasing exercise of a Divine power. Yet such theories were only an attempt to regulate the universe by celestial intelligences like our own, and by standards within our reach. It required the discovery of an all-pervading law, universal throughout all space, to enlarge the thoughts of men, and one which, while it widened the conceptions of the universe, reduced the earth and solar system to true dimensions. It is by the investigation of the finite on all sides that we obtain a higher conception of the infinite—

"Willst du ins Unendliche schreiten,
Geh nur im Endlichen nach allen Seiten.'

Ecclesiastical authority had been already undermined by earnest inquirers such as Wycliffe and Huss before Luther shook the pillars of the Vatican. They were removers of abuses, but were confined within the circles of their own beliefs. Newton's discovery cast men's minds into an entirely new mould, and levelled many barriers to human progress. This intellectual result was vastly more important than the practical advantages of the discovery. It is true that navigation and commerce mightily benefited by our better knowledge of the motions of the heavenly bodies. Still, these benefits to humanity are incomparably less in the history of progress than the expansion of the human intellect which followed the withdrawal of the cramps that confined it. Truth was now able to discard authority, and marched forward without hindrance. Before this point was reached Bruno had been burned, Galileo had abjured, and both Copernicus and Descartes had kept back their writings for fear of offending the Church.

The recent acceptance of evolution in biology has had a like effect in producing a far profounder intellectual change in human thought than any mere impulse of industrial development. Already its application to sociology and education is recognised, but that is of less import to human progress than the broadening of our views of Nature.

Abstract discovery in science is, then, the true foundation upon which the superstructure of modern civilisation is built; and the man who would take part in it should study science, and if he can advance it for its own sake and not for its applications. Ignorance may walk in the path lighted by advancing knowledge, but she is unable to follow when science passes her, for, like the foolish virgin, she has no oil in her lamp.

An established truth in science is like the constitution of an atom in matter—something so fixed in the order of things that it has become independent of further dangers in the struggle for existence. The sum of such truths forms the intellectual treasure which descends to each generation in hereditary succession. Though the discoverer of a new truth is a benefactor to humanity, he can give little to futurity in comparison with the wealth of knowledge which he inherited from the past. We, in our generation, should appreciate and use our great possessions—

"For me your tributary stores combine,
Creation's heir; the world, the world is mine."

NOTES.

DIVIDEND.—A return of 5s. per share is announced by the liquidator of the Devon and Cornwall Electric Light and Power Company.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending 31st August amounted to £3,780.

THE LALANDE-CHAPERON BATTERY.—The Lalande-Chaperon (oxide of copper) battery has been adopted for exchange and line service by the Société Générale des Téléphones of Paris.

TELEGRAMS FROM SPAIN.—A telegram from Spain, dated Sunday night, says:—There are still great delays in the transmission of telegrams from Madrid, and telegrams in cipher have been entirely stopped.

NOTES FROM THE FAR EAST.—The telegraph line opened to Bokhara is said to be much appreciated by the traders. The men sent to Bombay to learn the working of the electric light have returned to Cabul.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th September are £2,027, as compared with £2,134 in the corresponding period of 1884.

ANTWERP EXHIBITION AWARDS.—The "Phœnix" dynamo has been awarded a gold medal at the Antwerp Exhibition.—The Patent "Berthoud-Borel" Electric Cables of the Kinetic Engineering Company have also obtained a gold medal.

THE TELEPHONE IN BELGIUM.—The subscribers to the different telephone exchanges in Belgium continue to increase in number. At the end of July, 1885, there were 774 subscribers in Brussels; 971 in Antwerp; 198 in Charleroi; 374 in Ghent, and 356 in Verviers.

INTERRUPTIONS.—It is announced that the cables between Dominica and Martinique, and between St. Vincent and Grenada are interrupted, thus cutting communication with Martinique, St. Lucia, St. Vincent, and Barbadoes. Messages can be sent by special boat with a delay of about five hours.—The cable between Fao and Bushire is also interrupted.

THE SS. "SHERARD OSBORNE."—The Eastern Extension, Australasia, and China Telegraph Company's steamer the "Sherard Osborne," Captain Worsley, left the New Harbour Docks (Straits Settlements), on August 5th, for Sydney and Melbourne, to lay a cable between the last-named place and Tasmania, and then to proceed to New Zealand to repair the cable in Cooks' Straits.

A CURIOUS ACCIDENT.—The *Scientific American* contains an account of a curious accident which recently happened at Camilla, N.Y. It appears that five horses were standing with their necks over a wire fence, when suddenly a flash of lightning struck the fence at a distance of 1,000 feet from the animals. The current traversed the wire, and went to earth through the horses, killing them instantly.

APPOINTMENT.—Mr. Reginald Webb, who has for the last five years occupied a post in the office of the accountant to the Anglo-American Telegraph Company, has just been appointed traffic manager to the West Coast of Africa Telegraph Company, and will proceed soon to Bathurst, near the Gambia. The cables will be made and laid by the India Rubber, Gutta Percha, and Telegraph Works Company.

AN ELECTRIC RAILWAY FOR BOSTON, U.S.A.—It is reported that Boston will soon have an opportunity to see the practical workings of the electric railway system on one of her streets. A line is being laid on Huntington-avenue in connection with the Metropolitan Street Car line. If it works satisfactorily there, after a thorough test, it will probably be adopted on some one or more of the roads in Boston.

THE ELECTRIC TRAMWAY AT BLACKPOOL.—As a result of Major-General Hutchinson's recent inspection of the electric tramway line on the Promenade at Blackpool, the town clerk has received the certificate of the Board of Trade that the permanent way is fit for public traffic. It is expected that the line will be worked by horses until the *fête* on September 29th, when it will be formally opened by the Mayor of Manchester, and the cars run by electricity.

UNDERGROUND WIRES IN BROOKLYN.—It is stated that the Brooklyn Commission on putting electric light wires underground will begin an experiment with the wires of the New York and New Jersey Telephone Company, on Fulton and Washington Streets. It is said that there are in that city 5,508 telegraph poles, 3,855⅝ miles of overhead wires, and 6·21 miles of cables. Additions by the Fire Department to the overhead wires will make the length 3,900 miles.

THE ELECTRIC LIGHT IN AN ABBEY.—The electric light has been installed in La Trappe de Bonneval (Aveyron). The dynamo, a small one, giving 15 amperes with a difference of potential at the terminals of 45 volts, is driven from a turbine, and charges a battery of 20 accumulators. The lamps employed are, of course, incandescents, of 2, 5, and 10 candle-power. Of the first there are 18 (8 volts, 0·9 ampere), 8 of the second (12 volts, 1 ampere), and 12 of the latter (34 volts, 0·8 ampere).

MALTON PUBLIC LIGHTING.—The Malton Local Board have lately taken the unusual step of advertising for tenders for the lighting of the public lamps of the borough. The clerk said that only one tender—that of the Malton Gas Company—had been received. Mr. Webster, the borough surveyor, reported that he had an offer to light the town by electricity, but the clerk reported that he was only instructed to advertise for gas tenders. Malton has something to learn yet, evidently.

POST OFFICE TELEGRAPHS.—At a recent meeting of the Wirrall Highway Board an application was read from the superintending engineer of the Postal Department, requesting the Board's permission to open up the ground on the Chester and Birkenhead-road between Backford Canal Bridge and Union-street, Tranmere, for the purpose of laying down a line of 3in. cast-iron socket pipes and telegraphs from Chester to Birkenhead. The request was granted, subject to the usual conditions.

THE TELEPHONE IN VENEZUELA.—The returns from Venezuela received by the Inter-Continental Telephone Company show that the result of the business for the quarter ending June 30th, 1885, was:—From rentals of subscribers at Caracas, La Guayra, Valencia and Porto Cabello, 7,880·91 dols.; from trunk lines between the cities, 3,172·50 dols.; total gross, 11,053·41 dols.; expenses same period, 4,616·77 dols.; net profits, 6,436·64 dols.; as against net profits for the first quarter of this year, 5,232·59 dols.; gain, 1,204·05 dols.

AN IMPUDENT THEFT.—It was recently discovered at Conshohocken, Pa., that three unknown thieves had mounted the telegraph poles from West Conshohocken to Bala station, a distance of seven and a half miles, and had stripped and stolen two lines of copper telegraph wire of the Postal Telegraph Company. The total length of wire stolen is 15 miles, weight nearly a ton, and value £100. The thieves operated in broad

Digitized by Google

daylight, passing along the road in a waggon, removing the wire and acting as if they were authorised *employés*.

CONTINENTAL ITEMS.—The installation in the Theatre Royal, Berlin, has given great satisfaction. The precincts of the Cathedral at Milan are now lighted by 15 arc lights of 1,000 c.-p. each. The New Theatre, which will be opened at Naples on the 1st proximo, has been provided with an installation of the electric light to the exclusion of all other illuminants. An installation is about to be put down in the workshops in connection with the construction of the large bridge over the Pô for the Parma-Casal-Maggiore-Piaderna Railway.

TOOK IT FOR A FIRE!—Our American namesake says:—At the southern limit of Chicago, on Cottage Grove-avenue, a new arc plant was recently installed, and the light suddenly flashed upon the vision of a fireman in the adjoining town of Lake. As the source of the light was hidden from view, and as he was unaware of the existence of the plant, duty compelled him to turn in a fire alarm. This is about as near as Chicago has ever come to having a fire from electric lighting, and should be noticed by the gas people as "almost a dangerous fire from electricity."

A CURIOUS EFFECT OF ELECTRICITY!—At the Croydon Borough Police-court recently, an elderly man, describing himself as an engineer, without a home, was charged with being a lunatic at large, and not under proper control. An officer said he found the defendant conducting himself in a peculiar way in North-end on the previous night. The defendant: "May I speak a word?" The Mayor: "Yes; certainly." The defendant: "I will tell you what has upset me. It is this American coming over here and charging the earth so heavily with electricity that has caused me to go giddy in my head." The Mayor sent him to the infirmary.

THE ELECTRIC LIGHT IN GUAYAQUIL, EUCADOR.—The Thomson-Houston International Electric Company has, we are informed, made a contract for furnishing a large electric light plant, combining arc and incandescent lights, for the city of Guayaquil, Ecuador, where a local company has been formed. The city has agreed to adopt the system permanently for street lighting purposes, and the present plant will be increased as rapidly as possible. The entire city will require about 150 arc lamps, besides a large installation of incandescents, which have already been ordered.

THE SELF-INDUCTION OF A COIL.—In order to determine the self-induction of a coil, the following method may with advantage be employed. Divide the current from a constant battery between a galvanometer circuit, in which is a coil, and a shunt circuit. At a given moment of time interrupt the shunt circuit and then the galvanometer circuit. Now, if P be the self-induction of the coil, it can readily be calculated from the throw of the galvanometer needle, the exact interval of time between the two interruptions having, of course, been correctly ascertained.

THE EARTHQUAKES.—The *Official Messenger* states that the city of Namangan, in Ferghana, where Skobeleff distinguished himself in the campaign against Khokand, has been visited all through the summer by repeated shocks of earthquake, which have hitherto been of very rare occurrence in those parts. The strongest shocks took place on April 17th and August 4th, but no very serious consequences resulted.—Repeated shocks of earthquake have occurred in the south-east of Lower Austria and in the north of Styria, and have been followed by shocks in Bosnia, described as moving from east to west.

APPOINTMENT.—We are informed that the vacant Chair of Physics and Engineering in University College, Bristol, has been filled by the appointment to the post of Prof. John Ryan, M.A., King's College, Cambridge, D.Sc., London, and member of the Institute of Mechanical Engineers. Dr. Ryan, who is a practical engineer, has hitherto held the appointment of Professor of Mechanics and Engineering in University College, Nottingham. At Bristol he succeeds Prof. Thompson, now Principal of the Finsbury Technical College, and Prof. Hele Shaw, recently appointed to the Professorship of Engineering in University College, Liverpool.

TELEPHONE CABLES.—We understand that Messrs. W. F. Dennis and Co. are continuing to receive large orders for Felten and Guilleaume's anti-induction telephone cables. Among the more recent demands, we may mention those of the Lancashire and Cheshire Telephonic Exchange Company for one and a-half mile lead covered cable, No. 19, copper; the Swiss Confederation Telegraph Department, seven miles of 27 core cable; Royal Bavarian Postal and Telegraph Department, four and a-half miles for the Nuremburg telephonic system; Copenhagen Telephone Company, 13 miles, 27 core; Imperial German General Post Office, nine miles, 27 core; &c., &c.

MEASUREMENT OF DISTANT TEMPERATURES.—At the Academy of Sciences, St. Petersburg, recently, Dr. Lent described a new and accurate method of measuring distant temperatures. This, it would appear, is based upon the known fact that a thermo-electric current is produced in an arrangement of two wires of dissimilar metals, such as iron and silver, soldered at their two extremities, when one of the junctions is at a different temperature to the other. A galvanometer is put into circuit, and the union at one station is gradually heated until the deflection shown by the galvanometer disappears. When this is the case the two temperatures would presumably be equal.

ARC LIGHTS AT THE ANTWERP EXHIBITION.—The arc lamps lighting the Antwerp Exhibition are distributed as follows:—Compagnie Générale d'Electricité of Brussels, 25 Gülcher (six with reflectors), 9 Gramme, and 8 Jablochkoff arcs; Société l'Electrique de Brussels, 45 Brush arcs; Ganz and Co., of Buda-Pesth, 20 Zipernowsky arcs; Heilman du Commun, of Mulhouse, 13 Gramme and Cance arcs; M. Jaspar, of Liège, 32 De Puydt and 6 Jaspar arcs; M. Pieper, of Liège, 24 Pieper arcs; Scrive, Hermite and Co., of Lille, 52 Patterson arcs; Spiecker and Co., of Cologne, 32 Spiecker arcs; Société des Forges de Gilly, 4 Crompton arcs; Schuckert and Co., 22 Piette and Krizick arcs. Besides these there are, of course, a large number of incandescents.

DEPREZ'S PROPORTIONAL GALVANOMETER.—According to the *Centralblatt für Elektrotechnik* this galvanometer consists of five permanent steel magnets of horseshoe shape placed horizontally one above the other, a pole piece being fitted on each leg of this compound magnet. The two pole pieces are hollowed out to a true cylinder, inside which is suspended an iron tube having a coil of wire wound on it, lengthwise. The iron cylinder, being close to the pole pieces, the magnetic field is both powerful and uniform. The iron cylinder and its coil of wire are supported by two stretched wires, one above and the other below, which serve at the same time to make connection to the coil. A pointer and scale complete the instrument, which gives reliable readings up to 120°.

CABLES FOR THE INDIAN GOVERNMENT.—The India Rubber, Gutta Percha, and Telegraph Works Company are at present shipping into their steamers "Dacia" and "Inter-

Digitized by Google

national" 513 miles of cable for the Indian Government, to be used for renewal of part of the first Persian Gulf Cable, laid in 1864. The whole work is being carried out under the superintendence of Lieut.-Colonel S. V. Bateman-Champain, R.E., the Director-in-Chief of H.M. Indo-European Telegraph Department, assisted by Sir H. Mance, C.I.E., the inventor of the heliograph. The testing of the cable during manufacture has been entrusted to the well-known firm of Clark, Forde, and Taylor, and Mr. F. C. Webb has also been consulted as to the machinery, distribution, of the cable and list of stores.

LAUNCH OF THE "RECORDER."—Recently Messrs. Robert Napier and Sons launched from their shipbuilding yard at Govan a steel telegraph cable steamer for the Eastern Extension, Australasia, and China Telegraph Company. The vessel, which was named the "Recorder," is something similar in construction to the "Magneta," lost last winter. She is 320 by 32 feet, and 24 feet deep, with a tonnage of 1,150. Her engines are of the compound type, capable of driving the ship at a speed of about 12½ knots an hour. Being intended for laying and repairing submarine cables, the vessel has been fitted with all the necessary gear and appliances, and has been subdivided into no less than 27 watertight compartments. The "Recorder" has been classed 100A at Lloyd's under special survey.

VON BEETZ'S GALVANOMETER.—This galvanometer, which has been designed for the purpose of experimental demonstration to large audiences, is constructed as follows:—In the centre of a circular metal plate, fitted with levelling screws, is a copper damper for the bell magnet, which is suspended from a fibre. On the damper are mounted two small columns, which carry the suspension tube. On one side of the suspended needle is a coil of thick wire, on the other side a coil of thin wire, the connections to which are carried through the base plate. Concentric with the axis of the needle is a large upright metal ring on which the divisions are marked in large figures. To the suspension of the needle is fixed a straw, carrying at its end a piece of white paper, which moves over the upright scale.

CAMBRIDGE LOCAL EXAMINATIONS.—The forms of entry for the Cambridge Local Examinations, to be held Dec. 14-19, can now be obtained from the local secretaries. All forms must be returned, duly filled, before Oct. 1. There will be a Higher Local Examination on the same days (in Groups B and C only), at the Cambridge centre, and also at the London centre, if a sufficient number of candidates apply to the local secretary before the 30th inst. The Syndicate have made the following alterations in their regulations for December:—Alternative papers will be set on Friday afternoon, Dec. 18, from 3 to 5 p.m., in the following subjects, for the convenience of candidates who wish to take papers set at the same time with these on Saturday morning:—Juniors: Mechanics (Sec. 7). Seniors: Statics, Dynamics, and Astronomy (E. 3); Statics, Dynamics, and Hydrostatics (F. c); Electricity and Magnetism (F. e).

THE TELEPHONE IN WEST CUMBERLAND.—Telephonic communication has recently been opened from the Whitehaven Exchange to the Parkside Mining Company's mines at Frizington, and to the mine of the Maryport Hematite Iron Company at Pallaflat. The opening of these routes completes the skeleton of the National Telephone Company's West Cumberland system, with the exception of the projected spur from Workington to Cockermouth, for which sufficient support has not been obtained. It is now possible to telephone from Whitehaven to Frizington and Pallaflat on the one hand, and to Workington and Maryport on the other, as well as between any two of those places. The longest distance that can be telephoned over at present in West Cumberland is about twenty-one miles, namely from Maryport to Pallaflat. In other districts the National Company have wires of over fifty miles in length.

SOME AMERICAN NOTES.—A proposition was recently made by a representative of the Evanston, Ill., Electric Light Company, to the trustees of that village, to light the streets by means of electricity. For the sum of 3,000 dols. the company proposes to place 30 arc lights at points where the trustees may direct, and maintain the same. In return they want an ordinance giving them the exclusive right to operate and maintain the business of electric lighting, together with the necessary license for erecting poles, &c.—A contract was signed 28th August, in New York City, by the American Electric Manufacturing Company and E. A. Noyes, chairman of the Street-Lighting Committee of Portland, Me., providing for the lighting of the streets of that city by electricity, at a cost of 25,000 dols. per year.—Fargo is preparing to erect three electric light towers.—Meadville, Pa., is contemplating having an electric light plant.

UNDERGROUND WIRES IN NEW YORK.—The Commission on Electrical Subways has held several meetings for the reception of plans for burying the wires. The following resolution was adopted on 13th August:—"Resolved, That every corporation, association, or person using or desiring to use any electrical conductor in the City of New York, do forthwith file with this Board such map or maps and other suitable descriptions as will fully inform this Board concerning the location, courses, termini, space, and all other details and requirements concerning the electrical conductors operated or desired to be operated by such corporation, association, or person in the City of New York, to the end that this Board may be enabled to make due provision for said conductors in the general plan and subway to be devised as aforesaid, and which it has full authority to require to be used for all the electrical conductors aforesaid."

LIGHTNING-STRUCK TREES.—A correspondent of *The Times* writes as follows:—"The most probable cause of the liability of certain trees to be struck by lightning is that they are bad conductors of electricity. The suggestion that oak trees are struck because they contain iron is both erroneous and absurd. If oak did contain iron it would in all probability increase its conducting power and act as a preservative. If oak contained an estimable quantity of that metal the wood would turn black on exposure to air, on account of the tannin which is present. This blackening may be seen surrounding the iron nails in any oak fence. The contour of the ground, nature of the soil, and the presence or absence of water have more influence in deciding the locality of an electric discharge than the height of a tree. Add to this the difference in conductivity between various woods and we have at once an explanation of the apparent peculiarity of tall trees escaping unharmed while shorter trees are destroyed."

RECENT INSTALLATIONS.—Messrs. B. Verity and Sons, of Covent Garden, have obtained the contract for the whole of the electric lighting at the new Constitutional Club next to the Grand Hotel, Northumberland Avenue. A view of this new building appeared in the *Graphic* a fortnight ago. There are to to be over 700 lamps in all, the light being also used in the kitchens, &c., and the machinery being in complete duplicate; the total capacity of the entire plant is to be 1,500 lamps. High-speed engines and the newest type of Edison dynamo machines, made in New York, will be used. Special double pole safety-blocks in earthenware will be used for this

Digitized by Google

installation. No expense will be spared to make this a model installation. We believe Sir Wm. Thomson is to be the advising electrician. The same firm are also installing nearly 600 16 candle-power incandescent lamps in the Criterion Restaurant. Owing to the extensive character of the building the wiring is of a difficult character. The grill room and buffet are already lighted up, the fixtures being glass pendants of quite a new design.

THE INSTITUTION OF CIVIL ENGINEERS.—From an abstract recently issued by the Institution, we notice amongst the subjects upon which original communications are invited by the Council the following:—"Electric-motors; their theory, practical construction, efficiency, and power." "The Construction of Dynamo-electric Machines and their Prime-movers." "The Working and Cost of the Treble and Double-wire Systems of Distributing Currents for Electric Lighting," and "Thermo electric Batteries, and their Application to Electric Lighting, Electro-plating, and other purposes." Among the premiums awarded for papers during the Session, 1884-85, are the following:—A Telford medal and a Telford premium to Peter William Willans, for his paper on "Electrical Governors;" a Telford premium to Andrew Jamieson, F.R.S.E., Assoc. M.Inst.C.E., for his paper "Electric Lighting for Steamships;" a Telford premium to Claude William Kinder, Assoc. M.Inst.C.E., for his paper "Notes on Electric Blasting in China;" and a Miller prize to Frank Geere Howard, Stud. Inst. C.E., for his paper on "Secondary Batteries."

A LABORATORY EXPERIMENT.—An investigation has been made by Herr W. Peukert, at the laboratory of the Technical High School of Hanover, for the purpose of determining how much of the electrical energy supplied to different types of incandescent lamps reappears as light and heat respectively. In these experiments the heat evolved from the lamps was ascertained by registering the rise in temperature of a weight of water in which they were immersed for a stated time. The photometrical measurements were made by the aid of Von Hefner-Alteneck's normal flame. The illuminating power of the various lamps experimented upon was recorded while they were immersed in water as well as when hanging in air, the loss of light in the former case being from one twenty-fifth to one-eighth with different lamps. As the result of Herr Peukert's examination, it appears that in one of Siemens and Halske's 8-candle incandescent lamps, 74 per cent. of the total work of the current was lost as heat, while 26 per cent. was represented by the light emitted. With Edison's 16-candle lamp, 66 per cent. of the current was returned as heat, and 34 per cent. as light. In Swan's 30-candle lamp, 72 per cent. of the current was transformed into heat, and 28 per cent. into light.

MURDER.—The American papers contain an account of a murder which occurred in the city of Lawrence, Mass., on August 27, both parties being well known citizens who had been intimately associated with each other in the telephone business. Henry K. Goodwin, at ten o'clock on the morning of that day, called upon Albert D. Swan at his office, where they engaged in conversation regarding previous business transactions. The bookkeeper in the adjoining room was soon after startled by the sound of a pistol shot, and turning quickly saw Mr. Swan reel and clutch the corner of his desk, with blood spurting from a wound in the back of his head. He fell to the floor and died in a few moments. Goodwin, who had deliberately shot him with a 32-calibre revolver, walked over to the telephone, notified the police that he had committed the deed, and offered to deliver himself up. He alleged that Swan had robbed him of all he possessed. The murderer was one of the pioneers in the telephone business, which he embarked in as a member of the firm of Goodwin and Caldwell. Selling out to Swan and his partner, he went to Buenos Ayres in charge of the Bell telephone system there. Returning two years ago he entered the employ of the Molecular Company. He is a native of Lawrence, where he has a family, and is about thirty-eight years of age.

CONCOCTED TELEGRAMS.—"It must be obvious to every one that the great telegraph companies have it in their power (and it would certainly be to the interest of their shareholders) to expose and put an end to the shameless manufacture of pretended foreign telegrams. When they find that a message has been entirely fabricated, or that it has been imprudently 'expanded,' they owe it as a duty to the public to at once declare what was really the number of words, if any, which passed through their wires. Slight discrepancies explainable by the addition of articles and other unimportant words for the sake of greater clearness no one would consider a reproach. Deliberate manufacture, however, should be mercilessly exposed, and thus the public would not only be able to give credit to enterprise where credit is really due, but would have a means, at present denied to them, of judging of the authenticity of the news submitted to them." The foregoing appeared in the correspondence columns of a recent issue of the *The Times*. Its author has apparently not taken into consideration two facts, *i.e.*, that the telegraph companies are paid to transmit messages and not to gossip (secrecy is, of course, the most essential point); and that if they were disposed to commit what would be nothing less than a breach of confidence, it would be impossible for them to speak with any degree of certainty, for the reason that a very large number of the messages transmitted by them are in code, and the mere mention, therefore, of the precise number of words contained in any particular telegram passing over these lines would afford no indication to the actual number in its text.

THE NEW TARIFF FOR TELEGRAMS.—A correspondent of the *Daily Chronicle* takes exception to the charge of 2d. made by the postal authorities for telegram receipts. He says:—"It is stated upon the new form of telegram that 'a receipt for the charges on this telegram can be obtained, price 2d.' It is not easy to understand the existence of any considerable demand for such a receipt or why so much should be charged for the rendering of so small a service, and in contrast with the considerable reduction made by the new rate it seems very disproportionate. The idea of charging 2d. for giving a receipt for 6d. is a shock to common sense, and is absurd. I venture to suggest that a 1d. at the most should be charged for this receipt, and that for 2d. the telegraph officials should examine and stamp with the stamp of the office, as certifying the same to be correct, a copy of the telegram to be made by the sender. Under the last Bankruptcy Act the contracting stationers of the Court made, examined, and obtained the seal of the Court to copies of documents filed at a remuneration of 2d. per folio of 72 words, and I have reason to believe the contract was not unprofitable to them. The Post Office might well, then, for this sum peruse and stamp a paper containing on the average not a quarter of such a length. If the suggestion I make be adopted it will, I believe, be a great gain to those engaged in professional life, as well as to those engaged in the circles of commerce."

THE ELECTRIC LIGHT AND COLLIERIES.—An installation of incandescent lamps, supplied by the Maxim Weston Electric Company, and fitted up under the supervision of Mr. W. C. Cockburn, their agent in Newcastle, was recently tested at Ashington Colliery. The Ashington Company naturally

Digitized by Google

desire to have their heapstead illuminated as perfectly as possible, and no expense has been spared to achieve that end. There are three dynamos, two of which are capable of supplying 60 circuits of 20 candle-power, and thirty of 50 candle-power. At present, however, only about fifty 20-candle and twelve 50-candle lamps have been fitted. The third dynamo is to work two arc lamps of 2,000 candle-power. The incandescent lamps are distributed at the pit heap and screens, and when in use gave a steady glow that is much admired. It is evident that but trifling alteration of position is requisite to make their application a perfect success. The two arc lamps, suspended at the extreme ends of the heapstead, and intended to illuminate the sidings, &c., give the utmost satisfaction. On the occasion of the trial run they burned clearly and steadily during the whole of the night, and gave a beautiful illumination of the area in front of the pit. The company seem to have made colliery illumination a special feature, for they have already fitted up Cornsay, Burradon, and Page Bank Collieries, and made an installation at Backworth a few nights ago.

A Plea for De Sauty.—In a letter to the American *Operator*, and under the above title, Mr. T. D. Lockwood gives a brief biographical sketch of Mr. C. V. de Sauty, who will be known to many of our readers. The following is the substance of Mr. Lockwood's letter:—"Mr. C. V. de Sauty was simply the operator—nothing more—at the Newfoundland end of the short-lived Atlantic cable of 1858. The cable of 1858 was successfully landed on 6th August, and was operated by the 10th; it worked with some degree of success until the 1st of September, exactly 23 days. The messages show Mr. de Sauty to have been what he truly was, an industrious, ingenious, able and careful electrician. He had no particular desire to be immortalised as an optimist in cable matters, but he naturally telegraphed from Newfoundland to New York to his superiors the state of the cable from day to day, and they equally naturally published his statements. The cable lived long enough to save the British Government 250,000 dols., by enabling them to regulate the movement of troops, and finally gave out on the very day that the New York celebration in its honour was held, after four hundred messages, comprising 21,421 letters had been transmitted over it and understood, ten messages having been transmitted on the very last day of its life, September 1, 1858. De Sauty, instead of being desirous of issuing daily bulletins of 'all right,' was noted for his extreme reticence, and only occasionally could be induced to say anything about the cable; and once visited by some United States coast survey officers, refused to allow them to enter the office or examine the apparatus. He was subsequently engaged on the later expedition of 1865, acting as electrician on the 'Great Eastern,' and in 1866 was appointed electrician of the Malta and Sicily Cable Company. Still later he filled for some years with great ability the office of electrician of the Gibraltar and African Cable, being stationed at Gibraltar, and while there made seem valuable inventions in duplexing submarine cables. I have for some time lost sight of him, but I am of the impression that he died about two years ago." We are happy to be able to give our readers and Mr. Lockwood some further information in regard to this gentleman, and to correct one or two of the statements contained in the letter we have quoted. Subsequent to the decease of the 1858 cable Mr. de Sauty was engaged as electrician-in-chief of the firm of Messrs. Glass, Elliot, and Co., afterwards the Telegraph Construction and Maintenance Company, and on the later Atlantic Expedition of 1865 acted as electrician on the "Great Eastern." After the 1866 Atlantic Expedition he visited New Zealand, where he remained in the telegraphic service until 1870, when he joined the Falmouth, Gibraltar, and Malta Telegraph Company, and was appointed superintendent at Gibraltar. He is still alive, and retains direction of the Gibraltar station in the service of the Eastern Telegraph Company.

The Bessbrook and Newry Electric Tramway.—On Saturday last a special trip was made over the new electric tramway line from Newry to Bessbrook, the construction of which has just been completed, and the official inspection of which has just taken place. Amongst those present at the trial trip were Mr. J. L. D. Mears, C.E. (chief engineer of the line), Dr. John Hopkinson, F.R.S., London; Dr. Edward Hopkinson, electrical engineer; and others. The new line, although but little more than half the length of the Portrush and Bushmills line, yet presents many new and improved features. One great difficulty in connection with all railways and tramways heretofore has been that the rolling stock cannot be used on the ordinary public roads. This difficulty, we are informed, the promoters of the Newry and Bessbrook Tramway Company have solved in a most satisfactory manner. The generating dynamos, two in number, have been fixed at Millvale, where a turbine has been erected. They are of the Edison-Hopkinson type, manufactured by Messrs. Mather and Platt, of Manchester. The present machines were designed by Dr. Edwd. Hopkinson especially for the purposes of this line. The current from the generating dynamos is conveyed from a convenient switch-board to a central rail, and from this rail the current is conducted to the receiving dynamos on the car. The cars are geared so as to run at a maximum speed of fifteen miles per hour, and this speed is easily attained. They are carried on bogies at either end, and though 35 feet long pass easily over any of the turns or curves on the line. At each terminus there is a pear-shaped loop, around which the cars pass for reversal and return. The line has been constructed, not on the public road, but across the country. Only at one point does it touch the public road, namely, at Millvale, where there is a level crossing over fifty yards in extent. The electric conductor at this point is stretched overhead, at a height of 15 feet, supported at either end by poles. This plan has been patented by Dr. John Hopkinson, F.R.S., and would of course be applicable for the whole line if so desired. The plan, by which the difficulty has been overcome and by which the waggons used on this line can be also used on the ordinary public roads, &c., is the invention of Mr. Henry Barcroft, of Newry. The wheels of the waggon are constructed without flanges, and of a sufficient width of tyre to run upon ordinary roads. By the side of the ordinary tramway rails second rails have been laid at a lower level, on which the flangeless wheels run, while the electrical locomotive car is fitted with ordinary flanged wheels, and runs upon the inside rail, which acts as a flange to the waggon wheels. The front part of the waggon is carried on a bogie, which can either be pinned so as make a fixed wheel base, or can be allowed freedom of motion as in an ordinary loaded vehicle. To the fore bogie horse shafts can be attached when the waggon is to be used on the ordinary roads. These waggons are constructed to carry two tons. The maximum gross load carried is 26 tons, the electrical locomotive weighing eight tons, and being capable of carrying 34 passengers. This load can be brought up inclines, averaging one in 85, at a speed of seven miles per hour, and can be started at any point of the line, even where the gradient is as steep as one in 50. This is very much in excess of the work done at Portrush. All the electrical details and all the matters connected with the electrical equipment of the line have been designed and carried out by Dr. Edward Hopkinson, of Manchester.

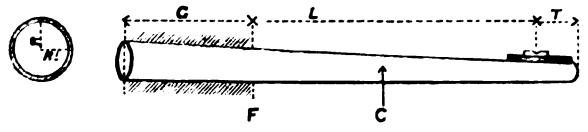
ON THE STRENGTH OF ROUND TIMBER.

By W. H. Preece, F.R.S., M.Inst.C.E. A Paper read before the British Association at their meeting at Aberdeen.

TABLE I.—*Tests of Ten Creosoted Poles* (A to K), *and of a Red Deal Scantling* (l), *made at* Gloucester-road Factory (January, 1885).



Details of **L** *and* **T**.

M = cubic contents : feet.

C = distance of centre of gravity from F.

W = weight in lbs.

Details of Load.

$W^1 = \frac{W \times C}{L}$.

$W^2 = \left\{\begin{matrix}\text{Jockey ... 9}\\ \text{Saddle tree 84}\\ \text{Scale..... 165}\\ \text{Chain ... 35}\end{matrix}\right\} = 293.$

$W^3 =$ Added load.

For poles $= \frac{W \cdot L}{47 \cdot (R^2 \times R^1)}$.

For scantling $= \frac{W\,L}{D^2\,B}$.

Note.—For explanation of the headings see Table of Tests *a* to *k*, made at Gloucester-road Factory in January, 1885, Table I.

Note.—Poles indexed ..... *l* to *q* are believed to have been erected in 1871 or 1872.

,, ,, ... *m*, *n*, *p*, *q* were taken down in March, 1882.

,, ,, ... *l* and *o* were taken down in August, 1883.

Quality of Timber and Remarks.—(12) Hard grown, very sound, fracture 2ft. from **F** ; (13) sound timber, still smells strongly of creosote, fracture short 17in. from **F** ; (14) medium quality, fracture by compression 3in. from **F** ; (15) soft grown, fracture by compression 18in. from **F** ; (16) knotty and soft grown, fracture 3ft. from **F** ; (17) hard grown and tough, fracture by compression 18in. from **F** ; (18) soft, fracture by compression 18in. from **F** ; (19) sound hard wood, fracture 31½in. from **F** ; (20) no cut, fracture 2ft. from **F** ; (21) no cut, fracture 6ft. from **F**.

The resistance of timber to rupture has frequently been experimentally investigated both at home and abroad, but almost invariably with the view of determining the dimensions or scantling of beams, trusses, and framed structures. Few experiments have been made upon naturally grown trees with a view of utilizing them in their native condition.

Fincham's* experiments on the relative qualities of timber used for the masts of ships were made upon cut pieces, 4ft. in length and 3 square inches in sectional area. The strength of square balks was investigated by Messrs. Tredgold, Barlow, and others, the results giving a constant of 1,341 for red pine in the formula

$$w = K\frac{b\,d^2}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots 1$$

* "Papers on Naval Architecture," Vol. I., pp. 53-4.

Digitized by Google

where w = breaking weight in lbs.
b = breadth in inches
d = depth ,,
l = length ,,
K = a constant dependent on the character of the timber.

The formula for round timber based on the same value of the constant K becomes

$$w = K \frac{4 \cdot 7 r^3}{l} \quad \ldots \ldots \ldots \ldots \quad 2$$

r being the radius.

The value of the constant quoted above was obtained by experiments on small sections of timber one and two inches square only. Wisely distrusting results obtained in this manner, Mr. Edwin Clark, during the construction of the Britannia tubular bridge, caused trials to be made with beams of red pine 12in. square, which gave a constant of 810 only, whilst experiments on balks of Baltic fir made by the Mersey Dock Board gave results varying between 771 and 873. Mr. Gavey, during certain investigations made in Bristol in 1876, obtained a constant of 804 from square sections cut out of Norway round telegraph poles.

Telegraph poles in England now consist principally of native grown unhewn Norwegian or Swedish red fir preserved with creosote.

They have acquired their pre-eminence by a species of natural selection, after extended trials of cut Memel timber, native grown larch, and preserved Scotch fir. The Scandinavian red fir is now almost exclusively employed. It seems to have been provided by nature specially for telegraphic purposes.

The specifications for telegraph poles, in addition to quoting dimensions, prescribe that they are to be winter felled, sound and hard grown (*i.e.*, well-hearted, with the annual rings closely pitched), straight, free from large or dead knots and other defects, to have the bark completely removed, and to contain the natural butt of the tree. They are usually from 5 to 6in. in diameter at the top, and they grow with a taper that accords satisfactorily with the theoretical law that should give the greatest strength at each section of their length.

No systematic inquiry has, so far as I am aware, been made into the mechanical properties of Scandinavian red fir in its native or unhewn state, though at different times isolated experiments have been made on its resistance to flexure.

The immense growth of the telegraph system in this country, the increased utilisation of public highways with their bends and curves, the wind pressures arising from the rapid multiplication of wires, have forced closer attention to the stresses applied, and to the more scientific bearing of the question. The selection of the proper scantling has been very much a rule of thumb process, but stability has been obtained by struts, stays, and double poles framed together. Subsequent experiments have, however, shown that practical experience has not erred in specifying dimensions.

As considerable doubt existed as to whether constants obtained from square timber could be accurately applied in calculating the strength of naturally grown trees, in which the annual rings of growth were unsevered, it was determined by the Post Office authorities to make careful and accurate measurements of the strength of the poles actually used, and a substantial testing apparatus was constructed for the purpose. A stout wrought-iron cylinder, 14in. in diameter and 6ft. long, was rigidly held down on a suitable framing by two 2in. tie rods. The butt of the pole to be tested was placed inside this cylinder to a depth of 5ft. 6in., carefully packed all round and tightly rammed with gravel to represent the conditions when in use. It was then placed horizontally, a scale pan was suspended from what would be the resultant point of a line of wires at the further end of the pole, and weights were added until the pole broke. An oak plank or saddle distributed the load as would be the case on an actual line of telegraph.

Table No. I. contains the results of the experiments made upon ten comparatively newly creosoted poles.

This gives a mean constant with formula 2 of 1,337, that obtained from the seven stout poles alone being 1,302, and from the thin light poles 1,417.

As the investigation referred primarily to lines built with stout poles, 1,302 is the value used in calculating subsequent tables.

Table No. II. contains the results of similar experiments made upon six old poles creosoted 15 years ago, and upon three new creosoted poles, the constants being 1,276 and 1,232 respectively.

As previously stated, formula 2 is really derived from experiments made on square timber, a multiplier being used to reduce results when round timber is in question. But obviously the strength of round timber varies as the cube of the diameter, so a constant has been obtained for the formula

$$w = K \frac{D^3}{l} \quad \ldots \ldots \ldots \quad 3$$

D being the diameter;

whilst for poles of elliptical section it becomes

$$w = K \frac{D^2 \times D_1}{l} \quad \ldots \ldots \ldots \quad 4$$

D being the axis in the line of stress, and D_1 that at right angles to it.

TABLE III.

The calculated strength of round poles, one foot long.

Diameter meters.	Breaking weight in lbs.	Diameter meters.	Breaking weight in lbs.
6	13,776	10	63,773
6·25	15,568	10·25	68,678
6·5	17,517	10·5	73,819
6·75	19,611	10·75	79,218
7	21,873	11	84,874
7·25	24,304	11·25	90,798
7·5	26,902	11·5	96,992
7·75	29,725	11·75	103,454
8	32,648	12	110,196
8·25	35,807	12·25	117,219
8·5	39,166	12·5	124,555
8·75	42,716	12·75	132,182
9	46,491	13	140,100
9·25	50,467	13·25	148,344
9·5	54,678	13·5	156,901
9·75	59,102	13·75	165,782

To obtain the strength of any pole divide the tabulated breaking weight by the length of the pole in feet between the ground line and the resultant point of the load.

The value of K, for formulæ 3 and 4, as deduced from the mean of the experiments on new stout creosoted poles, is 765.

It appears from these experiments that creosoting does not impair the strength of red fir, and age has had no apparent influence on its qualities.

The curves formed by the poles in bending were very perfect. Rupture invariably took place at the ground line, and about half broke by fracture of the upper fibres under tension, while the other half buckled in the under fibres under compression, showing that nature had proportioned them well to their work.

An important question that arises out of this inquiry is what shall be the proper scantling of timber and the span separating the poles on telegraph lines of varying number of wires.

In solving this problem we have not only to take into consideration the proper factor of safety to be allowed, and the wind pressure to be exerted upon the wires and the poles, but the fact that the diminution of spans beyond certain limits is impracticable owing to the injurious lowering of the insulation by the multiplication of supports.

The factor of safety is 4 and the maximum wind pressure per square foot is taken at 18·75lbs., reducing the effective area in the ratio of 10 to 6, owing to the circular section of the wires. We know very little of the average pressure on a long wire supported close to the ground. Most records have been made in exposed positions, and at consider-

Digitized by Google

able heights, whereas the average height of a trunk line of wires is but 20ft. above the surface. The President of this Section (Mr. Baker) thinks 30lbs. per square foot a fair average to take for telegraph wires, but considering the frictional resistance of the ground and the obstructions due to hedges, banks, walls, trees, &c., I am inclined to consider this too high. We have usually taken 18·75lb. per square foot as a fair measure of the wind pressure on our wires, and the results of practice very much confirm this view.

Table III. has been drawn up showing the strength of round poles one foot long, and varying in diameter from 6 to 13½in. To obtain the strength of any pole it is only necessary to divide the tabulated breaking strain by the length of the pole in feet.

TABLE IV.

WIND PRESSURE, 18·75 per sq. ft.—*factor of safety of* 4 : STRAINS AND STRENGTH *of* 17 *wire line; 60 yards spans; calculated to constants obtained at Gloucester-road:—*

Length of pole.	No. 8 wire.		No. 14 copper.		Present specifn. diameter.
	Moment of pressure in lbs.	Safe diameter.	Moment of pressure in lbs.	Safe diameter.	
26	8344·0	8·25	3953·6	6·0	8·25

40	14224·0	9·75	6742·4	7·5	10·75

TABLE V.

WIND PRESSURE, 18·75 per sq. ft.—STRAINS AND STRENGTH *of 20 wire line: 60 yards span: Calculated on Constants obtained at Gloucester-road.*

Length of pole.	No. 8 wire.		No. 14 copper.		Specification diameter.
	Moment of pressure in lbs.	Safe diameter.	Moment of pressure in lbs.	Safe diameter.	
26	9811·2	8·5	3953·6	7·5	8·25
28	10964·8	9·0	5196·8	8·0	8·75
30	11547·2	9·0	5465·6	8·0	9·0
32	12700·8	9·25	6014·4	8·5	9·25
34	13854·4	9·5	6563·2	8·5	9·75
36	15545·6	10·0	7369·6	9·0	10·0
40	16732·8	10·25	7907·2	9·5	10·75

The strength of the timber being satisfactorily settled, and a maximum wind pressure and factor of safety having been accepted, the length of spans for varying lines is readily calculated. Tables IV. and V. give the stresses on 17 and 20 wire lines, so arranged as to fulfil the implied conditions.

The experiments and calculations in this paper were done by Mr. Andrew Bell and Mr. James Gavey, of the Post Office Telegraph Department.

THE RELATIVE MERITS OF IRON AND COPPER WIRE FOR TELEGRAPH LINES.*

BY W. H. PREECE, F.R.S.

Copper is gradually replacing iron for aerial telegraphs, owing to its greater durability in the atmosphere; but its greater cost has led to the use of smaller-sized wires. This can be done without detriment to the economy of the line, for the resistance of copper, as compared with iron, varies very nearly inversely as its price per ton, and hence the cost per mile remains about the same. Hitherto only short lengths have been erected in smoky towns and through districts where chemical industries filled the air with gases destructive to iron wires; but the Post Office Telegraph Department has recently erected a No. 14 copper wire, ·080in. in diameter, weighing 100lb. per mile, all the way from London to Newcastle, 278·08 miles in length, and it became desirable to measure very accurately its electrical elements, so as to see if it possessed, as was anticipated, any marked advantage as a telegraph line over the galvanised iron wires hitherto used.

There were two series of experiments made. In the *first* series the relative electrical condition of the two kinds of wires was determined, and in the *second* series their relative rates of working.

The first series, the results of which are given in Tables I., II., III., and IV., was divided into two parts, the one consisting of tests made from Bishop Auckland to Teams, near Newcastle, a distance of 30·235 miles on the north side, and to Pierce Bridge, a distance of 9·172 miles on the south side, and the other consisting of tests of a section of line between Pierce Bridge and Baldersby Cross Roads, 26·7 miles in length. The poles carried 10 wires. The tests were made in dry and favourable weather by Messrs. Kempe and Eden.

The electrostatic capacity of an aërial line is known to vary as

$$\log \frac{4h}{d}$$

where h is the height of the wire above the ground, and d its diameter. Now, the average height of the copper wire on the sections between Bishop Auckland and Teams and between Pierce Bridge and Baldersby Cross Roads is 23ft., and that of the iron wire (on a lower arm of the pole) 22ft., their diameters being ·080in. and ·171in. respectively. We have, therefore, for copper wire

$$\log \frac{4h}{d} = \log \frac{4 \times 23 \times 12 \times 1000}{80} = 4{\cdot}1398791,$$

for iron wire

$$\log \frac{4h}{d} = \log \frac{4 \times 23 \times 12 \times 1000}{171} = 3{\cdot}7906678,$$

and

$$\frac{3{\cdot}7906678}{4{\cdot}1398791} = {\cdot}916 \text{ nearly},$$

which makes the capacity of the copper wire to be 100 – 91·6, or 8·4 per cent. less than that of the iron wire. This result agrees pretty closely with the mean value of the differences of capacity obtained by actual measurements on these sections—viz., 9·1 per cent.

For the Bishop Auckland-Pierce Bridge section we have:—

For copper wire

$$\log \frac{4h}{d} = \log \frac{4 \times 21 \times 12 \times 1000}{80} = 4{\cdot}1003705.$$

For iron wire

$$\log \frac{4h}{d} = \log \frac{4 \times 20 \times 12 \times 1000}{171} = 3{\cdot}7492751$$

and

$$\frac{3{\cdot}7492751}{4{\cdot}1003705} = {\cdot}914$$

making the capacity of the copper wire to be 100 – 91·4, or 8·6 per cent. less than that of the iron, whilst the actual value was found to be 9·7 per cent. The differences between the calculated and the experimental values are probably due to the influence of trees, buildings, &c., which cannot be allowed for theoretically. These measurements were made when the other wires on the poles were left insulated. The effect of having all the other wires to earth when the capacity of any one wire was measured was very marked. Thus, on one wire the capacity was increased from ·352 to ·451 microfarad, or 22 per cent. It would therefore appear that the mean capacity per mile of a single iron wire of ·171in. in diameter, placed about 20ft. above the ground, is ·0131 microfarad, while an iron wire of the same size, suspended at the same height, but surrounded by other wires forming telegraphic circuits, would have a mean capacity of ·0169 per mile. The capacity of copper wire of ·080in. diameter under similar conditions would be about ·0120 and ·0142 microfarad per mile respectively.

* A Paper read before the British Association at the meeting at Aberdeen.

As regards the induction between wire and wire tests the effects obtained were very slight, though their actual value was determined with comparative accuracy.

The second series of experiments were conducted between London and Newcastle, and were designed, as stated above, to test the working efficiency of the copper wire as compared with iron wires. They were conducted by Messrs. Chapman and Eden. The results of the numerous trials of speed with various arrangements of the apparatus are given in Tables V. and VI., and are summarised in Table VII.

It will be observed that copper shows a very decided superiority over iron, the speeds being as follow :—

	Copper.	Iron.	
Simplex working...	414	345	words per minute.
Duplex ,, ...	270	237	,, ,,

It is anticipated that the superiority of copper over iron indicated by these experiments will have a beneficial and economical influence on our telegraph system, and that its extended use will enable us not only to work better, but to

rapid changes of electric currents than iron; for when the resistance and capacity of the copper and iron wires were equalised by the insertion of resistance coils and condensers, the speed on the former was not thereby diminished. Possibly the magnetic susceptibility of the iron is the cause of this. The magnetisation of the iron acts as a kind of drag on the currents. It is well known that telephones always work better on copper than on iron wires, doubtless for the same reason.

These experiments also show the high speed of working that is now attained by the Post Office authorities with the Wheatstone automatic apparatus. The following table gives an interesting *resumé* of the different stages of the progress made, and its rate of growth:—

THE TELEGRAPH CONFERENCE.

Owing to a desire to give as much of the proceedings of the British Association as possible in this issue, we refrain from commenting upon the differences of opinion which characterised the concluding part of the Conference at Berlin. The labours of the Conference have ended, and we shall be better able in another issue to view them in their completed state.

THE SIXPENNY TELEGRAM REGULATIONS.

On Wednesday the morning papers were authorised to publish an official communication embodying the regulations which are to come into operation with Sixpenny Telegrams on the 1st October. These regulations are substantially those we foreshadowed a fortnight ago, when we were able to give our readers a facsimile of the new telegram form, differing only in greater precision as to the counting of streets and names of places in towns. As to these, we are inclined to agree with *The Times* that some further concession may be called for, not so much to remedy an injustice as to remove ambiguity. It may be quite proper to count Ludgate Hill as two words and Malvern Wells as one, but the public will not think so; and what the public thinks right the public is sure to act upon, with resulting disputation and friction. It is rather hard at first sight to understand why, for example, Chester-le-Street should pass as one word while Chester-street must be paid for as two; or, to take a different case, why Lincoln's Inn Fields counts three, whereas Moorfields, of course, will be accepted as one. In strictness Street is a word distinct from its designation, just as much as Place, Terrace, Avenue or Square; but we shall be agreeably surprised if the pressure of public opinion, which in this instance would be genuine though rather unreasonable, does not compel the Post Office to add this concession to the many it has already vouchsafed for the sake of peace and quietness.

With that exception, the Rules are not only manifestly sound, but extremely liberal. With characteristic ingratitude the public press has expressed but lukewarm appreciation of the positive gains under the new Rules, whilst it instantly falls foul of the single and insignificant restriction. A probable explanation is that the advantages, though far more substantial, are not so obvious as the drawback. A little reflection, however, will show how enormous the advantages are. In the first place the sender is neither compelled nor invited to insert either his name or address. In many cases—the official communication on the subject says in most—he will save himself the expense of signalling these particulars, which he can generally do by altering the phraseology of his message, substituting his name for the personal pronoun, or by trusting to his indentity being recognised. These remarks apply to domestic messages chiefly; business men will adopt special methods of their own to which we need not particularly refer. Secondly, the names of all towns and villages, no matter how compounded or whether they occur in the text or address of the message, will count as one word. The same rule will apply to names of persons, that is to their surnames, though double-barrelled names of the Lane-Fox type and the like will have to pay for their singularity. Combinations of letters, such as those representing the London Postal Districts, the a.m. and p.m. representing morning and afternoon, the familiar f.o.b. and c.f.i., which in shipping business stand respectively for "free on board" and "cost freight and insurance," and all similar groups of not more than five letters, will be treated each group as a word. We may be sure that in practice the principle here recognised will be applied pretty freely by the public, and that the Post Office will give the benefit of the doubt to their customers in all cases not specifically met by the Rules.

But the most important concession of all is that which assimilates the inland method of counting figures with that of the Continent. Any group of figures, or symbols joined with figures, not exceeding five, will count as one word, instead of being charged separately as they are at present. The ordinary public will feel the benefit of this chiefly in the address, but frequently also in the hour of the day. Half-past twelve would count as three words, but it will go for a halfpenny if written 12:30. Similarly, amounts such as 2/7/6 are to be counted as one word. It is to be regretted that the symbol £ is not to be treated as a figure; but its equivalent can generally be represented by converting the pounds into shillings—thus 100/- will stand for £5. To the commercial community this alteration in the treatment of figures will be an immense boon; they are employed pretty largely even now, and very soon uses will be found for them to economise words to an extent which is perhaps little dreamed of at present.

On the whole, therefore, it will be seen that the regulations under which the reduced tariff is to be worked are quite in harmony with the principles on which the scheme was promoted. We never favoured the reduced rate; but we have always upheld the principle of charging for the addresses, and of conceding liberal rules in respect to counting as a set-off to the free addresses. If a Sixpenny Telegram scheme can be made to pay in the United Kingdom this one will pay, and we hope it may. But whatever its financial fate may be, we are quite sure that the fame predicted for the measure by *The Times* the other day was a piece of journalistic clap-trap. We were told that nobody cares for the Vote whilst everybody cares for the Telegraph, and that the Act which gives us Sixpenny Telegrams

Digitized by Google

will be gratefully remembered when the Franchise Act is buried in well merited oblivion. We strongly advise the Post Office not to reckon on this public gratitude, any more than *The Times* seriously reckons on the futility of the county voter.

No comparison of these two things can be made except in a way that is flattering to neither. The Telegraph has taken its final plunge, and in that sense, perhaps, the incident may be memorable; whereas there remains for the Franchise some yet lower depths, in descending which the memory of this year's exploit will be effaced altogether. Our chief misgiving with regard to the former has been, not that it will be forgotten, but that in cheapening it we may be spoiling a very precious gift, taxing it with frivolous errands, and maiming its capabilities for matters of weight and moment. We can only hope that the energy and resources which have made British telegraphy the fastest and surest in the world may be able to avert the decadence which in other countries has overtaken the administration whenever cheapness and popularity have been sought at the expense of efficiency and speed.

CORRESPONDENCE.

DOUBLE POLE SWITCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am somewhat at a loss to know what conclusion to draw from Mr. Killingworth Hedges' reply to my letter advocating the use of double pole switches and double pole safety cut outs.

He cannot mean to deny the utility of double pole fittings, because he says "*the double pole cut out has been found of service in preventing accidents*," also that the "*Boston Fire Underwriters' Union recommend a separate cut out to be placed on each wire*," and again, "*double pole switches may be advisable sometimes*."

In all this he has simply strongly endorsed my own views.

It certainly then seems to me that his letter narrows down to an expression (his own, let it be known) that *English electrical engineers would not profit by using American fittings.* The italics are mine, and I am sure that from the many sidedness of electrical science electrical engineers, of all men, will be the most free from insular prejudices, and will take up whatever is best.

The installation of the Edison Company in America where he did not find double pole fittings must decidedly have been some of the first put in. The only other part of the letter calling for serious comment is when he states *a short circuit may occur on the block itself between the fusible plugs.* I assert that this is practically impossible, and it has never been known to occur yet, although it might possibly have occurred in some of an inferior make of blocks that have been used in this country.

The double pole fittings of *Bergmann* have been used in only two or three installations other than our own, and all engineers under whose notice we have brought them have said they are the best things of the kind they have seen.

However I do not propose to carry on an argument with Mr. Hedges to no advantage.—Yours, &c.,

JNO. B. VERITY.

31 and 32, King-street, Covent Garden, W.C.,
September 14, 1885.

THE LIFE OF INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

"The most important table of the life of incandescent lamps ever published."

SIR: Confessing at the outset my utter and hopeless ignorance of the methods of computation adopted in the calculation of statistics referring to incandescent lamps, would Mr. Grundy kindly make clear how he arrives at the value of the average life of incandescent lamps by dividing the total lamp-hours for a short period by the number of lamps lost in that period?

To a non-mathematical mind like my own it would seem that if 500,000 lamps be run at a moderate efficiency for one hour, probably not more than 10 will be destroyed. If so, then $\frac{500{,}000 \text{ lamp-hours}}{10 \text{ broken lamps}}$ gives, on Mr. Grundy's method, 50,000 hours as the normal life. But we can obtain more than this. If we run these lamps for one minute the chances are not one will be lost if the cracked lamps have been eliminated, not even if the lamps are run at 1·5 watt per candle. Therefore, we should have $\frac{500{,}000}{6{\cdot}0} = 8{,}333$ lamp-hours $\frac{8{,}333}{0} = \text{infinity}$.

Therefore, the life of lamps at 1·5 watt per candle is infinite! Will Mr. Grundy kindly correct?—Yours, &c.,

London, S.E., Sept. 17, 1885. CARBON.

FACSIMILE TELEGRAPHY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to the note in your last week's issue concerning a method of transmitting handwriting in facsimile by telegraph, it may be worth while noting that this "invention" is far from new. More than fifteen years ago I read a description of an exactly similar apparatus in a small work dealing with electrical matters, and published—if I may trust my memory—some twenty years ago.—Yours, &c.,

A. DALGLEISH.

57, Holborn-viaduct, London, E.C., 14th Sept., 1885.

[Our correspondent speaks of the principle, and not of an instrument. Our note referred to the latter. There are, of course, several methods by which handwriting can be transmitted in facsimile by telegraph.—ED. *E.*]

MANCE'S METHOD OF ELIMINATING POLARISATION;

ITS EMPLOYMENT FOR TESTING THE RESISTANCE OF THE HUMAN BODY.*

BY DR. W. H. STONE.

At the Southport meeting of the British Association I gave a short account of some observations tending to show that the resistance of the living human body to electrical currents was considerably—indeed, surprisingly—less than that usually given in works on medical electricity and physiology. Even such authorities as Rosenthal, in Germany, and Dolbear, in America, assigned values varying from 10 to 100 times the real figure. I produced evidence to prove that this was in the main due to imperfect contact between the body itself and the poles of the measuring instrument. By immersing the patient's extremities in saline solutions, and using large leaden electrodes, this initial error was eliminated, and a fair approximation to the real determination laid before the meeting.

But two secondary difficulties at once presented themselves, first, that the human body possesses considerable electrostatic capacity, and acts as a condenser; second, that it acts as a secondary battery, and sets up a very appreciable counter electromotive force.

In my Southport paper I described a method of alternating momentary contacts with a reversing key, by which the second of these difficulties was minimised. But even on this plan the later readings were always somewhat higher than the earlier, and the resistance seemed to rise slowly to a maximum. This was clearly counter electromotive force due to polarisation, and the resistance actually noted was the real resistance plus an indeterminable polarisation quantity.

So far at Southport. It was, however, then suggested to me to use the alternating current of an induction coil, and to replace the galvanometer by a telephone. At this latter method, which is extremely elegant, I worked steadily for the following year, and as I incidentally discovered that the alternating current of the induction coil introduced to physio-

* Paper read at the Aberdeen meeting of the British Association.

Digitized by Google

logical research mainly by Du Bois Raymond had not been measured, I set myself this task, first by means of Kohlrausch's dynamometer, and, secondly, by a modification of Sir. W. Thomson's quadrant electrometer. But from the first the results by this method were so singularly discrepant from those I had obtained by the other that I suspected its accuracy.

For instance, in a very tall and athletic man, a student at St. Thomas's Hospital, the resistance from foot to foot was always about 1,000 ohms, but by this method never above 600 ohms. By Mance's method it comes out by two separate observations to be 1007·6 and 1009 ohms, a good result.

It became evident that there were two opposite causes of error, a condenser action spuriously lowering the reading specially strong with alternating currents and a polarisation fallaciously raising it very marked with continuous currents.

To ascertain the exact amount and proportion of either of these presented a task of no small difficulty, and one, indeed, at which I am still working. I hope fairly to complete it in time for the Lumleian lectures, which the Royal College of Physicians have requested me to deliver in the early part of next year.

It struck me that the human body, besides being an imperfect conductor, resembles a very leaky condenser—in fact, it has three attributes, it is a conductor, a condenser, and an electrolyte, and is not dissimilar to a faulty submarine cable.

On these points I consulted Mr. Latimer Clark, who referred me to a paper by Mr. Henry Mance, read before the Society of Telegraph-Engineers on May 8, 1884.*

By the kindness of Messrs. Clark, Muirhead, and Co., I have been able to procure one of Mance's beautiful instruments for exhibition at this meeting.

Mr. Mance very kindly assisted me with his advice, and corrected some of my early results, one of which is on the black board.

R_1 945·6	R_2 950·950	result 939	Foot to foot.
R_1 920·933	R_2 1040·1066	result 905·46	Foot to hand.

Now, if the resistance can thus be correctly obtained the subsequent work is much facilitated. I have already a few rough results, and am steadily increasing their number.

ELECTRIC LIGHTING AT FORTH BRIDGE WORKS.†

BY JAMES N. SHOOLBRED, B.A., MEM. INST. C.E.

In the summer of 1883, the contractors for this most important engineering work, Sir Thomas S. Tancred, Arrol, and Co., decided to make use of electricity in the illumination of the large works required for the preparation and construction of this large undertaking. The author was by them entrusted with the preparation of the necessary plans, together with the supervision of the arrangements to enable the lighting by electricity to be thoroughly and suitably carried out.

For the construction of the bridge, and the proper preparation of the large amount of steel which enters into it, very large workshops have been erected at South Queensferry, where also are concentrated the principal offices, central stores, canteen, &c. A steep incline conveys the materials from the height on which the workshops stand down to the shore of the Firth, the lines of way being then continued on a broad wooden jetty, 50ft. in width, projecting into the Firth for about 700 yards, up to the Queensferry main piers, whence springs the southernmost of the two large spans of the bridge.

The Island of Inch Garvie, situate in mid channel, with its group of workshops, offices, &c., necessary for the operations carried on at this isolated and exposed situation, forms the next spot requiring, at present, the use of the electric light.

On the northern, or Fife shore of the Firth, the operations about the Fife main piers, the northern end of the second of the large spans, together with the branch workshops, stores, &c., connected therewith, as well as portions of the land viaduct extending northwards, and a part of the large stone quarries and shipping stages in the vicinity thereof, are the spots requiring to be lighted by electricity.

The conditions to be fulfilled in the illumination of the above localities (owing to the ever-changing extent of the demands upon the lighting, and the variation in the position of each light—a matter which varied constantly with the progress of the work in its vicinity, with the state of the tide and from other causes) rendered it evident that the details of the arrangements for the lighting must be such as to allow of the requisite changes being effected readily and expeditiously.

Again, it was evident also that portions of the cables, wires, and other working parts of the lighting apparatus, would be constantly within reach of the workmen. The primary condition, therefore, demanded a system of lighting simple in its arrangements, and which would inspire confidence in the new illuminant among the workmen.

It became evident that while arc lights would be required for the outside, the offices, residential premises, stores, &c., demanded incandescent lights; and again, that other buildings, such as the large workshops, necessitated the use of both arc and incandescent lights. Also, that the use of storage accumulators, as well as the transmission of power by electricity, might be desirable.

To meet these various conditions it was decided—1st, to adopt continuous current machines; 2nd, that the type of dynamo for the outside arc lights, limited to six lights in series, should not have a greater E.M.F. than 300 volts between the terminals; 3rd, that the type of dynamo for the incandescent lights, or for the arc and incandescent lights used conjointly, should be on the compound-wound principle, with a maximum E.M.F. of 120 volts between the terminals. The incandescent lamps, in parallel series, used with these machines, to have an E.M.F. of 110 volts; while in the large workshops arc lamps in pairs (in series with one another, with the addition of a suitable resistance) would be used, where required, conjointly with the above incandescent lights.

Near to the large workshops are a number of parallel lines of rails, forming a large uncovered workshop, and termed the "Drill Roads." Upon these roads circulate large movable huts, each containing an engine, drilling machines, and a circular frame, intended for the formation of the various steel tubes of the bridge. Here, as in the large workshops, the use of both arc and incandescent lights is necessary. But, as the exact site where each kind of light might be wanted depended upon the whereabouts of the hut upon the rails, it became necessary to provide for this, at certain fixed spots, supply or "service" boxes, whence readily fixed flexible branch-mains lead the current to the desired site of the lights.

Tenders having been invited for the carrying out of the necessary works, all the lighting on the South Queensferry side was entrusted to and very efficiently carried out by Messrs. Siemens Brothers and Co., while the works on the north side and on Inch Garvie were executed in a very satisfactory manner by Messrs. R. E. Crompton and Co.

The electrical plant contained in the above installations may be stated briefly as thirteen dynamo machines, developing about 150 electrical horse-power; 100 large arc lamps (of 2,000 candles each); 500 incandescent lamps (of 20 candles each). A total length of about twelve miles of mains has been laid down in the various circuits, exclusive of branch wires to lamps. The lighting by electricity has been carried on continuously, and with satisfactory results for nearly two years, by means of the above arrangements. That the peculiar requirements of the situation, together with the storms of winter, have been successfully coped with attests the careful and thorough manner in which both of the well-known firms who executed the works performed the part entrusted to them.

During that period of working several points of interest have arisen, and among them the following:—

1st. The excessively varying conditions which are constantly occurring with regard to the outside arc lights, both as regards the number in actual use, and as to the exact position of each light (dependent greatly upon the character of the particular work going on in its vicinity, the state of the tide, &c.) have been satisfactorily met in the following manner:—The duty of each series machine was limited to six arc lights, as already stated, in order to avoid an excessive E.M.F., the actual number

* This method is described in the Society of Telegraph-Engineers' *Proceedings* last year.

† Paper read at the Aberdeen Meeting of the British Association.

Digitized by Google

lighted being varied between one and six at will, by means of resistance frames. Furthermore, arrangements have been made on a general switch-board by which any of the circuits (sometimes as many as six in one locality) could be coupled with each other; so that the six lights or less, the complement of one machine, might be made to occur, if desired, over a circuit of very varied length (sometimes more than a mile long).

2nd. The lighting of the large workshops, the drill roads, &c., demanded a combination of arc and of incandescent lights, the relative proportions between the two kinds being subject to constant variations. It was also necessary that the position should be readily varied, and also that additional lights of either kind might be easily obtainable at will. The use of compound-wound dynamos with the lamps in parallel circuit (the arc lamps being in pairs, in series with each other, with a suitable resistance in addition) provided for the first condition, while the second was complied with by the use of "service-boxes," containing "plug sockets," into each of which was inserted the plug end forming the extremity of a certain length of flexible twin-leading wire, attached to each portable arc or incandescent lamp. The lanterns in which these several lamps were placed varied considerably in form—with arc lights for outside, or for workshop use—while for incandescent hand-lamps, reflecting bulls' eyes, divers' or miners' lanterns, &c., might be required.

The advantages attached to this mode of working lamps in parallel circuit have proved very considerable. The ease with which lights of either kind can be added to or diminished fn number, together with the comparatively low E.M.F. (110 volts), are points which must be appreciated by practical electrical engineers. At South Queensferry alone as many as 50 arc lights (or, in lieu, 600 incandescents) are being worked on this principle. Great credit is due to Messrs. Siemens on this head, for at the time of their first being used nothing on so extended a scale on the parallel system existed elsewhere, and certainly the working in pair series was quite unique.

3rd. Perhaps nowhere have more points of interest arisen than in the illumination of the working chambers of the deep water caissons, which were constructed to assist in getting in the foundations of the main piers. Each of these circular steel caissons, 60ft. in diameter, and rather more in height, has its sides projecting downwards for about 8ft. below the diaphragm or ceiling which extends across this part of the cylinder. The lower chamber which is thus formed is open-mouthed, and becomes a huge diving-bell. In it a number of workmen, having passed down from the surface through a tube 3ft. 6in. in diameter, excavate the bottom (passing the *débris* up another tube), and gradually sink the caisson to the requisite depth. This is, of course, done under air compressed according to the height of the water outside. In the caissons for the Queensferry main piers, where the bottom was of clay, the illumination was effected by means of Swan incandescent lamps, eighteen in number, of the ordinary 110 volt, 20 candle-power type used throughout the works, but each protected by a strong spherical wire guard for protection from any blow. They were pendant from the ceiling, hung on to a hook or wherever else required, each having a certain length of twin wire attached, terminating at the other end in a contact plug. The two gutta percha covered mains for conveying the electric current from the dynamo pass from the outer air into the air-lock chamber through a stuffing box, and thence down the descent tube into the working chamber, where they are led along the ceiling to a distributing box, and thence, when required, to a second or even a third box. These distributing boxes each consist of solid copper rods, kept sufficiently apart, and embedded in a wooden block, having a number of square openings in it, each opening exposing sufficient of the copper rods to allow of a good contact being made. This contact is effected by the insertion, when required, of the "plug-end," which is, at the extremity of the flexible lead, attached to each lamp, which, at the moment of insertion, automatically lights up. In the caissons at Inch Garvie a different mode of lighting had to be adopted, owing to the rocky bottom, which necessitated blasting, and the shock of which would, most probably, have shattered the incandescent lamps. Here three arc lamps (of the same type as on the surface) have been used on two circuits working in parallel (a resistance replacing the fourth lamp, which was not required).

Above each lamp in the ceiling is a sort of hood, into which it is entirely drawn during blasting operations, in order to avoid any damage. A small pipe in the top of this hood leads off the products of combustion into the vertical shaft, and so into the air-lock, whence they are discharged into the air.

The firing of the dynamite charges is performed from the same dynamo which does the lighting. A special pair of mains are carried from the dynamo down the descent shaft to a distributing box on the ceiling of the working chamber. The arrangement of the plugs, &c., is the same as for the incandescent lamps—a firing fuse of a very simple construction replacing the incandescent lamp. At the top of the descent shaft the two mains are both secured and kept permanently in that state. By means of a peculiar double-contact maker connection can be made instantaneously. When everything is ready for firing, the foreman, who alone has access to the box where is the contact maker, fires readily the number of charges that may be required. A great deal of the successful working of the lighting arrangements in the caissons, as also in other parts on the surface, is due to the ingenuity and assiduous attention of Mr. Sydney Baynes, the resident electrician at the Forth Bridge Works.

The preceding gives a brief description of the general arrangements which have been in use, so far, for the lighting, not merely of what may be termed the comparatively permanent part of the works (such as the offices, stores, workshops, &c.), but also for the actual operations of the foundations of the bridge itself. Shortly this stage will be at an end, and the erection of the superstructure will necessitate probably far different arrangements—lights scattered considerably, and of a very portable character. Then may, perhaps, come into play, as valuable adjuncts, these two other applications of the electric current—its utilisation in connection with storage accumulators, and for the transmission of power, objects the possibility of the future use of which led the author to adopt continuous current dynamo machines for the lighting by electricity of the Forth Bridge Works.

THE GENERATION OF A VOLTAIC CURRENT BY A SULPHUR CELL WITH A SOLID ELECTROLYTE.*

BY SHELFORD BIDWELL, M.A., LL.B.

So far as I am aware there has never yet been constructed a voltaic cell having a solid electrolyte which, at least at ordinary temperatures, would produce the smallest indication of a current in the most delicate galvanometer. Sir William Thomson has described† a cell consisting of a piece of flint glass between plates of zinc and copper. After the glass had been warmed to 50° C. the plates were found to give indications of the existence of an electromotive force when connected with an electrometer. Profs. Ayrton and Perry have made similar experiments,‡ using paraffin wax, gutta percha, india rubber, and shellac. But it is needless to say that with electrolytes of such enormous resistance as these, no current could be generated which could be detected in the ordinary way by any galvanometer, however sensitive.

The present paper contains an account of some experiments with cells in which the electrolytes consisted of sulphides of silver and copper between plates of the same metals. In nearly every case these arrangements were found to be capable of generating sensible currents, which sometimes, indeed, measured several thousand micro-amperes, and were capable of producing deflections in coarse galvanometers with pivoted needles. Some of the results obtained are curious and even opposed to what might have been expected, but they will in general be given without any comment or attempted explanation. The copper and silver plates used were in every case 3 cm. square.

(1). A cell was made by compressing a thin layer of

powdered silver sulphide between plates of silver and copper. When connected with a shunted reflecting galvanometer the cell produced a deflection indicating a current of about 30 micro-amperes. The direction of the current was from copper through sulphide to silver. On the following day, the circuit having been open in the meantime, the cell generated a current of only four micro-amperes. The copper plate was found to have acquired a purple colour; the silver was untarnished.

(2). The same cell was charged with equal parts of silver sulphide and sublimed sulphur mixed together. It now gave a current in the same direction of about 1·5 micro-ampere.

(3). A layer of precipitated copper sulphide was placed between plates of copper and silver, which were squeezed together in a screw press. When connected with the galvanometer (unshunted) this arrangement produced no deflection whatever.

(4). The cell was recharged with a mixture of two parts of copper sulphide with one part of sulphur, and when connected with the galvanometer it was found to give a very small current from *silver to copper*, indicated by a deflection of two or three scale divisions. The deflection was reversed as often as the connections with the binding screws of the cells were reversed, and the existence of a small electromotive force was undoubted. The internal resistance was ·088 ohm.

(5). Sufficient sulphur was added to the mixture to bring the resistance up to 2,700 ohms. The cell, when remade, produced a galvanometer deflection which was at first about 100 divisions (indicating a current of ·08 micro-ampere), but soon increased somewhat irregularly to 250 divisions. The direction of the current was, as before, from silver to copper through the cell.

(6). A plate of copper was heated, and upon it was spread a mixture consisting of five parts sulphur and one of copper sulphide. A plate of silver, previously heated, was laid upon the melted mixture and the two plates pressed together. The thickness of the sulphur mixture between the plates was 3 mm. When this cell, after cooling, was connected with the the galvanometer, the spot of light was at once deflected off the scale. Dr. Fleming was kind enough to make a very accurate measurement of its electromotive force by comparison with one of his standard Daniell cells. It was found to be ·0712 volt, and its internal resistance was 6,537 ohms.

(7). A similar cell was made with a mixture of equal parts of sulphur and copper sulphide. Its internal resistance was much lower, being only 13 ohms, but its electromotive force was also lower, being ·007 volt. This result agrees with those of (3) (4) and (5) in showing that the electromotive force is diminished when the proportion of sulphide to sulphur is increased.

(8). Another cell was made in the same manner as the two last described, but the sulphur was mixed with silver sulphide instead of with copper sulphide. This gave a strong current in the same direction as that produced when copper sulphide was used, and opposite to the direction of the current generated by the cells (1) and (2). This reversal of the current may be accounted for by the fact that copper sulphide is formed when the melted mixture of sulphur and silver sulphide is brought into contact with the hot copper plate.

(9). In order to ascertain whether sufficient sulphide to maintain a current could be formed entirely in this manner, pure sulphur was melted on a clean plate of copper, and, when just liquid, a warmed plate of silver was laid upon it, and pressed down by a weight until cold. The cell gave a strong current from silver through sulphur to copper.*

(10). Thinking that the function of the free sulphur (without which, as has been seen, copper sulphide is incapable of generating a current) might be to form silver sulphide by contact with the silver plate, I constructed a cell as follows:—A thin layer of copper sulphide was spread upon a plate of copper, a polished steel plate was laid upon the sulphide, and the whole was strongly compressed in a vice. The steel plate was then removed, and a thin layer of silver sulphide was spread upon the smooth surface of the copper sulphide. The cell was completed by pressing a silver plate upon the silver sulphide. It gave a current of 240 micro-amperes through an external resistance of 3·5 ohms, the direction through the cell being from silver to copper. This form of sulphide cell seems to be exactly analogous in its action to a Daniell cell, consisting of plates of zinc and copper in solutions of zinc sulphate and copper sulphate. The quantity of the copper sulphide would be gradually diminished, copper being deposited upon the copper plate, while the quantity of silver sulphide would continually increase with consumption of the silver plate.

A similarly constructed cell with plates 2½in. by 2in. gave a current of 2,500 micro-amperes through an external circuit of ·5 ohm.

(11). Certain indications led me to believe that the cell last mentioned was short-circuited, and it appeared possible that this might be due to the penetration of particles of copper sulphide through the silver sulphide. The silver plate was therefore removed from the cell, and after being brushed over with a weak solution of sulphur in bisulphide of carbon, it was heated over a gas flame, and soon became covered with a perfectly uniform and continuous coating of sulphide. The heating was continued until all the free sulphur was driven off. When the cell was remade with this prepared plate it generated a current of 6,800 micro-amperes through an external circuit of ·2 ohm. The cell was found able to produce deflections in a roughly made galvanometer with a pivoted needle. Its electromotive force was ·05 volt, and its internal resistance, therefore, was about 7 ohms.

Experiments with other metals would probably lead to the construction of a sulphur cell of greater power than any of those described in this paper. Silver may, indeed, be the best or only possible metal for the positive plate, but it is by no means certain that the copper of the negative plate might not be advantageously replaced by some other metal.*

* A thin layer of sublimed sulphur was compressed between *cold* plates of silver and copper, which were connected with the galvanometer. A deflection of three divisions was produced, indicating a minute current from silver to copper. The experiment was repeated several times with the same result. (Moisture in the sulphur would have caused a current in the opposite direction.) This effect can, I think, only be explained by supposing that sulphides were formed in small quantities and diffused through the sulphur; but little importance can at present be attached to it.

ON THE SENSITIVENESS TO LIGHT OF SELENIUM AND SULPHUR CELLS.†

BY SHELFORD BIDWELL, M.A., LL.B.

The fact, first announced by Mr. Willoughby Smith in 1873, that the electrical resistance of crystalline selenium is temporarily diminished by the action of light has been fully confirmed by subsequent experimenters.‡ Mr. Smith's original piece of selenium was in the form of a rectangular plate, having electrodes of platinum wire fused into the shorter ends. Others have used the substance in the form of rods or bars similarly furnished with wires, but since the effective action of light is mainly limited to the surface exposed to it, and since the specific resistance of crystalline selenium is always very high, various more or less complex arrangements have from time to time been devised for the double purpose of obtaining as large a surface as possible relatively to the volume of the selenium used, and at the same time reducing the distance between the electrodes to the smallest practicable limit. To these devices the name of "cells" is now generally given; but it will be convenient to include in this term any arrangement, however simple, in which two metallic electrodes are connected together by a mass of crystalline selenium.

* In a paper recently communicated to the Physical Society, which will be published in its *Proceedings*, and also in the *Phil. Mag.*, experiments are quoted showing that the action of light *diminishes* the current generated by these sulphide cells, while heat increases it. Some very curious polarisation effects are also described.

Of the many investigations which have been undertaken in reference to this subject by far the most valuable and exhaustive are those of Prof. Adams and Mr. R. E. Day, an account of which was published in 1876-7. From their paper in the *Philosophical Transactions** the following conclusions are abstracted :—

1. On exposure to light while a battery current is passing through it the electrical resistance of a piece of selenium is apparently diminished. Experiments with a Bunsen flame, with weak sources of light, and with moonlight, seem to show that this effect is due to the illuminating power rather than to the heating effect of the source.

2. The apparent change in the electrical resistance is directly proportional to the square root of the illuminating power of the light.

3. A slight increase of temperature of a piece of annealed selenium is accompanied by a large increase of electrical resistance.

4. There is on the whole a general diminution of resistance as the battery power is increased.

5. The first current sent through the selenium causes a more or less permanent "set" of the molecules, in consequence of which the passage of the current during the remainder of the experiments is more resisted in that direction than it is in the opposite one.

6. The passage of the current in any direction at any period of the series of observations produces a slight "set" of the molecules, which tends to facilitate the subsequent passage of a current in the opposite, but obstructs one in the same direction.

7. After the current from a voltaic battery has been passed for some time through the selenium, and when the electrodes have been disengaged from the battery and connected with a galvanometer, a polarisation current in the opposite direction to that of the battery is found to pass through the galvanometer.

8. Under certain circumstances the action of light is capable of developing an electromotive force in pieces of selenium through which a battery current has never been passed. Currents due to this electromotive force are called by the authors *photo-electric* currents.

With regard to the action of light in producing these photo-electric currents, and also in diminishing the resistance of a piece of selenium through which a battery current is passing, Messrs. Adams and Day have suggested the following explanation :† "Light, as we know, in the case of some bodies tends to promote crystallisation, and when it falls on the surface of such a stick of selenium tends to promote crystallisation in the exterior layers, and therefore to produce a flow of energy from within outwards, which, under certain circumstances, appears in the case of selenium to produce an electric current. The crystallisation produced in selenium by light may also account for the diminution in the resistance of the selenium when a current from a battery is passing through it. For in changing to the crystalline state selenium becomes a better conductor of electricity."

Others of their observed results led them to the conclusion that selenium conducts electrolytically,‡ but it may be inferred from the paper—and was, indeed, expressly stated by Prof. Adams at the meeting of the Physical Society on June 13 last—that the authors did not suppose that actual electrolysis occurred, but rather that the molecular structure or crystalline condition of the substance was altered or modified by the action of a current of electricity in such a manner as to produce effects analogous to those which would have occurred if the selenium were an electrolyte and actually decomposed by the current.

As regards the effect of temperature, the author's conclusion that a slight rise of temperature greatly increases the resistance of selenium appears at first sight to be inconsistent with the results obtained by Werner Siemens, Draper, and Moss, and others who found that the resistance of selenium was diminished by heat. But Adams and Day appear never to have submitted their selenium to a higher temperature than 30° C., and some experiments of my own, made with several different specimens,* revealed the curious fact that selenium cells, whether in the dark or exposed to light, have a temperature of maximum resistance which is generally a few degrees higher than the average temperature of the air. The observations of Messrs. Adams and Day are therefore not necessarily inconsistent with those of others.

At the meeting of the American Association held last year at Philadelphia, a paper was read by Mr. C. E. Fritts, descriptive of a new and very ingenious form of selenium cell, which is said to exceed any previously made, both in sensitiveness to light and in the power of the "photo-electric" current which it is capable of generating.†

He melts a thin film of selenium upon "a plate of metal, with which it will form a sort of chemical combination. . . . . During the process of melting and crystallising the selenium is compressed between the metal plate upon which it is melted and another plate of steel, or other substance with which it will not combine. . . . . The non-adherent plate being removed after the cell has become cool, [he] then covers that surface with a transparent conductor of electricty, which may be a thin film of gold leaf. . . . . The whole surface of the selenium is therefore covered with a good electrical conductor, yet is practically bare to the light which passes through the conductor to the selenium underneath."

Upon reading this description it occurred to me that the conduction of selenium when prepared in the form of cells might be in reality, and not merely in appearance, electrolytic. It will be noticed that Mr. Fritts spreads his selenium upon "a plate of metal with which it will form a sort of chemical combination." Now, selenium will, I believe, combine more or less readily with all metals, the combination being assisted by heat. And in the preparation of selenium cells it has been the usual, if not the universal, custom to submit the selenium to prolonged heating while in contact with metallic electrodes. This operation has hitherto been called "annealing," and the undoubted fact that it diminishes the resistance of the selenium and increases its sensitiveness to light has been explained by supposing that the process is favourable to perfect crystallisation. I have recently suggested,‡ as an alternative explanation, that the prolonged heating by promoting the combination of the selenium with the metal of the electrodes results in the formation of a selenide, which completely surrounds the electrodes, and is perhaps diffused to some extent throughout the selenium when it is in a liquid condition; and that the apparently improved conductivity of the selenium, together with the electrolytic phenomena which it exhibits are to be accounted for by the existence of this selenide. I found that while the specific resistance of the selenium contained in a good cell having copper electrodes was ·9 megohm, that of a similar piece of selenium annealed in a glass mould without contact with any metal was as much as 2,500 meghoms.§ This enormous difference must, I think, be attributed to the presence of selenide of copper in the selenium of the cell.

I do not know whether, when the electrodes are of platinum, which was the metal used by Adams and Day, any appreciable quantity of selenide would be formed at the temperature employed for annealing. But a very small proportion of an electrolyte would account for the observed phenomena, and it is not impossible that a sufficient quantity might be contained as an impurity in the selenium as supplied by the manufacturer. Prof. Graham Bell, who collected various samples of selenium from different parts of the world, found amongst other impurities iron, lead, and arsenic,‖ all of which would form conducting selenides. He adds, it is true, that when these impurities were eliminated the selenium appeared to be more constant in its action and more sensitive to light; but it must be remembered

that in constructing his cells he always melted the selenium upon electrodes of brass or copper. "All former experimenters," he says*, "seem to have used platinum for the conducting part of their selenium cells, except Werner Siemens, who found that iron and copper might be employed. We have also discovered that brass, *although chemically acted upon by selenium*, forms an excellent and convenient material; indeed, we are inclined to believe that the chemical action between brass and selenium has contributed to the low resistance of our cells by forming an intimate bond of union between the selenium and brass."

I am not sufficiently versed in chemistry to be able to submit the hypothesis here suggested to the test of direct experiment. But certain indirect evidence in support of my views has been forthcoming. Selenium is an element which in its properties closely resembles sulphur, and attempts have from time to time been made, hitherto without success, to develop in sulphur that peculiar sensitiveness to light which is such a remarkable characteristic of selenium. It occurred to me that if this property of selenium were really due to the accidental existence of metallic selenides, then the admixture with sulphur of metallic sulphides might be expected to lead to similar effects. Several cells were therefore constructed in which selenium was replaced by sulphur containing a proportion of silver sulphide, the electrodes being formed of silver wire, and they all turned out to be more or less sensitive to light.† When one of these cells was connected in circuit with a battery and a galvanometer, and a piece of magnesium wire was burnt at a short distance from it, the galvanometer deflection was instantly increased, being in some cases more than doubled, and when the light was extinguished the deflection immediately fell to nearly its original value. If a telephone was substituted for the galvanometer, and the cell exposed to a rapidly interrupted beam of light, the telephone at once gave out a musical note which was nearly as loud as that produced when a good selenium cell was used.

The resistance in most of these cells was diminished by heating, and a number of experiments were therefore made for the purpose of ascertaining whether the effects described above were due to the direct action of radiation or to the rise of temperature by which exposure to radiation is accompanied. It was conclusively proved that the direct action of radiation was in itself competent to produce the effects. Firstly, the diminution of resistance due to light was instantaneous, while that produced by heating the cell was gradual. Secondly, the interposition of a glass trough containing a saturated solution of alum made no great difference in the result. Thirdly, a rise of temperature sufficient to produce any sensible effect could not possibly have been caused by the amount of light which was able to diminish the resistance in a marked degree. This was proved by the following experiment:—On a cloudy day the cell with the alum trough before it was placed at a distance of 16ft. from a small window, all the other windows in the room being darkened. With a battery of one Leclanché cell and a reflecting galvanometer it was found that closing the window shutter caused an instantaneous swing of the spot of light through ninety scale divisions in the direction indicating increased resistance; and when the shutter was again opened there was immediately an equal swing in the opposite direction. A delicate thermopile, connected with a galvanometer of low resistance, was then put in the place of the sulphur cell. On opening the window shutter a deflection occurred indicating a current which was found by trial to be equal to that produced by the radiation of the human body at a distance of 10ft. 6in. Now a nearly red hot brass rod held at a distance of little more than an inch from the cell produced a gradual fall of the resistance which in 15 seconds was indicated by only twenty-three scale divisions, and it is needless to say that the heat communicated by the human body at 10ft. 6in. was entirely without visible effect. Lastly, in the case of one cell (which contained sulphur and silver sulphide in equal parts) light and heat produced opposite effects. A paraffin lamp at a distance of 18 inches diminished the resistance. When the lamp was placed at a distance of 10 inches, the galvanometer needle first moved in the direction indicating a further fall of resistance, but after a few seconds, when the temperature began to rise, it turned in the opposite direction. On moving the lamp to a distance of 4 inches from the cell, there was at once a large deflection, indicating increased resistance, the temperature effect completely predominating over that of radiation.

When, as in the case of these cells, a current of electricity passes between silver electrodes through a mass of sulphide of silver, silver will be deposited upon the cathode and sulphur upon the anode. Now, sulphur has an enormously high resistance, and the existence of a mere film of free sulphur upon one of the electrodes would be sufficient to stop the current altogether. The current is not in fact stopped, because the deposited sulphur at once combines with the silver of the anode, merely adding a new layer to the electrolyte. Thus the metal of the anode gradually combines with the sulphur of the eloctrolyte, and the conductivity of the arrangement will depend to a great extent upon the facility with which this combination is effected, the quantity of electricity which can pass in a given time being limited by the quantity of sulphur which is capable of uniting with the electrode in the same time.

Sulphur combines with silver far more readily than with iron. If, therefore, my views are correct we should expect a cell with an iron anode to offer a much greater resistance than one which had an anode of silver, the material of the cathode, so long as it was a good elementary conductor of electricity, being of comparatively little importance. To test this idea a cell was made consisting of electrodes of iron and silver imbedded in a mixture of sulphide of silver and silver. The cell being connected with a battery and a galvanometer, it was found that its resistance was nearly thirty times as great when the current passed from iron to silver as when the direction of the current was from silver to iron.

It might therefore be expected that the resistance of a sulphur cell with silver electrodes would be diminished by any influence which assisted the combination of silver with sulphur. Experiment seems to show that such an influence is exerted by light.

A glass plate covered with silver leaf was placed, with the silvered side downwards, over a crucible of boiling sulphur. One half of the plate was covered with a piece of black cloth, and the arrangement was exposed to bright sunshine. In a short time the visible portion of the silver was darkened, owing to its partial conversion with sulphide; the cloth was then removed, and the silver beneath it was found to be scarcely discoloured.

Since this effect might possibly have been due to other causes than the action of light (such as the unequal condensation of sulphur-vapour upon the covered and uncovered portions of the plate), the experiment was made in another form. A piece of silver-leaf attached to glass was brushed over with a solution of sulphur in bisulphite of carbon, and, in order to keep the temperature low and uniform, the silvered glass plate was immersed in a basin containing cold water, which was placed in the sunshine.

A board was laid across the top of the basin so as to shade one half of the plate, the other half being exposed to the direct rays of the sun. In a quarter of an hour the exposed portion of the silver had acquired a dark brown colour, while that which had been protected was of a pale yellow tint, the outline of the shadow of the board being sharply defined. I think we have here the strongest evidence that the combination of sulphur with silver is assisted by light.

But it is not perhaps necessary to assume that the effective action of light is confined entirely to the electrode. It seems reasonable to suppose that any circumstances which are favourable to the union of two substances when they have a tendency to unite would also be favourable to their separation when from any cause they have a tendency to separate. If, then, as is commonly supposed, electrolysis involves a series of decompositions and recompositions, both these processes

* *Nature*, XXII., p. 502.

† Several different forms of these cells are fully described in a paper recently communicated to the Physical Society, and published in the *Phil. Mag.* for August, 1885.

Digitized by Google

would be assisted by the same agency which under ordinary conditions favours the union of the constituents of the electrolyte. The electrolysis of silver sulphide may therefore be assisted by light, and its electrolytic resistance at the same time diminished.

All the sulphur cells hitherto mentioned were made with silver sulphide and silver electrodes. Silver was in the first instance chosen as being especially suitable for the purpose on account of the facility with which it combines with sulphur. A few experiments have since been made with copper and copper-sulphide, but no indication of sensitiveness to light has yet been obtained with these materials, though I do not consider the results conclusive. But even if it should turn out to be the case that silver is the only metal which in conjunction with sulphur is capable of forming a combination sensitive to light, it would still, I think, remain probable that the action of light upon the resistance of selenium, in conjunction with any metal whatever with which it formed a sensitive combination, is of a similar nature to that which occurs in the case of sulphur and silver.

ON ATMOSPHERIC ELECTRICITY.*

BY PROF. C. MITCHIE SMITH.

The commonly-accepted opinion that during fine weather the air-potential is always positive is not accurate for Madras. There it is found that with a dry land wind (*i.e.*, westerly wind) the potential of the air is usually negative during several hours of the day. In the early morning and up to about 9 a.m. the potential is usually positive, then it becomes negative, reaching a maximum between 10 and 11 a.m., and continues negative till the sea breeze sets in in the afternoon. During the prevalence of land winds there are frequent local showers, but these are evidently not the cause of the negative readings. Negative readings are never obtained in fine weather, except when the wind is westerly, and not even then unless the ground is dry. A shower of rain, which cools the ground, makes the succeeding readings positive for some hours. A marked feature during the prevalence of land winds are the great clouds of dust which fill the air, and it seems probable that there is some connection between these dust clouds and the negative electrification of the air.

TESTING KEYS.

Every electrician who has had much to do with the testing of submarine cables or with laboratory experiment has doubtless grumbled on occasion at certain of his apparatus. The Bavarian, reversing, testing keys and the galvanometer short-circuiting key now in use are especially deficient. The reversing keys give a great deal of trouble at times by failing to make good contact between line or earth and battery through the loosening of the cam usually employed to hold the lever, whichever it may be, down. A key we have lately had the pleasure of inspecting, however, seems admirably calculated to remedy this difficulty. The cam is dispensed with altogether, and a spring latch is introduced which when the lever is depressed, automatically catches and holds it with certainty in position until it is released by pressing the ebonite knob on the insulating pillar, as shown in our illustrations. The movement, either in depressing the lever or releasing it, can of course be easily effected with one hand. The advantages of this key, which is the invention of Mr. Pell, well known in connection with the Eastern Extension Telegraph Company, will be readily appreciated by all electricians. The absence of the cams and their supporting pillars, besides improving the insulation and allowing of the key being more easily cleaned, makes it look neater, and prevents the lacquered surface of the brass work being disfigured, as is invariably and unavoidably the case when the cams are used. A short-circuiting key upon the same principle has also been constructed for Mr. Pell, by Messrs. Johnson and Phillips; the spring in this case is, however, somewhat stronger, to prevent unintentional locking when the key is tapped by the finger for observing the range of the deflection on the galvanometer scale. Another advantage possessed by this latter key, and one that is by no means without its value, is that of size. The old pattern key it will be admitted is absurdly small, and its general unhandiness, even for purposes of ordinary testing, is notorious. All sorts of dodges have to be resorted to if more than four wires are required to be connected to it, and any transposition of even these wires, if it be necessary, is always productive of some degree of difficulty and vexation.

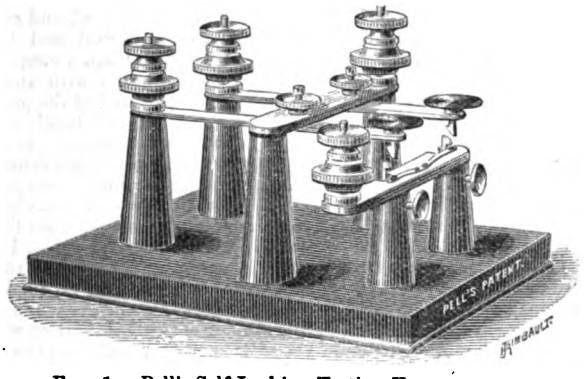

FIG. 1.—Pell's Self-Locking Testing Key.

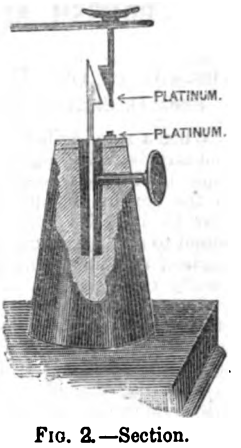

FIG. 2.—Section.

SIXPENNY TELEGRAMS.

The following are the official regulations relating to nland telegrams, to come into force on the 1st proximo. Our readers will, however, notice that the substance of these regulations was given in our issue of the 4th inst.:—

1. Every word, including the addresses, is to be charged for. As a rule, the only address which will be signalled will be that of the recipient, and this will come at the head of the message, the sender's name and address, if to be telegraphed, being signalled after the text. 2. The instructions "By Post" or "By Train," forming as they do part of the address, are to be charged for. 3. The words "Reply Paid" will still not be charged for. When twelve words of reply are paid for, "Reply Paid" is to be signalled in the instructions; when more than twelve words are paid for, "Reply Paid —— words" is to be signalled. In order to diminish the chances of Reply Paid instructions being overlooked, a new prefix has been adopted, viz., SRP and XRP, which is to be used in all cases in which replies have been prepaid. 4. The names of all towns and villages are to be counted as one word each. But the old rule will still apply as regards places in towns like Park Lane, Charing Cross, &c., which are to be counted as two words each. 5. Names of persons, like O'Neil, De la Rue, &c., are to be counted as one word each; but double names like "Smith-Payne" are to be counted as two words. 6. Initial letters are to be counted as formerly, with the exception that the London District initials are to be counted as one word for each set of initials. Thus "S.W." is to be counted as one word. 7. Figures are to be counted, as in Continental telegrams, at the rate of five to a word. Thus "38563" will be one word; "12:35" will be one word; and "2/7/6" will be one word. 8. Mixed figures and letters are to be counted in the manner shown by the following examples:—

104a = two words. | 42nd = two words | 7s. 6d. = four words.

9. a.m. and p.m. when written thus: "am" and "pm," are to be counted as one word each. In fact, any group of letters not exceeding five is, as heretofore, to be counted as one word. 10. The charge for re-direction will be 6d. for every telegram re-directed within the same town, and the full rate for every telegram re-directed from one town to another. Each London District is to be

* Abstract of paper read at the Aberdeen Meeting of the British Association.

Digitized by Google

regarded as a separate town. 11. The words "Re-directed from ——" are no longer to be written at the end of the address on the C form, but after the name of the office at which the telegram was originally handed in. The C form of a telegram handed in at Liverpool and re-directed from Birmingham to Cheltenham at 3:20 will read thus :—

Handed in at the } *Liverpool Office and re-directed from Birmingham Office* at 3:20 p.m. Received here at } ——m.

12. Multiple address telegrams are to be charged for in the following manner :—First the total number of words in the addresses and in the text are to be counted and charged for, then 2d. a copy is to be charged for each telegram entitled to be delivered at the reduced rate, and then the text is to be charged for of any telegram (other than the original telegram) not entitled to be delivered at the reduced rate. Handbills explaining this more fully will be sent to every telegraph office, with the book of instructions. 13. The amended address fee is to be 6d. where it formerly was 1s.

BRITISH ASSOCIATION MEETING, 1885.

ADDRESS TO THE MATHEMATICAL AND PHYSICAL SECTION, BY PROF. G. CHRYSTAL, M.A., F.R.S.E., PRESIDENT OF THE SECTION.

When a man finds himself unexpectedly in some unusual situation his first impulse is to look round and see how others have done in like circumstances. I have accordingly run through the addresses of my predecessors in the honourable office of president of Section A, which is fated this year to be filled somewhat unworthily. This examination has, I am bound to say, comforted me not a little. I have found precedents for all kinds of addresses, long and short, even apparently for none at all. The variety of subjects is also suggestive of great latitude. I have found reviews of the progress of mathematical and physical science, discussions of special scientific subjects, dissertations on the promotion of scientific research, and on the teaching and diffusion of science, all chosen in their turn for the subjects of this opening address.

Following some of the most eminent of my forerunners, I propose to be brief ; following the last of them, Prof. Henrici, I shall take for my subject, so far as I have one, the Diffusion of Scientific Knowledge. Apart from the fact that Prof. Henrici's address greatly interested me, and that I find many of his conclusions in agreement with the results of my own experience, and that, therefore, I wish to second him with all my power, I have other reasons for this choice. For more than half the year I am employed with absolute continuity in teaching mathematics, and it has happened for the last eight years or so that the other half has been mainly occupied in a variety of ways with science teaching generally. This is the thing concerning which I have had most experience, and I hold it to be the most respectful course towards my audience to speak to them on the subject that I know best.

Ever since I began to study science I have been deeply interested in the question of how it could best be taught. I believe my meditations in that direction were awakened by some unsuccessful boyish efforts to apply to the satisfaction of a ploughman, who was my friend and confidant, certain principles of natural philosophy to explain the action of his plough. Wisely and unwisely I have always been ardent about the improvement of scientific teaching. I was so long before I dreamt that I should one day be called upon to put my ideas through the cold ordeal of practice. It would not be becoming that I should speak at any time, more particularly to-day, regarding the success of my own efforts, or even regarding my alternate fits of hopefulness and despair. It is enough to say that, in such a cause,

> "Tis better to have loved and lost,
> Than never to have loved at all."

The British Association, by its title, exists for the advancement of science. Now, I hold that one of the essential conditions for that advancement is the existence of a scientific public—a public, like the Athenians of old, eager to hear and tell of some new truth ; eager to discuss and eager to criticise ; ready to appreciate what is novel ; to receive it if sound, to reject it if unsound. It is to such a public that the British Association appeals, and certainly in the past it has not found its public wanting in generosity. What I should wish to see is less of mere friendly onlooking and more participation in the dance.

I am not speaking now merely of a professional public, such as is so prominent in Germany, for instance, made up of teachers and others professionally concerned with science. I refer mainly to that amateur but truly expert public which has always been so honourable a feature of English science, as examples of which I may mention Boyle and Cavendish in former days, and Joule and Spottiswoode in our own. It is quite true that much of that scientific public came in days of yore from the leisured class, whose ratio to the rest of the nation will not improbably decrease in the course of our social development. I think, however, that the loss we may thus sustain will be more than compensated by the continual increase of those who have received higher education of some kind or other, and whose daily occupations give them an interest, direct or indirect, in one or more branches of science.

It may not be amiss to insist for a little on the advantages to science of a great body of men unofficially engaged in scientific research, in writing regarding science, or even in merely turning scientific matter over in their minds. It will not have escaped the notice of those among you who have studied the history of science, that few scientific ideas spring up suddenly without previous trace or history. It is perfectly true that in many cases some mind of unwonted breadth and firmness is required to formulate the new doctrine, and carry it to manifold fruition ; but a close examination always shows that the sprite was in the air before the Prospero came to catch him. It is very striking to notice, in the history of algebra for instance, long periods in which great improvements were effected in the science, which cannot be traced to any individual, but seem to have been due merely to the working of the minds of scientific men generally upon the matter, one giving it this little turn, another that, in the main always for the better. Like every other thing that has the virtue of truth in it, science grows as it goes, not like the idle gossipping tale by the casual accretion of heterogeneous matter, but by the chemical combination of pure element with pure element in reasonable proportion.

I know of no greater advantage for science than the existence of an army of independent workers sufficiently enlightened for self-criticism, who shall test the results and theories of their day. Great and indispensable as are the uses of professional schools of scientific workmen, they are open to one great and insidious danger. The temptation there to swear by the word of the master is often irresistible. Not to speak of its being often the readiest avenue to fame and profit, it is the perfectly natural consequence of the contact of smaller mind with greater.

There are few things where the want of an enlightened scientific public strikes an expert more than in the matter of scientific text-books. If the British public were educated as it ought to be, publishers would not be able to palm off upon them in this guise the ill-paid work of fifth-rate workmen so often as they do ; nor would the scientific articles and reviews in popular journals and magazines so often be written by men so palpably ignorant of their subject.

We all have a great respect for the integrity of our British legislators, whatever doubts may haunt us occasionally as to their capacity in practical affairs. The ignorance of many of them regarding some of the most elementary facts that bear on everyday life is very surprising. Scientifically speaking, uneducated themselves, they seem to think that they will catch the echo of a fact or the solution of an arithmetical problem by putting their ears to the sounding-shell of uneducated public opinion. When I observe the process which many such people employ for arriving at what they consider truth, I often think of a story I once heard of an eccentric German student of chemistry. This gentleman was ill, but, like all his nation, systematic. When he had a precipitate to weigh, instead of resorting to his balance, he would go the round of the laboratory, hold up the test-tube before each of his fellow-students in turn, and ask him to guess the weight. He then set down all the replies, took the average, and entered the result in his analysis.

I will not take up your time in insisting upon the necessity of the diffusion of science among that large portion of the public who are, or ought to be, appliers of scientific knowledge to practical life. That part of my theme is so obvious, and has been of late so much dwelt upon, that I may pass it by and draw your attention to another place in which the shoe pinches. All of you who have taken any practical interest in the organisation of our educational institutions must be aware of the great difficulty in securing the services of non-professional men of sufficent scientific knowledge to act on School Boards, and undertake the direction of our higher schools. It is no secret among those who carefully watch the course of the times in these matters that our present organisation is utterly insufficient ; that it has not solved, and shows every day less likelihood of solving, the problems of higher education. This arises, to a great extent, from the fact that a scientifically educated public of the extent presupposed by that organisation really does not at present exist.

If the existence of a great scientific public be as important as I think I have shown it to be, it must be worth while to devote a few moments to the consideration of the means we adopt to produce it both in the rising and in the risen generation.

It would naturally be expected that we should look carefully to the scientific education of our youth, to see that the best men and the best means that could be had were devoted to it ; that we should endeavour to make for them a broad straight road to the newest and best of our scientific ideas ; that we should exercise them when young on the best work of the greatest masters ; familiarise them early with the great men and the great feats of science, both of the past and of the present ; that we should avoid retarding their progress by making details and illustrations or particular rules and methods ends in themselves. Granting that it is impossible to bring every learner within reach of the fullest scientific knowledge of his time, it would surely be reasonable to take care that the little way we lead him should not be along some devious by-path, but towards some eminence from which he might at least *see* the promised land. The end of all scientific training of the great public I take to be, to enable each member of it to look reason and nature in the face, and judge for himself what, considering the circumstances of his day, may be known, and not be deceived regarding what must to him remain unknown. If this be so, surely the ideal of scientific education which I have sketched is the right one ; yet it is most certainly not the ideal of our present system of instruction. To attain conviction on that head it is sufficient to examine the text-books and examination papers of the day.

Let us confine ourselves for the present to the most elementary of all the exact sciences, viz., geometry and algebra. These two, although among the oldest, are, as Prof. Cayley very justly reminded the Association not long ago, perhaps the most progressive and promising of all the sciences. Great names of antiquity are associated with them, and in modern times an army of men of genius have aided their advance. Moreover, it cannot be said that this advance concerns the higher parts of these sciences alone. On the contrary, the discoveries of Gauss, Lobatschewsky, and Riemann, and of Poncelet, Möbius, Steiner, Chasles, and Von Stawdt, in geometry, and the labours of De Morgan, Hamilton, and Grassman, not to mention many others, in algebra, have thrown a flood of light on the elements of both these subjects. What traces of all this do we find in our school books ? To be sure *antiquity* is stamped upon our geometry, for we

Digitized by Google

use the text-book of Euclid, which is some two thousand years old ; but where can we point to the influence of *modern* progress in our geometrical teaching? For our teaching of algebra, I am afraid, we can claim neither the sanction of antiquity nor the light of modern times. Whether we look at the elementary or at what is called the higher teaching of this subject, the result is unsatisfactory. With respect to the former, my experience justifies the criticism of Prof. Henrici; and I have no doubt that the remedy he suggests would be effectual. In the higher teaching, which interests me most, I have to complain of the utter neglect of the all-important notion of algebraic form. I found, when I first tried to teach University students co-ordinate geometry, that I had to go back and teach them algebra over again. The fundamental idea of an integral function of a certain degree, having a certain form and so many coefficents, was to them as much an unknown quantity as the proverbial x. I found that their notion of higher algebra was the solution of harder and harder equations. The curious thing is that many examination candidates, who show great facility in reducing exceptional equations to quadratics, appear not to have the remotest idea beforehand of the number of solutions to be expected ; and that they will very often produce for you by some fallacious mechanical process a solution which is none at all. In short, the logic of the subject, which, both educationally and scientifically speaking, is the most important part of it, is wholly neglected. The whole training consists in example grinding. What should have been merely the help to attain the end has become the end itself. The result is that algebra, as we teach it, is neither an art nor a science, but an ill-digested farrago of rules, whose object is the solution of examination problems.

The history of this matter of problems, as they are called, illustrates in a singularly instructive way the weak point of our English system of education. They originated, I fancy, in the Cambridge Mathematical Tripos Examination, as a reaction against the abuses of cramming bookwork, and they have spread into almost every branch of science teaching—witness test-tubing in chemistry. At first they may have been a good thing ; at all events, the tradition at Cambridge was strong in my day that he that could work the most problems in three or two and a-half hours was the ablest man, and, be he ever so ignorant of his subject in its width and breadth, he could afford to despise those less gifted with this particular kind of superficial sharpness. But in the end it came all to the same ; we were prepared for problem working in exactly the same way as for bookwork. We were directed to work through old problem papers, and study the style and peculiarities of the day and of the examiner. The day and the examiner had, in truth, much to do with it, and fashion reigned in problems as in everything else. The only difference I could ever see between problems and bookwork was the greater predominance of the inspiriting element of luck in the former. This advantage was more than compensated for by the peculiarly disjointed and, from a truly scientific point of view, worthless nature of the training which was employed to cultivate this species of mental athletics. The result, so far as problems worked in examinations go, is, after all, very miserable, as the reiterated complaints of examiners show ; the effect on the examinee is a well known enervation of mind, an almost incurable superficiality, which might be called Problematic Paralysis—a disease which unfits a man to follow an argument extending beyond the length of a printed octavo page. Another lamentable feature of the matter is that an enormous amount of valuable time is yearly wasted in this country in the production of these scientific trifles. To the occasional working and propounding of problems as an aid to the comprehension of a subject, and to the starting of a new idea, no one objects, and it has always been noted as a praiseworthy feature of English methods ; but the abuse to which it has run is most pernicious.

All men practically engaged in teaching who have learned enough, in spite of the defects of their own early training, to enable them to take a broad view of the matter, are agreed as to the canker which turns everything that is good in our educational practice to evil. It is the absurd prominence of written competitive examinations that works all this mischief. The end of all education nowadays is to fit the pupil to be examined ; the end of every examination not to be an educational instrument, but to be an *examination* which a creditable number of men, however badly taught, shall pass. We reap, but we omit to sow. Consequently our examinations, to be what is called fair—that is, beyond criticism in the newspapers—must contain nothing that is not to be found in the most miserable text-book that any one can cite bearing on the subject. One of my students, for example, who was plucked in his M.A. examination, and justly so if ever man was, by the unanimous verdict of three examiners, wrote me an indignant letter because he believed, or was assured, that the paper set by the examiners could not have been answered out of Todhunter's "Elementary Algebra." I have nothing to say, of course, against that or any other text-book, but who put it into the poor young man's head that the burden lay with me to prove that the examination in question ought to contain nothing but what is to be found in Todhunter's "Elementary Algebra?" The course of this kind of reasoning is plain enough, and is often developed in the newspapers with that charming simplicity which is peculiar to honest people who are at the same time very ignorant and very unthinking. First, it follows that lectures should contain nothing but what is all to be found in every text-book ; secondly, lectures are therefore useless, since it is in the text-book ; thirdly, the examination should allude to nothing that is not in the text-books, because that would be unfair ; fourthly, which is the coach or crammer's deduction, there should be nothing in the text-book that is not likely to be set in the examination. The problem of the writer for a text-book has come now, in fact, to be this—to write a booklet so neatly trimmed and compacted that no coach, on looking through it, can mark a single passage which the candidate for a minimum pass can safely omit. Some of these text-books I have seen, where the scientific matter has been, like the lady's waist in the nursery song, compressed "so gent and sma'," that the thickness of it barely, if at all, surpasses what is devoted to the publisher's advertisements. We shall return, I verily believe, to the Compendium of Martianus Capella. The result of all this is that science, in the hands of specialists, soars higher and higher into the light of day, while educators and the educated are left more and more to wander in primeval darkness.

When our system sets such mean ends before the teacher, and encourages such unworthy conceptions of education, is it to be wondered at that the cry arises that pupils degenerate beneath even the contemptible standards of our examinations? These can hardly be made low enough to suit the popular taste. It is no merit of the system we pursue, but due simply to the better among our teachers, men many of them who work for little reward and less praise, that we have not come to a worse pass already. Some even of the much-abused crammers have conceptions of a teacher's duty far higher than the system-mongers of the day, whom it is their special business to outwit ; and it is but fair to allow to such of these also as deserve it part of the credit of stemming the torrent of degeneration. We place our masters in positions such that that their very bread depends upon their doing what many of them know and will acknowledge to be *wrong*. Their excuse is, "We do so and so because of the examination."

The cure for all this evil is simply to give effect to a higher ideal of education in general, and of scientific education in particular. Science cannot live among the people, and scientific education cannot be more than a wordy rehearsal of dead text books, unless we have living contact with the working minds of living men. It takes the hand of God to make a great mind, but contact with a great mind will make a little mind greater. The most valuable instruction in any art or science is to sit at the feet of a master, and the next best to have contact with another who has himself been so instructed. No agency that I have ever seen at work can compare for efficiency with an intelligent teacher, who has thoroughly made his subject his own. It is by providing such, and not by sowing the dragon's teeth of examinations, that we can hope to raise up an intelligent generation of scientifically educated men, who shall help our race to keep its place in the struggle of nations. In the future we must look more to men and to ideas, and trust less to mere systems. Systems have had their trial. In particular, systems of examination have been tested and found wanting in nearly every civilised country on the face of the earth. Backward as we are here, we are stirring. The University of London, after rendering a great service to the country by forcing the older universities to give up the absurd practice of restricting their advantages to persons professing a particular shade of religious belief, has for many years pursued its career as a mere examining body. It has done so with rare advantages in the way of Government aid, efficient organisation, and an unsurpassed staff of examiners. Yet it has been a failure as an instrument for promoting the higher education—foredoomed to be so, because, as I have said, you must sow before you can reap. At the present time, with great wisdom, the managers of that institution have set about the task of really fitting it out for the great end that it professes to pursue. If they succeed in so doing they will confer upon the higher education one of the greatest benefits it has yet received. They have an opportunity before them of dethroning the iron tyrant Examination which is truly enviable. This movement is only one of the signs of the times. Among the younger generation I find few or none that have any belief in the "learn when you can and we will examine you" theory ; and small wonder, for they have tasted the bitterness of its fruit. *Laissez faire* as a method in the higher education no longer holds its place, except in the minds of inexperienced elderly people, who cling, not unnaturally, to the views and fashions which were young when they were so.

All the same, the task of reformation is not an easy one. Examinations have a strong hold upon us, for various reasons, some good, some bad, but all powerful. In the first place, they came in as an outlet from the system of patronage, which, with many obvious advantages, some of which are now sorely missed, had become unsuited to our social conditions. There is a certain advantage in examinations from the organiser's point of view, which any one who, like myself, has to deal with large quantities of pretty raw materials will readily understand. Again, there is an ordinary bustle about the system that pleases the business-loving eye of the Briton. Yearly the printed sheets go forth in every corner of the land. The candidates meet and, in the solemn silence of the examination hall, the inspector, the local magnate, or the professor, sits, while for two or three busy hours the pens go scratching over the paper. A feeling of thankfulness comes over the important actor in this well-ordered scene, that the younger generation have such advantages that their fathers never knew. It is only when the answers are dissected in the examiner's study that the rottenness is revealed underlying the fair outward skin. But then the examiner must go by his standards ; he must consider what is done elsewhere, and what is to to be reasonably expected. Accordingly he takes his report and quickly writes so many per cent. passed. Then the chorus of reporting examiners lift up their voices in wonderful concordance ; and all, perhaps even the examiners, are comforted. There is something attractive about the whole thing that I can only compare to the pleasure with which one listens to the hum of a busy factory or to the roaring of the forge and ringing of the anvil. But what avails the hum of the factory if the product be shoddy, and what the roar of the forge and the ring of the anvil if the metal we work be base?

In conclusion, let us consider for a moment what might be done for the risen generation, who are too old to go formally to school, and yet not too old to learn. In their education such bodies as the British Association might be very helpful. Indeed, in the past, the British Association has been very helpful in many ways. It can point to an admirable series of reports on the progress of science, for which everyone who, like myself, has used them, is very grateful. It is much to be desired that these reports should be continued, and extended to many branches of science which they have not yet covered.

Digitized by Google

The Association has at present, I believe, a committee of inquiry into science-teaching generally. This is typical of a kind of activity which the Association might very profitably extend. This Association, with its long list of members bristling with the names of experts in every science, not drawn from any clique or particular centre, but indiscriminately from the whole land, might take upon itself to look into the question of scientific text books and treatises. Even if it did not set up a censorship of the scientific press, which might be an experiment of doubtful wisdom, although some kind of interference seems really wanted now and then, it might set itself to the highly useful work of filling the gaps in our scientific literature. There is nothing from which the English student suffers so much as the want of good scientific manuals. The fact is that the expense of getting up such books in the country is so great, and the demand for them, though steady, yet so limited, that it will not pay publishers to issue them, let alone remunerate authors to write them. In my student days the scarcity was even greater than it is now, and in fact then no one could hope to get even a reasonable acquaintance with the higher branches of exact science unless he had some familiarity with French or German at the very least—a familiarity which was rare among my fellow students either in England or in Scotland. Might not the British Association now and then request some one fitted for the task to write a treatise on such and such a subject, and offer him reasonable remuneration for the time, labour, and skill required?

Another field in which the Association might profitably extend its labours appears to me to be the furnishing of reports, from time to time, on the teaching of science in other countries, and the drawing up of programmes of instruction for the guidance of schoolmasters and of those who are reading for their own instruction. There is no need to impose these programmes on any one. I would leave as much freedom to the teacher as I would to the private student. The programme drawn up by the Society for the Improvement of Geometrical Teaching, for example, has been very useful to me as a teacher, although I do not follow it or any other system exclusively. The great thing is not to fall asleep over any programme or system. For the matter of that, Euclid would do very well, in the earlier stages of school instruction at least, provided he were modernised, and judiciously discarded at that part of the student's career where a lighter vehicle and more rapid progress become necessary. In such programmes as I contemplate the bearing of recent discovery on the elements of the various sciences could be pointed out, and the general public kept in this way from that gross ignorance into which they are at present allowed to fall.

The British Association has of late, I believe, given its attention to the encouragement of local scientific activity. There can be no doubt that much could be done in this way that is not done at present. The concentration of scientific activity in metropolitan centres is beginning to have a depressing effect in Great Britain. This is seen in the singularly unequal way in which Government aid is distributed over the country. Large sums are spent—sometimes we outsiders think not to the best purpose—through certain channels, simply because these channels happen to have a convenient opening in some Government office in London, or in some place in that important city which has easy access to the ruling powers; while applications on behalf of other objects not less worthy are met with a refusal which is sometimes barely courteous. The result is that local effort languishes, and men of energy, finding that nothing can be done apart from certain centres, naturally gravitate thither, leaving provincial desolation to become more desolate.

I think that our great scientific societies—the Royal Societies of London and Edinburgh and the Royal Irish Academy—might do more than they do at present to prevent this languishing of local science, which is so prejudicial to the growth of a scientific public. Besides their all-important publishing function, these bodies have for a considerable time back been constituted into a species of examining and degree-conferring bodies for grown-up men. That is to say, their membership has been conferred upon a principle of *exclusion*. Instead of any one being *admitted* who is willing to do his best, by paying his subscription or otherwise, to advance science, every one is *excluded* who does not come up to the standard of a certain examining body. Now, against this proceeding by itself I have nothing to say, except that it appears to belong to the pupillary age both of men and nations. It is not the honouring of the select few that I think evil, but the exclusion of the unhonoured many. The original intention in founding these societies was to promote the advancement of science. How that is done by excluding any one, be it the least gifted among us, who is honestly willing to contribute his mite towards the great end, fairly passes my comprehension. If it is thought necessary, for the proper cultivation of the scientific spirit among us, that the degree-conferring function should be continued, let there by all means be an inner court of the temple, a place for titular immortals; but let there be also a court of the Gentiles, where those whose fate or whose choice it is to serve science unadorned may find a modest reception. I believe that the adoption of this suggestion would enormously extend the usefulness of our great scientific societies, and give to their voice a weight which it never had before. At all events, if the trammels of tradition, or some better reason with which I am unacquainted, should prevent them from broadening their basis in the way I indicate, nothing prevents the British Association, with its more liberal constitution, from considering what may be done for the scientific plebeian.

There is one other function of the British Association in connection with which I wish to venture another suggestion. During the annual meeting, scientific men have an opportunity of making each other's acquaintance. Great men exchange ideas with great men; and, most important of all, young and little men have a chance, rarely otherwise afforded, of taking a nearer view of the great. What I would suggest for consideration is, whether it might not be possible to form an organisation which would in a certain sense carry this advantage through the whole year. I have already alluded more than once to the difficulties that the scientific public—and here I include professional men generally, in fact all but the leaders of science—have in keeping pace with recent advances. Would it not be possible to have an arrangement enabling at least every large centre of the higher education to have periodically the benefit of communion with and instruction from the high priests of the various branches of science? How glad we, the teachers of science in Edinburgh for example, would be to have a course of lectures once every three or four years from Professors Cayley, Sylvester, Stokes, Adams, Lord Rayleigh. In this way effect would be given to the principle which cannot be too much insisted upon, that the power of the spoken word far exceeds that of the written letter. Not only should we learn from the mouths of the prophets themselves the highest truths of science, but the present generation would thus come to know face to face, as living men, those whose work will be the glory of their time and a light for future ages. From the want of a proper circulating medium the influence of great scientific men very often does not develop until they and the secrets of their insight have gone from among us. The object of what I propose is to make these men more of a living power in their own lifetime.

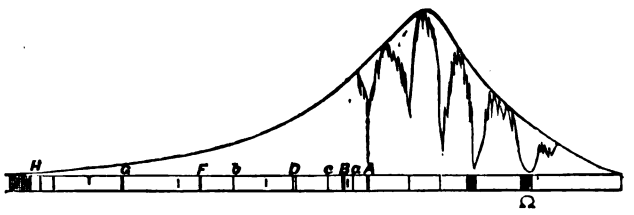
THE ELECTRIC LIGHT AND ATMOSPHERIC ABSORPTION.*

The absorption of light by the earth's atmosphere is a subject of very great importance, for it affects and modifies our views of everything around us. We recognise its importance to ourselves when we reflect that seeing is our only means of direct communication with bodies at a distance. The sense of smell carries us a little way out of ourselves, and the sense of hearing carries us a little farther, the one through fine particles carried by the atmosphere, and the other by its regular vibrations; yet the direct effects of these are manifest only in the immediate neighbourhood in which they are produced, and it is only by means of some agency—such as electricity or some other mode of motion—that sounds can be transferred into some other form of energy and retransferred so as to reproduce themselves as signals at considerable distances. The sense of sight reveals not only the outline and colour of bodies immediately around us, but that very absorption by the atmosphere of which, as our president has told us, we know so little, and of which I have to speak. It enables us to judge of distance and lends the charm of tone and colour to the landscape; it warns us of the gathering cloud, and in the twilight of the morning it tells us of the coming sunshine. Light reveals to us not only things within our atmosphere, but Prof. Stokes, in his course of lectures here, has shown the various ways in which it may be employed to investigate the condition and composition of the sun and stars, and to resolve the nebulæ. Within the last ten days it has revealed to us that in the centre of a nebulous mass of matter there is said to be a concentration of the luminous gases into a central mass, as though a new sun were just caught in the act of its formation. Yet, we must remember that we have now only received the record of an event which happened many thousands of years ago, and that the waves which have brought it to us, travelling at the rate of 192,000 miles a second, have been on their journey for that long period of years. Since the days of Newton we have learned to regard the sun's light as composite in character. With a wedge or prism of glass he showed that it consists of different kinds of radiations, which are bent or refracted in different degrees on passing through the prism, and that the result is a spectrum of different colours—red, orange, yellow, green, blue, and violet, where each degree of bending is accompanied by a special shade or colour, and the sum of all combined makes up the total sunlight. The sun's heat has been studied independently, and has also been found to consist of radiations, or we may call them rays, which are bent in different degrees on passing through a prism. The same is true of the actinic power or chemical action of the sun, each degree of bending corresponding to a definite amount of chemical or photographic power. Not only so, but corresponding to a given degree of bending by the prism, or rather corresponding to a given wave-length, the heat, the light, and the actinic power from the same source are always present in the same proportions. The same is true of the spectrum of the electric light from glowing carbon poles, or of the radiations from a glowing gas. Take, for instance, the green band of thallium. The burning of this substance at the temperature of the electric arc causes it to give out its own special radiation in the green, which possesses a certain amount of heating, light-giving, and actinic powers, and these are so related that whatever alters the amount of the one alters each of the others in the same proportion. If, for instance, the vapour of thallium at a lower temperature absorbs one-fourth of the light, it also absorbs one-fourth of the heat and one-fourth of the actinic power of this green ray. This statement is not inconsistent with the fact that there are rays of obscure heat which give no light, and rays which are chemically active which give no light and very little heat, but will embrace these cases, only the proportion of light in them is nothing. Take again the rays of different wave length, such as we may regard radiant heat, light, and actinic power as only different results, or as different forms of the energy of the self-same radiation. Let us examine the spectrum of selenium. In each of these rays, then, the heating power, the light-giving and actinic power are each present there, in a definite and always in the same relation to one another, but not in the same proportions for the different *bands* (colours). Any substance which absorbs a ray of definite wave length will have absorbed its heating, its light-giving, and its actinic powers in the same proportions, although we may not be able to detect the presence of them. And here comes our

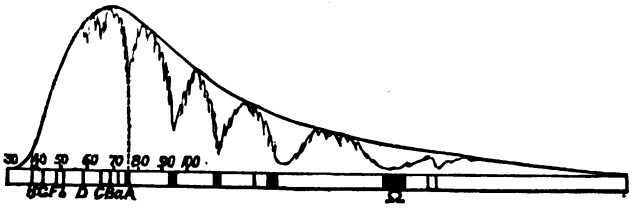
* Evening lecture delivered before the British Association, at Aberdeen, on Friday, Sept. 11, 1885.

Digitized by Google

difficulty, the difficulty of measuring and comparing these effects, which are not absolute but relative, and which are always being dissipated, so diminishing our stock of useful energy. To get over this difficulty of the measurement of the energy of radiations, one takes his photographic camera, and, devoting himself to *fastening on* a special portion of the spectrum, he maps its energy by means of its action on certain prepared chemicals. In this field there are many workers at the violet and ultra-violet rays, which produce strong chemical action on salts of silver, but for the red and beyond the red end of the spectrum the progress made is especially due to Captain Abney, who has greatly extended our knowledge in this direction, and opened up and made accurate chemical measurements in parts of the spectrum which were before unknown, to which the door had only just been thrust a little open by Herschel and other investigators, who detected differences of chemical action in different parts of the red end of the spectrum. Another observer takes Melloni's thermo-electric pile, which measures the energy of radiations by the change of temperature produced by them at the junctions of two metals, antimony and bismuth, the change of temperature being measured by the thermo-electric current so produced. [Experiment with thermopile and galvanometer.] Now, to get nearer and nearer to the single radiations the breadth of the thermopile must be more and more reduced, and with it the electric current which deflects the needle of the galvanometer. With this instrument the general distribution of heat throughout the spectrum and beyond the red end have been measured. But even the line thermopile has considerable breadth, and so Prof. Langley invents his bolometer, wherein by the change of temperature of a wire of platinum from $\frac{1}{1000}$ to $\frac{1}{10000}$ of an inch in thickness, *i.e.*, so fine that it almost requires a microscope to see it, he measures the heating effect of solar and other radiations. With this instrument, which is far more sensitive than any linear thermopile, Prof. Langley has investigated the energy of the radiations throughout the solar spectrum. He has shown us that, although Capt. Abney had extended the spectrum nearly twice the length of the visible spectrum beyond the red, and had made far more accurate measurements in this region than any which had been made before, yet he had not told us half the tale, for Prof. Langley's investigations show that the portion beyond the red is six times as long as the visible spectrum. Let me explain what I mean when I speak of the length of the spectrum. With prisms we obtain spectra of different lengths and unequal spreading of the colours, *i.e.*, unequal bending of waves of the same length, according as we change the material of our prisms. Hence, in measuring the heat or the chemical action in a length of, say, 1 mm. of the spectrum, we get one value with a glass prism, another with quartz, another with rock-salt, and another with bisulphide of carbon in the same region of the spectrum, and with the same general bending of the waves we shall have a different amount of spreading out or dispersion of the waves of different lengths, and an unequal lengthening of the spectrum in its various parts. Not only so, but the long waves are compressed together, and the short waves are spread out, so that as regards wave-length our estimate of the heating and the energy of 1 mm. in the red, and beyond the red, is far too high, because the waves are there too much compressed. In the spectrum of the sun and of the electric arc the greatest heating in a length of 1 mm. of the spectrum formed by a prism is beyond the red; but if we arrange the distribution of the colours



Prismatic Spectrum.



Normal or Diffraction Spectrum.

of our spectrum according to wave-lengths, the greatest heating effect, or the maximum energy, lies in the yellow, *i.e.*, the part which gives the brightest light. We may get more exact ideas by comparing diagrams in which the length of the spectrum is represented as a horizontal line, and the intensity at any point of it is represented by a height drawn upwards from that point. The bounding line through all the upper ends will then enclose an area which will represent the [distribution of] energy throughout the spectrum. The prismatic spectrum is apt to give us wrong ideas, from the crowding together of the red end of the spectrum. Reckoning wave lengths in 10,000ths of a mm., the ultra-violet extends from about 4 to about 2½/10,000ths of 1 mm., the visible spectrum extends from 4 to about 7·6/10,000ths, and in the infra-red Captain Abney has measured to a wave-length of 12, and Prof. Langley has measured or shown the existence of waves whose lengths extend beyond 24/10,000ths of 1 mm., *i.e.*, nearly 1/10,000th of an inch. With the visible part, from wave-length 4 to 7·6/10,000ths, in which part also lies the region of maximum energy, we are principally concerned this evening. We have as yet no established photometric method for the absolute measure of visible radiations, but there is great promise that we are not far from as delicate a test for light as Prof. Langley's bolometer is for radiant heat. This delicate test depends upon the very remarkable sensitiveness to light which is possessed by the substance selenium. Specially prepared selenium has less electrical resistance on exposure to light than it has when kept in the dark, so that placing it in the dark and joining it up in an electric circuit with a battery and galvanometer there will be a greater current, causing a deflection of the galvanometer needle when the selenium is exposed to light. All the visible rays of the spectrum change the electrical condition of selenium, but the greatest change is produced by the greenish yellow waves, *i.e.*, the brightest part of the spectrum. The obscure heat rays produce comparatively little change, and the ultra-violet rays do not seem to have the power of producing any E.M.F. in the selenium; hence selenium gives a very delicate mode of measuring the illuminating power, or the energy of the visible radiations by the increase in the electric current as shown by the deflection of the galvanometer. Last year I received from Mr. Fritts, of New York, some selenium cells which were far more sensitive to light than any which had been previously made. Here is one (No. 23) whose resistance of 14,000 ohms in the dark was changed to 170 ohms in bright sunlight. Another (No. 129) had a resistance of 200,000 ohms in the dark, which was reduced to 940 ohms, *i.e.*, less than $\frac{1}{100}$th part of the original resistance by exposure to sunlight. I have found that exposure to one candle at a distance of one foot reduces the resistance of each of these to one half its previous value. Another cell had its electrical resistance reduced from 75,000 ohms to 43,000 ohms by the same exposure. In this change of 32,000 ohms for an illumination of one candle we see that we have a means of measuring very small differences of illuminating power, and therefore a means specially adapted to measure small differences due to absorption of light by the earth's atmosphere. Many will have seen the selenium eye made by Sir William Siemens to illustrate this action of light. A series of observations taken throughout the day with the *gold leaf face* of the selenium cell exposed to the south-eastern portion of a cloudless sky showed a gradual increase of current from 9:30 to 11:30 in the morning, a maximum steady current lasting until about 1:30, followed by a gradual diminution of current from 1:30 until 4 o'clock.

It will be seen that this substance—in which the energy of radiations in the visible spectrum seems to be directly converted into electrical energy—gives promise of a means of determining the energy of the simple radiations from the run or the electric light or any other source, and also of determining the amount of absorption by solid liquid or gaseous transparent media. When a beam of white light falls upon a coloured substance, such as gold leaf, a portion of each kind of light is regularly reflected, giving a reflected beam of white light; another portion of the light enters a little way into the substance, and after being reflected from molecule to molecule is thrown back again and scattered in all directions. This light reveals the presence and colour of the substance. The remainder of the light enters and penetrates deeper and deeper into the substance and becomes absorbed in it, the energy of these radiations being converted into energy of motion of the molecules of the body, or a portion may pass through. In that case its colour will be complementary to the colour of the light thrown back, or scattered by reflection in the case of thin gold leaf. The colour transmitted will be green. On looking down into a mountain stream after a heavy storm, when it contains fine particles of matter floating in it, the light reflected from the bottom is of a deep brown colour; so transparent is it that but little light is scattered except from its surface, but blue light is absorbed in greater abundance than the other colours. If a very little milk be added to a glass of water, the light passing through the mixture becomes browner than before, but the light scattered by reflection will be blue. At the same time a great quantity of white light is scattered, and the mixture is rendered less transparent; hence if two glasses—one of water from the mountain stream, and the other of milk and water—are placed side by side on a white cloth and looked at from above, the water from its transparency will appear brown, the source of light being the white cloth, but the milk and water will appear blue. The milk and water is so opague that it is mostly, or it may be entirely, seen by light which has been scattered by the particles, and in this light the blue is most abundant. Any mixture which is partly transparent and has very fine particles suspended in it will produce similar effects. Thus resin dissolved in alcohol and mixed with water gives a bluish tinge seen by reflected light, and imparts a yellowish-red or even red tinge to light which has been transmitted through it. Opalescent glass has the same property. The explanation of these facts is at once seen by examining the spectrum of light which has been reflected from the liquid. Those of us who come from the neighbourhood of London or from large manufacturing towns have abundant opportunity of studying the effect produced when sunlight is transmitted through various thicknesses of smoke full of very fine particles which have not been fully consumed. [Experiment with didynium]. When light from the glowing carbon poles of the electric arc falls upon a medium whose molecules have a great tendency to vibrate at certain definite rates, the vibrations of the ether will be absorbed in exciting sympathetic vibrations on the molecules of the medium, just as the energy of vibration of the air excited by the voice sustaining a sound of given pitch may be spent in producing sympathetic vibrations of the same wave-length in a string or organ pipe. A series of

Digitized by Google

slight knocks, if given in proper time, will set a pendulum in oscillation. The very slightest taps at the rate of 1 a second will cause ever-increasing swings in a seconds pendulum ; so when the natural time of vibration of the molecules of a body harmonises with waves of light of a certain length these waves falling upon those molecules will set them in vibration, and the energy of the wave motion will be spent in setting the molecules of the body in motion. The waves of the same period of vibration of the molecules of the body will be internally absorbed, and the light of this special wave-length will be stopped. The experiment of Bunsen and Kirchhoff with sodium vapour in front of the slit of a spectroscope shows what takes place. If the source of light behind the slit is of lower temperature than the sodium flame, the sodium flame will increase the brightness of the sodium band ; but if the source of light behind the slit is of higher temperature than the sodium flame, some of the vibrations will be stopped, and if there be sufficient difference of temperature in the two flames black bands will take the place of the bright sodium bands, and we at once have the explanation given by Bunsen and Kirchhoff of the dark lines of sodium and other substances in the spectrum of the sun. [Try the same experiment with the vapour of selenium.] The presence of the vapour of sodium and other substances in the upper regions of the sun's atmosphere causes the absorption of the bands peculiar to those substances, and the light from the lower regions of the solar atmosphere is deprived of those bands in passing through, and so comes to us with dark lines in the position of those bands. When the molecules can vibrate at different rates, the dark lines are sometimes grouped in one part of the spectrum, and weaken light of one colour more than of another, as for instance, with vapour of iodine ; in the liquid state the molecules are too close to allow of their free motion, their vibrations are disturbed, and the absorption bands widen out as the thickness of the medium is increased. The characteristic bands of substances and their changes may be studied in dilute solutions of liquids and in coloured glasses. But I will not dwell on this part of the subject, seeing that a few months ago it was so ably treated and explained by Prof. Stokes in his Burnet lectures, which are now within the reach of all. Not only glowing vapours, but gases at ordinary temperatures produce black lines in a continuous spectrum. We may see the lines of absorption by nitrogen and oxygen in the atmosphere by sending a beam of light through nitrous oxide fumes, giving many telluric black lines, which are mostly towards the less refrangible end of the spectrum. Besides these, there are many other gases and vapours in our atmosphere, and especially the vapour of water, each absorbing light of special wave lengths, and adding to the dark telluric rays ; but these vary greatly with the quantity of water vapour in the atmosphere, and with the length of path through the atmosphere traversed by the beam. The group D, known as the sodium band, is formed partly of metallic lines and partly rays of absorption, due to the vapour of water. These atmospheric lines, known as the rain bands, which have been carefully mapped by M. Cornu, vary in their appearance from day to day, and from hour to hour, according to the state of moisture of the air and the height of the sun above the horizon. The coefficient of absorption for any given ray may be found by measuring its intensity in the solar spectrum at different times of the day, so that the light travels a different length of path through the earth's atmosphere. Photographs of the solar spectrum, taken at different times of the day, show the growth of the telluric lines, or, with Prof. Langley, we may climb a mountain, and look down on the red dust and take observations of the spectrum and of the deep blue colour of the sky, getting deeper and deeper, almost to blackness, as we ascend, whilst some one else is observing down below with the extra thickness of half the earth's atmosphere between the two observers. The changes in the telluric rays due to water vapour are sometimes very rapid, as in M. Cornu's observations on a winter's day, when the air was very dry and cold, where the telluric rays were very intense at sunrise, but in less than an hour they were scarcely visible, and only the metallic lines remained. The breadth of the telluric rays and the energy consequently lost by their absoption depend upon the height of the sun above the horizon, and M. Cornu proposes to measure the absorbing power of the atmosphere and the amount of water vapour in it by comparing the telluric lines with the metallic lines near them for equality of blackening. We must distinguish between this purely selective aborption of separate rays, whereby dark lines are produced in definite positions in the spectrum, and a general absorption by the atmosphere, which has been shown to depend greatly on the presence of particles of matter or dust in it. Larger particles reflect and scatter a beam of light, and treat light of all kinds or colours nearly in the same way. This happens when the size of the particles is large compared with a wave-length of any kind of light. By these a beam of white light is said to be partially absorbed, but the sifting out of rays has been the same for the different kinds of light, and the remainder which passes through is still white light. The smaller particles of dust or mist begin to absorb selectively, being small enough to be affected differently by, and therefore to affect differently, the long and short waves of ether. In this case the short waves, or blue end of the spectrum, are absorbed more readily than the long waves of the red end of the spectrum, and in the beam which passes through the blue is wanting. As the particles are smaller and smaller we have less and less of absorption, even of the blue end of the spectrum, until the molecule or atom asserts itself by picking out those vibrations of the ether which harmonise with its own special rates of vibration, and leaves the transmitted beam with dark lines in the position of its special black absorption lines. These may by the analogy of sound be said to be the special tones of the gas or vapour, and may be distributed throughout the spectrum. Thus, for every different small portion of the spectrum there are different values of the coefficient of absorption by the earth's atmosphere in consequence of the selective absorption of the various parts, and, as Prof. Langley has shown, it will be necessary to measure these special coefficients of absorption in order to find the true nature of the solar light and heat. Investigations, many of them by Pouillet and others, made before the discovery of the cause of the dark lines of Frannhofer have given the amount of the general absorption of light from the sun or stars in passing through the earth's atmosphere as about 20 per cent. of the whole. Prof. Langley has shown that the effect of the absorption being selective instead of being the same for all the rays must necessarily be an increase in this percentage, which he is disposed to estimate at 40 per cent. rather than at 20 per cent. His investigations also lead him to the conclusion that the coefficient of absorption increases from the red end all the way along the spectrum, so that outside the earth's atmosphere the sun would have a strongly bluish tint, and that the maximum of solar energy would be in the green instead of the orange-yellow. The absorption by the earth's atmosphere may be studied by means of artificial lights on the surface of the earth. In mapping the spectra M. Jansen lit a bonfire, and observed the atmospheric lines from a point 13 miles away, and MM. Egoroff and Thollon have determined the order of disappearance of some of the more prominent absorption lines for different thicknesses of air between Mont Valerien and the Observatory at Paris. But it is only in considerable depths that the full effects of atmosphere on light can be made known ; this is especially the case with regard to the selective absorption of light of different colours. The varieties of colour in the sky at sunrise or at sunset, and the golden colour of the full moon at its rising, are due to the transmission of the sun's light through varying thicknesses of air, full of fine particles of matter and of aqueous vapour, which cut off more or less of the blue rays. Higher and higher above the horizon the thickness of the atmosphere diminishes ; more and more blue light of the illuminated haze scattered by reflection mixes with the transmitted light, which gradually diminishes and makes the colour gradually paler until near the zenith. There is no longer any transmitted light, and the colour of the sky is blue, and farther from the sun may be even violet, from the light scattered by reflection. Just as the sodium flame in front of a weaker flame adds to the intensity of the sodium light, so the blue illuminated haze in front of the blackness of space, or even in front of a dark hill, will give the blue colour to the sky, or tinge the hill with blue or violet light.

(To be continued.)

NOTES.

OBITUARY.—We greatly regret to have to chronicle the death of Mr. John Muirhead, senr., at his residence at Sydenham.

A CURIOUS EFFECT OF LIGHTNING.—Amongst the lepers at the Misken Hané, at Scutari, is one who is said to owe his malady to a lightning stroke.

THE ELECTRIC LIGHT IN CANADA.—The Light Committee of the Montreal City Council propose to consider the question of lighting the streets of that city by electricity.

SANITARY EXHIBITION AT LEICESTER.—We understand that Messrs. Woodhouse and Rawson have put down an installation of arc and incandescent lights in this Exhibition.

THE REVOLUTION IN EASTERN ROUMELIA.—A telegram from Bucharest announces that all strategic points on the Turkish frontier have been occupied by the Roumelian insurgents, the telegraph wires cut, and the bridges destroyed.

NEW TELEGRAPH STATION IN CHINA.—The Great Northern Telegraph Company announce that a new telegraph station has been opened at Chefoo. The rate by this company's lines from all stations in the United Kingdom is 10s. per word.

ANOTHER CENTRAL STATION.—We are informed that the German branch of the Edison Company have applied for a concession to establish at Frankfort a central station for the distribution of the electric light and the transmission of power.

ELECTRICITY AND CHOLERA.—Experiments have recently been made in France with a view to the application of electricity as a curative agent in cases of Asiatic cholera. The results, although interesting, have not yielded unqualified satisfaction.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 11th Sept. were £1,665, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

GOOD INSULATORS.—It is stated that liquid oxygen and nitrogen rank among the most perfect insulators. The resistance of copper decreases much more rapidly than the absolute temperature, and approaches zero at a temperature not very remote from that obtained by evaporating liquid nitrogen in a vacuum.

AN INTERNATIONAL SCIENCE ASSOCIATION.—It has been suggested that the twenty-five thousand dollars given by Mrs. Elizabeth Thompson for the advancement and prosecution of scientific research in its broadest sense should be administered by an International Association of Science. The idea, however, has not found much favour.

THE CHOLERA IN SICILY.—According to a telegram from Rome the advent of the cholera has completely demoralised the Sicilians. As an instance of the way in which they are endeavouring to take the law into their own hands, it is mentioned that at Alexandria della Rocca the railway and telegraphic connections were broken and other outrages committed.

MORE EXHIBITIONS.—The project of a new Electrical Exhibition in Paris has been announced. It is to be held next spring, and will be organised by the International Society of Electricians. Probably it will be a second edition of the exhibition held at the Observatoire a few months ago, with all the modifications and extensions that may be dictated by experience.

THE TELEPHONE AT LYNN, NORFOLK.—The Lynn Town Council have decided to have the town police station connected by telephone with the dock police office, at a yearly rental of £7 per annum, and to accept the offer of the South of England Telephone Company to provide and maintain telephonic communication between the police station and the waterworks, for £13 per annum.

EDISON.—A biographical sketch of Edison appears in the issue of *Science* for August 21, which says that "in his experimentation he is minute and painstaking, noting carefully the phenomena he is investigating, and recording accurately the results. Moreover, he is not only quick to observe facts, but prompt to detect their practical importance, and ready to seize upon such of them as may serve as the basis of an invention."

THE EARTHQUAKES.—Attwenty minutes before eleven o'clock on Thursday morning last week, the seismograph at Naples University registered a shock of earthquake, which lasted eight seconds.—A Reuter's telegram, dated Rome, Sept. 21st, says that repeated shocks of earthquake have occurred in Benevento. The inhabitants are terror-stricken, and are encamped in the open country. Several persons have fled from the province.

AMERICAN TELEPHONE STATISTICS.—The number of telephones in the hands of licensees Dec. 20th, 1884, was 325,574, an increase for the year of 26,994. The increase and decrease by months in the telephone output for the last eight months have been as follows:—Gain: March 60, April 1,691, May 2,442, June 2,411; total 6,604. Loss: January 298, February 594, July 314, August 544; total 1,750. Net output, eight months, 4,854.

THE INDIAN TELEGRAPHS.—The officers of the Indian Government Telegraph Department have commenced an agitation for the relief of their grievances, and have organised a defence committee for the purpose of working their cause systematically. They complain of the stagnation of promotion and of inequitable treatment as compared with other branches of the Government service, and they appear to make out a strong case.

THE CENTRAL STATION AT TOURS.—The Central Electric Lighting Station at Tours will probably be completed in about a month's time. The station is intended to supply current to about 3,000 Oppermann incandescent lamps of 16 candle-power, taking 40 volts and 0·9 ampere. The installation includes a supplementary battery of 50 Kabath accumulators, which will be held in reserve in case of a temporary breakdown of the engine or dynamos.

TELEPHONE FACILITIES IN BELGIUM.—In Belgium a large number of the hotels, cafés, and shops are subscribers to the telephone system, and no charge is made at these establishments for talking, it being supposed that the user will take a small refreshment, which is sufficient to recoup the infinitesimal amount represented by such operation. Of course this facility is invaluable, as it permits people to hold a conversation in any part of the town, and the system is well worked.

POST OFFICE TELEGRAPHISTS AND THE ROYAL ENGINEERS.—The twenty-four Post Office telegraphists still serving at Aldershot with the Royal Engineers are to be re-transferred to the Army Reserve at once. They will resume their duties at the telegraph offices under the Postmaster-General, where they were previously employed, and be re-attached to the 24th Middlesex Rifle Volunteers. They are to be entertained at a dinner in honour of their return at the Holborn Restaurant to-morrow evening.

Digitized by Google

THE RIVER PLATE TELEPHONE AND ELECTRIC LIGHT COMPANY.—There is an increase in the number of subscribers to this company in Buenos Ayres and Monte Video from 1,573 on 31st January, 1884, to 1,845 on the 31st January, 1885, and this increase represents a corresponding enlargement of income from £26,112 to £29,226. Later accounts, which are carried down to March, 1885, show that the number of subscribers has been raised to 1,885—the exact number of the year.

MUNRO AND JAMIESON'S POCKET BOOK.—This handy little pocket book of electrical rules and tables, by J. Munro, C.E., and Andrew Jamieson, A.M.I.C.E., F.R.S.E. (London, Charles Griffin and Co.), has reached its third edition. In the copy now before us several important additions have been introduced, among which is a comprehensive appendix on magnetic measurements. For purposes of ordinary reference in the testing room or laboratory this little work is a library in itself.

THE ORIENTAL TELEPHONE COMPANY.—It is believed that the shares of this company, which are of £1 each (11s. paid), will shortly be made 11s. shares fully paid. It will be recollected that the "Consolidated Telephone" shares were treated in a similar way, being "written down" to 15s. They are now at a premium! "Orientals" may, not improbably, rise to par on this becoming known. The company has just received £8,000 from the Government over the Alexandrian indemnity business, and no further calls will now, we understand, be required.

THE ELECTRIC LIGHT IN CHILI, S.A.—In the city of Santiago there are some 2,000 Edison lights being maintained from a central station. In Valparaiso there are 110 Brush lights employed in lighting the General Post Office, hotel dining rooms, billiard halls, and shops. The Brush people have lately exhibited a tower light consisting of five 4,000 candle-power lights, mounted on a mast 65ft. high, which is located on a hill some 200ft. high in the heart of the city. This light is seen at sea over 30 miles away, and similar lights are soon to be employed in lighting the towns of the interior.

THE BLACKPOOL ELECTRIC TRAMWAY.—The inspection of Major-General Hutchinson has resulted in the line being declared fit for public traffic. On Saturday last trams commenced to run by horse-power, and they have since been run by horses and very extensively patronised. The work of clearing out the central channel—which along South Beach was completely full of sand and shingle deposited by the tide—is being carried on as quickly as possible by a staff of men under the direction of Mr. Burnett. Other arrangements are in progress by which it is hoped that the line will be worked electrically on it being formally opened by the Mayor of Manchester, on Tuesday next.

ELECTRIC LIGHT IN TRAINS.—The Pennsylvania Railroad is experimentally lighting nine carriages with incandescent lamps. The current is supplied from a Brush storage battery, carried beneath the carriages. The batteries are charged once a week. Each carriage carries six trays or boxes, each tray containing four cells. The cell gives at first an E.M.F. of 45 volts, and is worked till the E.M.F. falls to 39 volts, when it is recharged. Swan lamps are principally used, though Stanley-Thomson lamps have been tried. The parlour-cars have ten 16 candle-power lamps, the passenger cars but six. The lamps are arranged that half may be switched on or off. A clock mechanism in connection with the wires regulates the time the lamps are on. If only half are on the mechanism of the clock registers the fact.

THE LIGHTING OF THE CITY.—At a recent meeting of the Court of Common Council, Deputy Fry asked the Chairman of the Commission of Sewers whether there was any probability of the electric light coming into use in the City during the coming winter. Mr. Johnson, in reply, said there was little or no such probability. The Commissioners had had the subject before them for two years, and had done their best to get some responsible company or persons to undertake the lighting of the whole or part of the City. They had several times hoped that the difficulties would be removed; but when the time came the companies backed out of their proposals. There might be an attempt to light Billiter-street before long by a private individual who used the electric light in his own large establishment.

UNDERGROUND TELEGRAPHS IN FRANCE.—As already announced in our columns, the underground telegraph line from Paris to Lyons and Marseilles is now completed, and the wires will be used as soon as the instruments destined for them are placed in the offices at Paris, Lyons, and Marseilles. This underground line, added to those overhead, will not only enable messages to be accelerated, but will enable communications to be kept up no matter what the state of the weather may be. Underground lines will also be laid between Marseilles, Toulon, and Nice. Marseilles and Havre are already connected by a direct wire, and this not only secures rapid communications between the two ports, but places Marseilles in direct connection with the United States, as the Marseilles-Havre wire is to all intends and purposes the prolongation of the Franco-American cable which abuts at Havre.

THE AMERICAN BROADWAY RAILWAY.—It is said that the Broadway Underground Railway scheme is assuming such business like shape as to insure the building of the road. The enterprise is one of enormous magnitude, and the six and a half miles now under contract from the Battery to Harlem and its branches will cost, according to surveys and estimates made and carefully supervised by General George B. M'Clellan, 1,200,000dols. to 1,400,000dols. per mile. The entire structure will, we are informed, be continually lighted by electricity, and the trains run by electric motors. Arrangements have already been made with the American Electric Manufacturing Company by which the American company will control the lighting of the great structure, supply the electric motors, as well as for the control of the right for placing telegraph, electric light, telephone, fire alarm, and other wires in the structure.

CONTINENTAL ITEMS.—On the occasion of the return of the troops after the late manœuvres in Bohemia, the station at Smichor was illuminated by ten arc lamps, installed by Messrs. Allmer and Zollinger, of Bubna, near Prague. The installation of the electric light in the Château de Chasse Impérial, at Lainz, near Vienna, is nearly completed. The château and its corridors, offices, &c., will be lighted by 300 incandescent lamps, and a road, two and a-half miles in length, in connection with the estate, is also to receive 130 lamps of the same kind. An engine room has been constructed some seventy yards distant from the château. This contains an engine of 50 h.-p. and four dynamos, two of which latter will supply the current to the lamps in the interior of the building, and the other two to the outdoor incandescents. The installation has been put down by Messrs. B. Egger and Co., of Vienna, well known in connection with the lighting of the new Hôtel de Ville.

CABLEPHONING!—The following story is going the rounds of the non-technical papers:—"The Press Association is

Digitized by Google

informed that a discovery has been made in electrical science, by which the problem of telephoning across the ocean through any of the existing Atlantic cables has been practically solved. The inventor has been led to the discovery through the very simple reasoning that if machinery and batteries of given power can convey the sound of the voice a certain distance, more powerful machinery might transmit it further. This theory has been confirmed by experiments with an instrument by which conversation was conducted over 2,300 miles of wire immersed in the Gulf of Mexico." Our *confrères* of the daily press will do well to abstain from swallowing too much of this glowing account of the impracticable. It is all nonsense to talk about machinery and batteries of great power. The carrying capacity of a long cable in regard to strength of current is just as limited as it is in regard to speed, and furthermore no cable company would sanction the use of high tension currents on its lines.

SOMETHING WANTING!—The Bournemouth Improvement Commissioners will never fully justify their title until they reconsider and reverse the decision they have just come to in regard to the installation of the electric light in Bournemouth. At a recent meeting of the Commissioners the Lighting Committee reported that they had considered a letter from Messrs. Laing, Wharton, and Down, asking for a definite answer in regard to the electric light. The committee advised the Board to take no further steps in the matter at present, and with the weakness which but too often characterises the actions of local authorities and so-called "Improvement Commissioners," the suggestion was approved. The following item from the Commissioners' half-yearly estimates will be found of interest: — *Lighting, estimated expenditure, £1,170. 7s. 0d.*, including £274 for lamp lighters' wages, £706 for gas to public lamps, and £110 for new lamps. So the lighting of Bournemouth costs at least £2,340. 14s. a year. Now Messrs. Laing, Wharton, and Down, What will you give them twice the amount of light at, per annum?

SUBMARINE EARTHQUAKES.—The schooner "Rosario," at New York, has reported that on the 23rd of last June, in lat. 29° 14′ N., long. 133° 35′ W., at 11 a.m., two heavy shocks of a submarine earthquake were experienced. These occurred at an interval of about sixty seconds; the last being much more violent than the first, and causing the ship to tremble violently. It is stated that the sea was remarkably smooth. Some of our readers may remember several shocks of the same kind have from time to time been experienced along the east coast of Africa. The Mozambique-Delagoa Bay section of the Eastern and South African Company's cables has been buried on two occasions either by volcanic or alluvial masses, and has had to be broken out of the sea bottom before the necessary repairs could be effected to it. The disturbances travelled north and south. A similar occurrence was not long ago reported by the commander of the German gunboat "Prinz Adelbert." Whilst lying in the roadstead of Aucon on the 10th of February last two short earthquakes were felt which lasted ten seconds, and were noticed very perceptibly on board ship. These also travelled north and south, and like the others of which we have spoken did little or no damage on shore.

WEST AFRICAN CABLES.—On Tuesday last the India Rubber, Gutta Percha, and Telegraph Works Company's ss. "Silvertown" arrived at the moorings off the works at Silvertown, and the shipping of the above-mentioned cables was commenced. These cables are destined to place the Cape Verde Islands in telegraphic communication with various points along the West Coast of Africa, and the system will be duplicated by connecting these points with the Spanish National Submarine Telegraph Company's station at St. Louis (Senegal). About 1,350 nautical miles of cable will be shipped, forming the first portion of a system of telegraphic communication to be carried out along the West Coast of Africa under concessions granted by the French and Portuguese Governments. The present expedition has for its immediate object, on the one hand, starting from the Cape Verde Islands, and on the other from St. Louis, to connect up and establish stations at the following points: — Dakar (Senegal), Bolama and Bissau (Portuguese possessions, about 250 miles to the south of Bathurst), and Rio Nunez or Conakry (French settlements, the latter about 80 miles to the north of Sierra Leone). The ss. "Silvertown" will probably leave for the West Coast about the first week in October.

A MANUAL OF TELEGRAPHY.—"A Manual of Telegraphy," written by Mr. W. Williams, M.S.T.E. and E., a superintendent in the Indian Government Telegraph Service, and published by Longmans, Green, and Co., has just been added to the existing works upon the subject. The manual, we believe, was written by order of the Director-General of Telegraphs in India, and is based on the substance of the papers on technical subjects set by the author at the general examinations of the Indian Telegraph Department. These subjects embrace a general description of the various instruments, batteries, and circuits which the telegraph official may be called upon to deal with; faults which may be met with, and their remedy; the conservancy of and modes of testing lines; batteries, instruments, lightning conductors, and earths; the general principle of telegraph working in its various forms; the electrical phenomena which interfere with communication, and the various methods by which their obstructive effect is overcome. We have no hesitation in recommending this work to our readers. Exception may be taken by some to the nomenclature and notation, which are identical with those adopted by the late Mr. Schwendler, but the book is a thoroughly good and valuable one.

THE TELEGRAPHS IN THE FAR EAST.—A telegram from Calcutta, dated 20th September, says the Indian Government has received news that the telegraph line is to be extended to Bokhara and to Merv. The Russian telegraph system is now so near to India that it would be a comparatively easy task to join it to the Indian system, thus giving an overland line from Calcutta to Europe. If only the Ameer could be induced to ask for lines to Cabul and Candahar, the Indian telegraph department could construct them without difficulty, and an important step would have been taken towards the establishment of a through overland line. Even if a through line were not yet carried out, still it is impossible to overestimate the importance of having direct communication between the Viceroy and the Ameer and between the Ameer and the Governor of Candahar, while a telegraph station at the latter place would enable news from Herat to reach India in three days, supposing the post messengers travelled only five miles an hour. If a portion of the breathing time which we seem likely to have before the next Russian advance were spent in making these lines, and in constructing the earthwork for a railway from Chaman to Candahar, we could then await the further development of the Central Asian question with more equanimity than will be possible in the absence of such precautions.

SOME AMERICAN NOTES.—The City Council of Davenport propose to light the city with electricity, and will advertise for tenders.—Two new electric lighting companies have been organised in New York, the points of operation, however, to be in Massachusetts. The first is to be known as the American-

Digitized by Google

Edison Illuminating Company of Worcester, Massachusetts, and the other having similar name, but for operation in Lowell, Massachusetts. The companies have capital respectively of 100,000 dols and 50,000 dols. The contract made recently by the American Company, of New York, to light the entire city of Portland, Me., in which the American Company will use a large number of the Edison municipal incandescent lamps, was the initial work under the American-Edison compact made in the early part of the summer. Central lighting stations are now to be introduced into Worcester and Lowell, Mass., and it is understood that the American Company is now laying its plans for general street lighting in every city in New England.—In a trial on the Ninth Avenue Elevated Railroad, in New York city, the Daft electric motor has, it is said, run at a speed of 25 miles an hour.—The Commission on putting electric wires underground in Brooklyn, New York, has decided that the law does not apply to wires owned and controlled by the city. The Commission will not prevent any extension of overhead wires by the American fire department.

SIXPENNY TELEGRAM REGULATIONS.—Yesterday's *Standard*, after sharply criticising the new regulations as ambiguous, contradictory, and vexatious, attributes them to "the pedantic idea that a telegram must be transmitted as a facsimile of the original, copied with Chinese fidelity and lack of intelligence." We ourselves have expressed the opinion that some of the regulations complained of will have to give way to simplicity; but it is not a matter of congratulation that in obeying the demand for a popular tariff the Telegraph Department is compelled in self-defence to either enforce strict regulations for counting, or to abandon all fidelity in transmission. Up till now it has been a matter of principle with English telegraphy that the sender's message shall reach its destination, textually at least, in facsimile; and assuredly there would have been a great outcry if the Post Office had systematically taken liberties with the text to avoid cumbersome signals. This, it appears, is henceforth to be called Chinese stupidity, and sixpenny laxity is to be the rule. We foresee that in a short space of time there will be no rules and no counting worth speaking about—and, consequently, no fidelity, Chinese or other, to the text. It is the inevitable law of the cheap and nasty; but it will bear rather hard upon people who do wish their telegrams to be accurately reproduced, and who neither for love nor money will be able to get the thing done.

CHARTERHOUSE SCIENCE AND ART SCHOOLS AND LITERARY INSTITUTE.—The winter session of this, one of the largest science and art schools in the United Kingdom, will, under the presidency of the Rev. Henry Swann, M.A., commence on Saturday, 3rd October. During the late session about 800 students, mostly elementary teachers, availed themselves of the privileges afforded by this institution, and of this number upwards of 500 presented themselves for examination, and were successful in obtaining a large number of first class certificates, and also a goodly number of honours certificates awarded by the Science and Art Department of South Kensington. The only Royal Exhibition taken by a London student this year was by a member of this science school. At a very nominal fee instruction of a practical character is given in most of the sciences; whilst in art, at an equally low rate, students, under the direction of five competent instructors, can be advanced in their studies. Those desirous of studying art in the daytime can do so. Students, who aim at becoming proficient in chemistry (organic or inorganic) have the opportunity of working in a well-fitted laboratory, capable of accommodating 60 students. Aspirants for university honours can at a small expense be assisted in their studies. Lessons in Latin, Greek, French, German, and music are given by well-qualified teachers. Classes for the study of photography and watchmaking, &c., will be commenced this session. Full particulars can be had of the organising secretary, C. Smith.

LIGHTNING AND TREES.—The following letter appeared in *The Times* of the 23rd inst.:—"I shall be pleased to give testimony to one or two facts with reference to the subject of various letters which have recently appeared in *The Times*. During surveys in the forests of the United States, when I necessarily lived under canvas, I often had the opportunity of witnessing the effects of lightning on trees, and my experiences lead me to believe that trees are only destroyed by lightning where they have been previously wetted by rain. A sojourner in the woods, whether he is taken in pursuit of game or with the object of prospecting timber, minerals and land, is always careful to erect his tent under a short thick tree in order to escape the danger of lightning or of trees falling and bringing down others in their way on him; and it was often while thus situated I noticed after stormy nights when lightning and thunder were accompanied by rain that many trees had fallen. The report of the snapping of the trunks would remind one of that of the firing of a cannon, and when lightning and thunder were not accompanied by rain (in the immediate locality of our camp, at any rate) no trees had been struck. I infer from the same observations that the lightning always strikes the tallest trees, whatever their specie may be, for the taller white pines and poplars were most often seen destroyed and the shorter maples, linden, birch trees, &c., rarely so; also that the sap between the wood and the bark of the tree does not increase the chance of its destruction."

ELECTRIC RAILWAYS IN AMERICA.—The Boston *Advertiser* thus summarises the workings of the electric railways in Baltimore and Cleveland:—"Electric motors for street railways are proving successful in Baltimore and Cleveland. The systems are different. The one in Baltimore has a central rail, insulated from the ground, but thus far exposed on the surface. Dogs and horses are occasionally shocked by it. There is talk of enclosing it. The motors used are the Morse and Faraday. One weighs about 4,500lb., and will haul a full horse car four miles in 25 minutes, most of the way up-hill, and some of it steep. The dynamos, of which there are two, are driven by a 35 horse-power engine. Each dynamo is of 50 horse-power, and one suffices for ordinary traffic. The Bentley-Knight railway in Cleveland differs from this in the respect that the electricity is conducted from the dynamo by a stationary cable in a conduit under the track, and through an opening in the top an electric brush reaches down from each car, taking up the electricity to a small motor under the car, from which bands run to pulleys on the axles. The inventors make the following estimates for five miles of double track and the operation of forty cars:—Estimate for newly constructed lines: Cost of horse road, 162,000 dols.; cost of electric road, 344,100 dols.; cost of cable road, 414,750 dols. Annual expense of motive power for horse road, 102,960 dols.; for electric road, 30,551 dols. 50c.; for cable road, 70,500 dols. Annual saving in cost of motive power: Electricity over horses, 72,408 dols. 50c.; electricity over cables, 40,038 dols. 50c.

THE TELEGRAPH AND THE BRITISH ASSOCIATION MEETING.—During the late meeting of the British Association the

Digitized by Google

instrument room of the Aberdeen Telegraph Office was each evening the scene of very active operations. From the first meeting of the Association till Wednesday night there were despatched from Aberdeen no fewer than 424,916 words, equal to about 212 columns of printed matter. The great bulk of press messages were despatched during the evening between six and ten o'clock, and in every case the news wires were cleared by half-past ten. There were two wires direct to London, one through Edinburgh, Glasgow, and Belfast, terminating in Dublin; another circuit extended along the west coast of England, supplying *en route* Glasgow, Manchester, Birmingham, Liverpool, and Bristol. Similarly along the east coast there was a wire to Dundee, Edinburgh, Newcastle, York, and Hull; while another circuit connected the midland counties, and included Bradford and Sheffield. In addition to all these, there were two wires exclusively for Glasgow and Edinburgh. It is also due to the efficiency of the operators at Aberdeen to say that the work has been done with wonderful accuracy—an accuracy which has warranted favourable comment from the leading metropolitan journal, as shown by the following remark in the letter of its correspondent in Thursday's issue:—"During the week a great increase of duty was imposed on the telegraph and Post Office officials, but the local staff performed their duties without a hitch. In particular to the telegraph department the Press owes its acknowledgments for the accuracy and despatch with which the many long and often difficult telegrams were despatched to London and elsewhere." We are glad to be able to add our testimony to that of our contemporary.

THE ANTWERP EXHIBITION AWARDS.—The awards, which were officially proclaimed on Monday, the 14th inst., in the presence of King Leopold II., are as follows for the 4th Section, Classes 84 to 103, "Electricity." *Diplomas of Honour:* Germany—Felten and Guilleaume; Heilmann Ducommun. Austria—Ganz and Co. Belgium—Administration des Télégraphes de l'Etat Belge; Compagnie Générale d'Electricité de Bruxelles; J. Jaspar; l'Electrique; Montefiore-Lévi; Schuckert; Bouckaert and Co.; Schubart (Theodore); Van Rysselberghe; Mourlon and Co. France—Menièr; L. Mors; J. O. Mouchel; Gaston Planté; Société Générale des Téléphones de Paris; The India Rubber, Gutta Percha, and Telegraph Works Company. Italy—Société Electro-Métallurgique Italienne. *Gold Medals:*—Germany—Hartmann and Braum; Spiecker and Co. Austria—Dr. Ochorowicz. Belgium—Ch. Alker; Bell Telephone Manufacturing Company; Compagnie Belge du Téléphone Bell; Veuve Ch. Devas; Flamach frères; H. Pieper; Richez and Co.; Ville de Bruxelles. France—P. Barbier and Co.; Arsène Boivin; Cance; L. Clémandot; Houry; Aboilard and Co.; Scrive Hermite and Hermite. Switzerland—Société d'Exploitation des Câbles Electriques. *Silver Medals:*—Germany—G. Lorenz; F. Heller; E. Leybold; Vennemann. England—Saxby and Farmer; Shippey Brothers. Belgium—V. Bartelous; Em. Closset; Alph. Dupont; Société Anonyme des Forges; Usines et Fonderies de Gilly; Léon Kelner; P. Lippens; Fred. Leduc; Clément Ommegang; Eng. Raikem; Léon Van Overstraeten. France—Em. Barbier; E. Cauderey; Delisle and Co.; A. Chertemps and Co.; Ch. Goodwin; Em.-Em. Lévy; J. Vernon. Italy—Cruto. Besides these 26 bronze medals and 18 certificates of honourable mention have been awarded in this Section.

THE POST OFFICE TELEGRAPHS.—To meet the extra demand anticipated upon the adoption of the sixpenny telegram rate, three new trunk lines of wire have been erected; the first from London *viâ* Peterborough, Doncaster, York, and Darlington, to Newcastle; the second from London, *viâ* Aylesbury, Widnes, Leamington, then north of Birmingham to the west of Chester, half-way between Manchester and Liverpool, through Wigan and Lancaster, to Carlisle; the third over the London and South Western Railway to Basingstoke, through Andover and Salisbury to Exeter and Plymouth. There are branches at various points from the main circuits. Similar extensions on a smaller scale have been made in Scotland, Ireland, and other places. Submarine three-wire cables for service under water have also been provided for the use of the Channel Isles, the Isle of Man, and the Orkney and Shetland Islands. About 20,800 miles of new wire have been erected on the new poles. At the various offices in London, and the districts of London where pneumatic tubes take the place of working by wire, an additional four miles of tubing will be used to meet the pressure. A new tube room has been specially prepared in the basement of the Central Telegraph Office. An additional number of 40 Wheatstone automatic telegraph instruments have been purchased. These instruments, which are of the latest and most improved pattern, are capable of telegraphing upwards of 300 words per minute. The following instruments have also been purchased:—Eight quadruplex and 300 duplex sounders, 350 single current sounders, 150 single needles, and ten repeaters. These are in addition to the duplex system, which will be completed in the case of 100 circuits. To work this enormous increase the staff in the United Kingdom will be augmented, as we stated some months past, to the extent of 1,200 telegraph clerks and over 1,000 messengers.

THE T. T. MOTOR!—Prof. Trowbridge has reported favourably upon the wonderful Patent Triple Thermic Water Vapour bi-Sulphide of Carbon Motor. We are to have no more steam as soon as the T. T. W. V. b-S. C. M. takes its proper place in the scientific and commercial world.

No more, "Steam," no more!
The word is spoken.
The spell attached to thee,
O "Steam," is broken.
Thy deeds may live, perchance,
On History's paper;
But now thou art exchanged
For water vapour.
The mighty steam which set
The wheel revolving
Is dead and gone
Or fast resolving.
Resolving into air,
Its final caper.
By parent carbon run to earth
(Bi-sulphide vapour).

Mathematical Chorus:

Sing hey for T – T1 H1,
And set the two last o'er cap T;
If T and T_1 are the temperatures,
You'll get the efficiency—see?

Every body municipal
Should acquire the potent Triple
Thermic motor! thermic motor!
Bi-the-carbon-sulphide cheap,
E'en the cripple, e'en the cripple,
Get a lump, and get a "kittle,"
Generate a triple—thermic leg
Before he goes to sleep.

Chorus by the General Public:

For we've finished with steam;
'Tis absurd, it would seem,
To continue its use in a motor.

A MERCURY CONTACT COMMUTATOR OF CONSTANT RESISTANCE.*

BY PROF. J. VIRIAMU JONES.

My attention was drawn two years ago to the construction of low resistance and constant resistance commutators of the form to be described by two needs :—

1. For lecture purposes in connection with induction experiments it occurred to me that it would be advantageous, for instance, in such an instrument as Delezenne's circle to do away with the brass spring contacts and substitute mercury contacts.

2. For experiments on the resistance of electrolytes that become polarised a commutator of constant resistance capable of successive quick reversals is a desideratum.

The first commutator of the kind I constructed is a simple extension of the old Siemens split ring commutator, but instead of using one split ring I use two, parallel, coaxal, and similarly placed, the halves being cross-connected. Commutation takes place twice in each complete revolution when the lines of separation of the half discs pass through the mercury cups in which the lowest part of the outside circumferences of the rings turn. The instrument will be readily understood from Fig. 1.

This for simple experiments in induction of electric currents is a very useful low resistance commutator; if it be adjusted to a coil rotating even in a weak magnetic field the current may, if the resistance of the rest of the circuit is very small, be considerable.

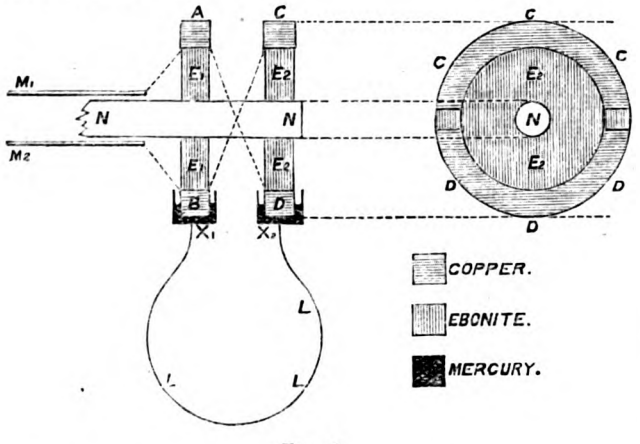

FIG. 1.

M_1, M_2, ends of wire of coil rotating on axis N N, in earth's or other magnetic field.
E_1, E_2, ebonite discs, each disc being surrounded by a split copper ring.
A, B the halves of copper ring on the first disc.
C, D the similarly situated halves of the copper ring on the second disc.
N, N axis of rotation.
X_1, X_2 mercury cups.
L, L, L external circuit.
M_1 is connected by copper wire with half ring A.
M_2 is similarly connected with B.
A and D are connected; and so also B and C.

With two other discs (not split, but complete) added, we have a commutator suitable for the second purpose, a commutator of constant resistance such as is required in measuring the resistance of electrolytes. The arrangement is indicated in Fig. 2.

When the commutator is continuously rotated the current (constant in direction through galvanometer) is reversed twice per revolution through the electrolyte, the resistance of the circuit being undisturbed by the commutator.

If it is required to produce more frequent reversal of the current, it may readily be done by a suitable modification. For instance, if we wish to reverse six times per revolution it is only necessary to have the rings on E_1 and E_2 split each into six parts, to cross-connect these, and to connect the first, third, and fifth segment on E_1 with the complete ring on E_3, and the second, fourth, and sixth segment on E_1 with the complete ring on E_4. The connections are shown in Fig. 3, where to make them plainer the discs are supposed removed from the axle and laid flat.

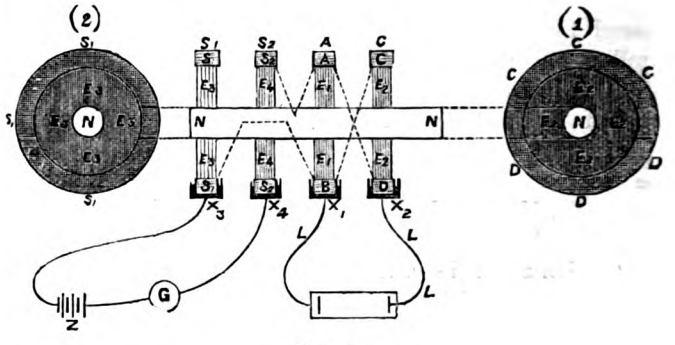

FIG. 2.

Z battery.
G galvanometer.
E_1, E_2, E_3, E_4 ebonite discs; E_1 and E_2 having on their circumference split rings (1); E_3 and E_4 being surrounded by whole rings. (See 21).
A, B the half rings on the first disc.
C, D ,, ,, second disc.
S_1, S_2 the complete rings on the third and fourth discs.
N, N axis of rotation.
X_1, X_2, X_3, X_4 mercury cups.
L, L, L circuit containing the electrolyte.
The connections between the different parts of the commutator are indicated by dotted lines, thus—

S_1 is connected with B.	A is connected with D.
S_2 ,, ,, A.	B ,, ,, C.

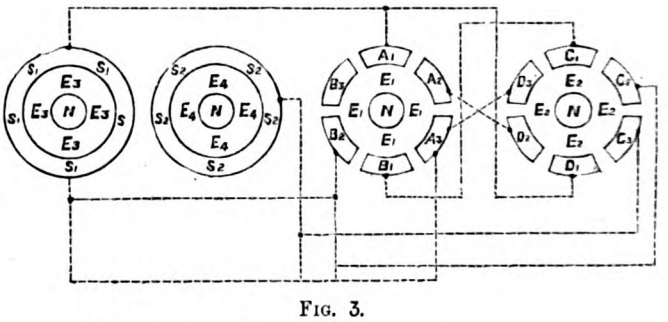

FIG. 3.

A_1 is connected to D_1.	B_1 is connected to C_1.
A_2 ,, ,, D_2.	B_2 ,, ,, C_2.
A_3 ,, ,, D_3.	B_3 ,, ,, C_3.

Also A_1, A_3, B_2, are connected to S_1; and A_2, B_1, B_3 to S_2.

As a further illustration of the utility of the method, we will take an arrangement which is of great convenience in adjusting resistance coils by Wheatstone's bridge.

Taking the following figure from Maxwell (Vol. I., p. 440)

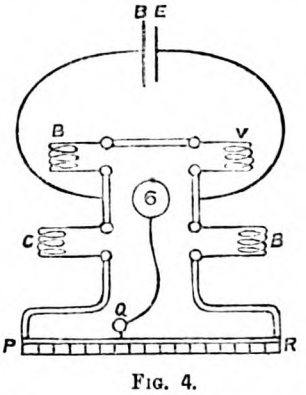

FIG. 4.

β is supposed to be a standard resistance coil, and we wish to adjust γ to be equal in resistance to β.

In making the measures it is requisite to reverse the direction of the current through β and γ; then to interchange β and γ

* "On a form of Mercury Contact Commutator of Constant Resistance for use in adjusting resistance coils and for other purposes." Abstract of Paper read before the British Association.

Digitized by Google

and to reverse the direction of the current in the new position. All this may be done by an arrangement of eight parallel coaxal ebonite discs, each having on its circumference a split ring, the rings being properly arranged relatively to one another and proper connections being made between the segments.

In Fig. 6 the connections are shown, the discs being supposed for simplicity of drawing removed from the axle and laid flat.

In Fig. 5 we see the general arrangement, the connections between the segments being omitted.

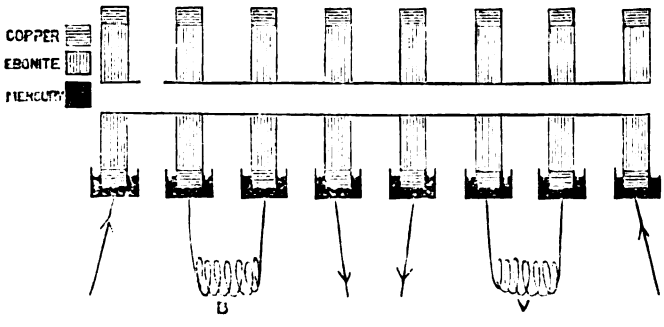

FIG. 5.

Turning through a straight angle from the position indicated in Fig 6 reverses the direction of the current through β and γ. A second turn through a right angle interchanges the coils; a third turn through a right angle reverses the direction of the current through the interchanged coils; and a fourth turn through a right angle brings the instrument back to its original position, again interchanging the coils.

The same commutator is useful in adjusting resistance coils by the differential galvanometer method.

In describing the apparatus I have ommitted details of construction, and one or two points in regard to the mercury cups, which are of importance.*

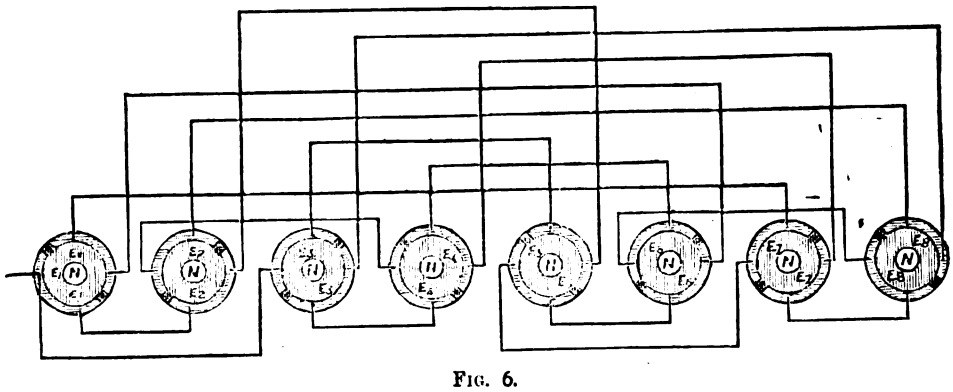

FIG. 6.

E_1 E_2.....Ebonite discs, each having on its circumference a split ring of copper. They are in the instrument arranged coaxially and parallel. The line of segmentation of E_1, E_4, E_5, and E_8 are parallel to each other and at right angles to those of E_2, E_3, E_6, and E_7. The connections are as indicated by the lines.

ON THE DEVELOPMENT OF THE PNEUMATIC SYSTEM AS APPLIED TO TELEGRAPH PURPOSES.†

BY J. W. WILLMOT.

It is probably not generally known by what means telegraphic messages are collected from the branch offices in large towns and conveyed to the central office for transmission by wire.

This service is performed by means of pneumatic tubes, through which "carriers" containing the actual written messages are propelled—in one direction by compressed air, and in the opposite direction by rarefaction of the air in the tube. A specimen of the carriers used may be seen on the table. (See diagram on next page.)

The system was first introduced by Mr. L. Clark, in 1854, who employed vacuum, drawing the carriers in one direction only. The first tube which came into operation was laid for the Electric Telegraph Company, between their office in Lothbury and their branch office at the Stock Exchange. This tube was in continuous use for over twenty years, and from a piece which I have here it will be seen that, beyond the inner surface being polished, the pipe is very little the worse for the service it has seen.

About the year 1866 Mr. C. F. Varley applied compressed air for propelling the carriers in the opposite direction from that in which they were drawn by vacuum, and very ingenious valves were at that time designed by him for effecting the necessary changes in the direction of the flow of air through the tube. With each of the foregoing systems it was necessary after the transmission of a carrier to restore the pressure in the tube to the normal atmospheric pressure before another carrier could be despatched. This caused considerable delay and loss of engine power.

In 1870 the author designed the double-sluice valve which is now in general use, and by means of which carriers can be despatched continuously without stopping the flow of air in the tube. The sectional and other diagrams fully explain how this is accomplished, the principle being that the upper sluice shall be closed before the lower one is opened and *vice versâ*. The employment of pneumatic tubes in London has been continually increasing, until the system, which in 1854 was represented by one 6 horse-power engine working a single tube a few yards in length, at the present time comprises four 50 horse-power engines (each indicating 130 horse-power) and forty-nine tubes, the aggregate length of which exceeds twenty-seven miles. These figures are exclusive of over a mile in short lengths of house tubes, also worked by the engines, as well as of over a dozen hand-worked tubes in various metropolitan offices.

The use of pneumatic tubes, however, has not been restricted to London alone. Each town, as it has become telegraphically important, has been provided with a pneumatic system. A list is appended, giving particulars of engines and tubes at present in use at the various important cities and towns of the United Kingdom. From this it will be seen that there are in London and the provinces one hundred and twelve tubes having a total length of over thirty-nine miles, and requiring fourteen engines, having a total of 364 (nominal) horse-power to work them. To these should be added, in order to fairly represent the pneumatic system, 95 shorter hand-worked tubes fitted at various less important places. With the air pressure employed—ten pounds pressure and eight pounds vacuum—an approximate speed of one mile in 70 seconds is attained in tubes not exceeding a mile in length. The speed varies inversely as the square of the length of the tube.

The pipes generally employed are of lead, having an internal diameter of 2¼in. These pipes are carefully drawn, and are joined together by means of a plumber's joint, made upon a heated steel mandril, which is drawn out by means of a chain after the joint has been made. The lead tubes are protected by being laid in ordinary cast-iron socket and spicket pipes. In view of the anticipated increase in the number of

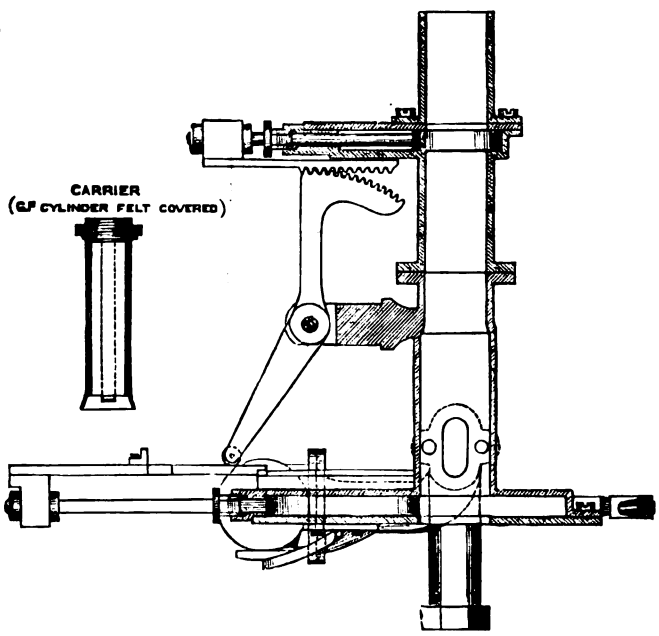
* The mercury cups are provided with copper strips, against which the rings rub lightly during rotation.

† Paper read at the Aberdeen meeting of the British Association.

Digitized by Google

messages which will result from the introduction of the six-penny telegram tariff, considerable extension of the existing pneumatic system has been made at several places, more especially at Liverpool. At that place six new tubes have been laid, and three 30 horse-power beam engines (each indicating up to 90 horse-power) have been erected. Of these engines two are kept working and one as spare. They were designed and constructed under the personal supervision of the author, and were made by Messrs. Easton and Anderson, of Whitehall-place, London, and Erith, Kent. The following is a detailed description of their general arrangement :—

The machinery, as shown by the diagram on the wall, consists of three engines, each working two pneumatic pumps, any two engines being capable of doing the full amount of work required. The third engine is kept in reserve. Steam is supplied from two multitubular Cornish boilers, one boiler being sufficient to work at one time. The engines are high-pressure condensing beam engines, and are completely self-contained on one continuous cast-iron bed-plate. The beam, which is cast iron, is supported by two A frames of box section, bolted on to the bed-plate. These also carry the entablature round the beam. The bed-plate itself is bolted down to brick piers. Placed under each extreme end of the beam, and connected to the air and vacuum mains, is a double-acting air pump of 2ft. diameter



Willmot's Pneumatic Double Sluice Valve.

and 3ft. 11in. stroke. At top and bottom of each pump on one side is a nest of valves, which valves open outwards, and on the other side are valves similarly arranged, which open inwards. On the passages between the valves and the pneumatic mains is a three-way sluice communicating either with pressure or vacuum mains, or with the atmosphere. Thus it will be seen that if the sluice on that side of a pump on which are the valves which open inwards be open to the atmosphere, while the sluice on the opposite side is open to the pressure mains, the pump will take by suction from the air, and deliver air after compression into the pressure main. Similarly, if the sluice on the inlet side of the pump be open to the vacuum main, while the sluice on the opposise side is open to the air, the pump will exhaust from the vacuum main and deliver to the air. Consequently the pumps are interchangeable, and may be worked at will for either pressure or vacuum. This arrangement is very simple, there being only two sluice valves on each pump instead of four, as in some other instances. Each pump is provided with a 2in. relief valve, so that the change from pressure to vacuum may be made while the engine is running, without unduly raising the pressure in the pumps. The pressure and vacuum pump valves are of leather, each valve having an area of ten square inches.

The steam cylinder is 18in. in diameter, with 2ft. 7in. stroke, steam jacketed, and lagged with felt and teak in the usual way. It is placed between the rear pump and the main A frames. The main slide valve is worked from an ordinary excentric on the crank shaft, but the expansion slide has an independent motion from the beam. A wrought iron lever is pivoted on a casting on the entablature frame, one end of the lever is connected by a link to the beam, while the other is connected to the expansion valve spindle, which passes through a bow bracket on the top of the slide chest cover; a bevel pinion on the slide rod gears into another small pinion in connection with a hand wheel carried by means of the above-mentioned bow bracket by which the expansion may readily be varied while the engine is running. The steam starting valve and injection cock are in close proximity, so that the engine man has all the means of regulating his engine close at hand.

The air pump and condenser are fixed underneath the bed plate. The former is bolted to the bed plate and is worked direct from the beam by the same system of parallel motion as the engine piston and pump rods. The condenser is of the ordinary "jet" description. In event, however, of shortness of water for condensation, provision has been made for working the engines non-condensing, exhausting the steam into the chimney shaft. As, however, arrangements are being made to cool and circulate the condensing water, it is only in very exceptional circumstances that it will be necessary to work non-condensing. The connecting rod is of cast iron, with the same stroke of crank as that of the piston. The entablatures which surround each beam are connected together, and are reached by a wrought iron stair from the engine room floor.

The two steam boilers are of the multitubular Cornish type, 6ft. 6in. in diameter and 20ft. 1½in. long, with double flues, the flues terminating in seventy-four tubes 3in. diameter and 6ft. long. The boilers are set on cast-iron chairs, with a return flue first underneath the boilers, dividing in front and returning along either side to the back, where the draught enters the main flue to the chimney shaft. The boilers are of mild steel throughout, and have been tested with hydraulic pressure up to 150lb. on the square inch to work at 70lb. steam pressure. It was found in working that one boiler was quite capable of providing steam for the two engines with the damper partially closed; on opening the damper the steam very soon began to blow off at the safety valves. The boilers are fitted with double dead weight safety valves and all other fittings required by steam users. For the supply of feed water each boiler is fitted with an injector, and in addition there is a donkey pump connected to both boilers.

The engines here described are situated in an engine-house, 320 yards distant from the Liverpool Head Post Office, with which they connected by two air mains, 12in. in internal diameter. These air mains consist of cast-iron pipes with carefully fitted male and female flanged joints. The joints are packed with thick vulcanised rubber rings between the flanges to allow for contraction and expansion of the pipes, and are perfectly air tight with an air pressure of 30lb. to the square inch.

REPORT OF THE STANDARDS COMMITTEE OF THE BRITISH ASSOCIATION.

The Committee report that during the year the standards of resistance, in terms of the legal ohm referred to in the last report, have been constructed, and their values determined in accordance with the resolution adopted on June 25, 1884.

The one ohm standards were generally referred to the original B. A. units of the Association by combination in multiple arc with the standard resistance of the 100 B. A. units, and determining by Carey Forster's method the difference between the combination and a single B. A. unit, and then assuming, in accordance with the resolution, that

1 B. A. unit = ·9889 legal ohm.

The following values were thus found for the two standards. The temperatures were taken by a thermometer graduated to tenths of a degree C., which had been compared with the Kew standards.

Resistance coil—Elliott, No. 139, (B.A. No.)100.

Date.	Temp.	Resist.
Nov. 24, 1884	11·4	·99878
,, 26 ,,	11·6	·99890
,, 27 ,,	12·9	·99916
,, 28 ,,	12·9	·99930
Dec. 5 ,,	13·5	·99931
,, 12 ,,	15·3	·99979
July 30, 1885	17·2	1·00027
,, 28 ,,	18·1	1·00061

Mean value ..... ·999515 at 14° C.
Temperature coefficient.. ·000250

Resistance coil—Elliott, No. 140, (B.A. No.)101.

Date.	Temp.	Resist.
Nov. 24, 1884	11·4	·99825
,, 25, ,,	11·5	·99827
Dec. 2, ,,	12·8	·99847
Nov. 27, ,,	12·9	·99851
Dec. 5, ,,	13·4	·99865
,, 12, ,,	15·4	·99917
July 30, 1885	17·2	·99961
,, 29, ,,	18·0	·99983

Mean value ..... ·998845 at 14·1°C.
Temperature coefficient.. ·000238.

The ten ohm standards were then compared with the one ohm by means of the arrangement suggested by Lord Rayleigh, and described in the report for 1883, and from these values were obtained for the coils of higher resistance. The results are contained below :—

No. of coil.	Resist.	Temp.
141 (B.A. No.)102	10·00415	16·7
142 103	10·00352	16·75
143 104	100·0304	16·05
144 105	100·0436	16·05
145 106	1000·694	17·4
146 107	1000·677	17·45
147 108	10006·8	17·35
148 109	10006·8	17·35

These experiments were carried out at the Cavendish Laboratory, by the secretary and Mr. W. Wilson, of St. John's College.

At the request of M. Mascart, the secretary compared with the legal ohms of the Association the mercury copies of a legal ohm constructed by Mr. J. R. Benoit, of Paris. The detailed account of their experiments was laid before the Physical Society. The values found are given below :—

No. of tube.	Value found by Mr. J. R. Benoit.	Value found by R. T. G.	Diff.
37	1·00045	·99990	·00055
38	1·00066	1·00011	·00055
39	·99954	·99917	·00037
Mean	1·00022	·99972	·00049

The work of testing resistance coils has been continued, and a table of the values found for the various coils examined is given :—

No. of coil.	R. in B. A. units.	Temp.
Elliott, No. 122	10·0163	19·8
(B.A. No.)	10·0017	15·2
	9·9885	10·5
Elliott, No. 58	9·9834	14·05

Legal Ohms.

No. of Coil.	R. in Legal Ohms.	T.
In 150	·99895	11·7
,, 151	·99974	13·9
Elliott 149 (B.A. No.)152	·99912	12·5
Elliott 136 (B.A. No.)153	·99977	12·4
(B.A. No.)154	1·00032	17·3

The Committee hope that arrangements may be made for issuing standards of electromotive force and constructing standards of capacity. In conclusion they would ask to be reappointed, with the addition of the names of Prof. J. J. Thomson and Mr. W. W. Shaw, with a renewal of the unexpended grant of £50.

THE CONFERENCE AND THE CABLE COMPANIES.

The work of the Berlin Telegraph Conference is none the less creditable for falling short of its original programme. That programme, as we predicted, and as the President had to confess, was too radical, or, as he preferred to call it, too premature, to be carried out in its entirety. But the bases of uniformity and simplicity of tariffs throughout the European systems have been established in an unexceptionable manner, and with probable advantage to all the nations concerned. As regards the Cable Companies the same cannot be said. The aims of the Conference, or, at all events, those of its presiding genius, were antagonistic to the interests of non-national telegraph property, and have been abandoned only after a struggle, which, however, did have the wholesome effect of extorting an admission that no fault could be found with the cable proprietors in respect to the liberal concessions they had voluntarily made to promote the welfare of international telegraphy.

These declarations of Herr von Stephan are a sufficient answer to the wild and conflicting accounts that have appeared in the English newspapers during the sitting of the Conference. In reality, its actual business was known only to those engaged upon it; and only such of its intentions were made known to English correspondents at Berlin as happened to suit the objects of the leading spirits among the delegates. So judiciously was this privilege worked in at least one quarter that a favoured English newspaper virtually became a semi-official organ of the party most opposed to English interests. Its lead was naturally followed by other organs even more ill-informed, with the singular result that during the concluding days of the Conference there was an unanimity of opinion—if an echo of an echo can be called an opinion—which would have been marvellous had it been less obviously inspired and less maliciously directed against one particular Company.

How unsafe it was to predict what would happen, or to describe what was supposed to have been actually settled, was curiously illustrated by the dramatic incident of last week, when the representative of Egypt surprised almost everybody by threatening to place Egyptian telegraphs within the European *régime* unless certain demands upon the Eastern Telegraph Company were complied with. The effect of yielding to this threat would have been to inflict a heavy fine upon that Company, which is not, and cannot be included in the Union, but whose system is interlaced with that of the Khedive's dominions. This catastrophe was to some extent averted; but solely by action on the part of the Company, the Conference itself apparently being quite willing to be made the instrument for victimising the owners of any telegraph property not enjoying the privilege of being governmental. The concessions extorted from the Company go exclusively into the pocket of the Egyptian treasury, the public benefiting by them not at all. Yet in reference to this subject the same English journal which a few months ago was loudest in its praises of the self-sacrificing patriotism of the Eastern Telegraph Company suddenly became foremost in condemning its selfishness and greed!

This Egyptian episode is of a piece with the whole proceedings of the Conference, so far as they affected the owners of Submarine Cables. We are ready to admit that the position of affairs is anomalous. Inland Telegraphs are everywhere the property of the nation, which has either erected or purchased them, whereas the oceanic systems are the property of private individuals. Moreover, the action of the European Telegraph Union has uniformly tended to internationalise the land lines, though leaving to each country undisturbed ownership and responsibility. The cable system alone remains outside this controlling tendency; and having no Government to father it, nor any recognised position in the Union, it has become the object of much jealousy and pressure, which, if not steadfastly opposed, would place it under the control of the national delegates, while neither separately nor conjointly would the nations they represent accept any responsibility for its financial welfare.

The anomaly, however, is the result of circumstances, and is, in reality, highly creditable to those who have created it To the courage, enterprise, and skill, chiefly of Englishmen, the world owes its magnificent trans-oceanic telegraph system. The nations did nothing to create it and hardly anything to encourage it. Private individuals have taken all the risks, sustained all the losses, and notoriously, with few exceptions, have reaped but small profits. That their property is not under the control of the Telegraph Union is no fault of the Companies; yet because they cannot afford to share its enthusiasm for "democratic rates," they are reproached with maintaining an anomaly opposed to the interests of a Cosmopolitan commonwealth. The bulk of the cables belong to British subjects; and with just as much reason the same accusation might be hurled against the British navy.

We do not complain of any legitimate efforts to lower the telegraph tariffs of the world; it is a natural tendency to which Cable Companies not less than national Governments have conformed. But to intimidate outsiders, or to require them to make heavy pecuniary sacrifices to please the European Governments, is conduct which any single nation would be ashamed of, and which only escapes absurdity by being the joint action

Digitized by Google

of many. Acceptance of the Egyptian proposal would have been an act of this kind; and a statement has got abroad that the Companies were threatened with opposition Cables if the Union's terms were not agreed to. The threat is too silly to have been made in earnest at all. When nations are of one mind as to this, they will probably be of one mind also in seeing that if they must have Cables of their own they can have them cheaper by buying those already laid rather than by laying fresh ones to compete on terms that would be ruinous to all. A combination of Governments to lay and maintain Submarine Cables which any one of the maritime parties to the bargain would instantly destroy in time of war may be expected when invading armies agree to respect the enemies' land wires and railroads.

It does not surprise us, however, that a suggestion for an international cable proprietorship has been put forward at this juncture. If it serves no better purpose it will push the pretensions of the Union to their logical outcome. Perhaps the delegates never thought of this; being only heads of departments, and not national representatives in any political sense, they may now perceive that there are political consequences bound up with their proceedings which they are quite incompetent to deal with. The English delegates at all events ought to see this. There are far worse things than anomalies, and one of them would be for England some day to discover that she to whom nine-tenths of the world's cable property belongs, in whose interests and for whose safety chiefly it has been created, had pledged it for the temporary friendship of nations who would have the strongest temptation to break their bargain at a pinch, and the very strongest motives for keeping her to hers. We see in the action of the late Conference certain indications of a jealous and hostile attitude towards England's pre-eminent position as mistress of the seas, beneath as well as above; and it behoves the English Government, but primarily the English Cable Companies, to look to their own safety without reference to the benevolent but selfish aims of the Continental nations. As to the tariffs, they can and will be cheapened when cheapening them will proportionately increase the receipts without increasing the expenditure. The nonsense talked about shilling telegrams to Australia, because there are to be sixpenny telegrams in England, may be dismissed until the day when *The Times* newspaper, for example, magnanimously accepts advertisements for nothing because it can earn "seven per cent." without charging for them; or when the P. and O. Company will take passengers to India for twopence because there are penny steamboats on the Thames.

CORRESPONDENCE.

ELECTROSTATIC CAPACITY OF OVERGROUND WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the late Prof. F. Jenkin's "Electricity and Magnetism" (p. 332, first edition) is a formula for the capacity of an overhead wire. Owing to the remark there made that experiment gave results nearly double as great as the formula which was attributed by him to induction between the wires and the posts and insulating supports, and thinking that the presence of neighbouring wires should have a marked influence in increasing the capacity, owing to the neighbouring wires being earthed, I verified this by working out the theoretical formulæ for the capacities (self and mutual) of overground parallel wires, and applying them numerically in a special case. (Paper in some back volume of *Journal* of S. T. E. and E. Cannot say which, as my separate copy of the paper has no date or reference, a curious omission I observe in all the S. T. E. and E.'s separate copies.) With one additional parallel wire the increase of the capacity of the first was 11 per cent.; with three additionals it was 24 per cent. As to further increase by more wires, it would not be *very* great, as they practically would be much further away. As a guess, it might run up to 50 or 60 per cent., with a large number of wires, but of course it would depend materially upon their mutual distances and height above the ground.

The recent measurements of capacities of wires in the North of England supply some definite information. Taking the case of a wire 20ft. above the ground of diameter ·08in., the calculated capacity, supposing there to be no other wires (nor trees, &c.), is ·0095 mcf. per mile. The average result observed is given in Mr. Preece's paper (p. 348, last number of *Electrician*) as ·0120 with the other wires insulated, and ·0142 when earthed. And for the iron wire, ·171in. diameter, supposed 20ft. above the ground, the similar three results are ·0103, ·0131, and ·0169. I take $v = 30^{10}$ instead of the 2880^{8} conv. used in the paper referred to.

In both cases we may observe that the experimental result with wires insulated is about midway between the calculated result and the experimental result with wires earthed, so that it would appear that the influence of surrounding objects (other than neighbouring wires earthed) in increasing the capacity was about equal to that of the neighbouring wires themselves. This might, of course, be true in some particular case, but we cannot safely conclude it from the above, on account of leakage, as may be seen thus. If the wire experimented on were perfectly insulated from earth through the poles, whilst the other wires (though insulated at the ends) were so very badly insulated at the poles that they could be considered as connected to earth, it is clear that a measurement of capacity of the first wire would give the highest result. And this would be true with fair insulation, if the total charge could be observed. But when the observation is made by throw of needle, only a part of the charge is observed, the remainder (due to the leakage of the neighbouring wires) going in slowly, or coming out slowly when discharge is taken. In any case, however, the effect of the imperfect insulation of the neighbouring wires is to make the apparent capacity greater, and so reduce the difference between the capacity with wires insulated and to earth. Thus bettering the insulation would shift the middle results above towards the lower.

How far this operates might be experimentally determined by charging the first wire with the others insulated, then waiting a little, and observing the extra charge produced by suddenly earthing the other wires. If the insulation be bad, the extra charge will be *nil*; if first-rate, it might nearly amount to the full difference.—Yours, &c.,

OLIVER HEAVISIDE.

ON DISTRIBUTION OF ELECTRICITY BY SECONDARY GENERATORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the *Philosophical Magazine* for September, Dr. J. Hopkinson has drawn attention to a possible source of danger in connection with secondary generators.

This communication was reprinted in your issue of the 4th September, and could not fail to have attracted the attention of your numerous readers.

In the International Inventions Exhibition the Edison and Swan United Electric Light Company are exhibiting at their stall, in the East Arcade, 200 Edison-Swan incandescent lamps, supplied from two of the annular induction transformers of MM. Zipernowski-Deri, constructed by M. Ganz and Co., of Buda Pesth. The exciting dynamo which supplies the primary current is in the American Court, at a distance of about 800ft., and the primary current is conveyed by a No. 10 B.W.G. copper wire to the transformers. Dr. Hopkinson has pointed out that as an induction coil also acts as a condenser, it is possible, if its electrostatic capacity considered as a condenser is sufficient, that a discharge current could be obtained from the

Digitized by Google

secondary circuit sufficient to be dangerous if passed through the human body. As soon as Dr. Hopkinson's communication appeared it occurred to me that this source of danger could be removed by connecting one wire of the secondary circuit to earth, and that in this case, even if the secondary generators have electrostatic capacity other than a very small quantity, this device will effectually prevent electrostatic accumulation of electricity in the secondary circuit, although a certain small loss of energy will result from the charging and discharging of the secondary generator by electrostatic induction.

At the Exhibition, accordingly, the experiment was immediately tried by taking a wire from one side of the secondary wire and connecting it to a good earth. This does not interfere in the least with the steadiness of the lighting. I mentioned this safeguard against this possible electrostatic accumulation to Dr. Hopkinson, and I have his permission to state that he considers it a complete insurance against any such danger as that to which he has called attention. It is satisfactory to find that so simple a means removes a doubt that might otherwise have arisen in the public use of secondary generators in connection with electric lighting.—Yours, &c.,

J. A. FLEMING,
Electrician to the Edison and Swan United Electric Light Company(Limited).

57, Holborn-viaduct.

ELECTRICAL CONDITION OF THE HUMAN BODY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In Dr. Stone's very interesting paper, published in your last issue, the human body is said to closely resemble a faulty submarine cable. As this is likely to give rise to some misapprehension on the subject, I should like to ask Dr. Stone for a clearer expression of his meaning. A submarine cable may be faulty in several ways, and it is only to one of these conditions, *i.e.*, an abnormally low insulation resistance, that the human body bears any resemblance. The currents set up by the body itself cannot be compared with the polarisation currents due, for instance, to a complete rupture of the cable and consequent exposure of the conductor; but the phenomena attending the electrification of the body present a very close affinity with those which may be observed when a long section of insulated cable having an appreciable and variable earth current is similarly treated. As regards the comparison made between the human body and a leaky condenser, I am glad to meet with a corroboration of my own views. I may mention that the results of some of my own experiments, using 20 volts, gave the capacities of three individuals as 3·0, 2·9, and 5·4 micros.; the mean effective insulation resistance of the latter, calculated by fall of potential, being 9 megs. In reference to the process of electrification of the body, in view of its alleged similarity to a faulty cable, the following figures may be of interest. It will be observed that the gradual fall in the deflections, and corresponding increase in the resistance indicated by it are, in the case of a submarine cable, by no means compatible with a faulty condition.

Subject A.—Z to right hand, standing 6ft. from galvanometer. Shunt 1 ohm. Fifteen Leclanché cells.

45″ ..... 398 to 403
1′ ..... 393 „ 410 = 401 = 7086 ohms.
2′ ..... 390 „ 421
3′ ..... 375 „ 412
4′ ..... 385 „ 353
5′ ..... 358 „ 343 = 350 = 8571 ohms.

Discharge after 1 min. E. = 5, neg. steady.

Subject B.—Same conditions.

Personal current = 1 division. Shunt 1 ohm.

1′ ..... 535 to 511
2′ ..... — 435
3′ ..... 438 „ 448
4′ ..... — 400
5′ ..... 355 „ 358

Discharge after 1 min. E. = 4, neg. steady.

Subject A.—Same conditions.

1 min. = 472 divs.

Discharge after 1 min. E. = 5, neg. steady.

Subject B.—1 min. not taken.

1′ 15″ ..... — 570 = 5272 ohms.
2′ ..... 510 to 520
3′ ..... 520 „ 600
4′ ..... 560 „ 480
5′ ..... 495 „ 450 = 6377 ohms.

Discharge after 1 min. E. = 6, neg. steady.

The slightest movement *or difference of pressure* had a considerable effect upon the readings. Probably the nature of the contact was altered.

These figures represent the actual resistance of the body from hand to hand in its *normal* condition. The body discharged itself readily to E, but if insulated had an E of 9 megs., as we have seen in, at all events, one case. Under electrification it behaved exactly as a submarine cable of low insulation resistance, and with, as I have said, a variable earth current.—Yours, &c., A. E. BAINES.

THE LIFE OF INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: "Carbon" has exposed the fallacy in Mr. Grundy's figures by means of examples evolved from his inner consciousness; he might, however, have taken an impressive example from Mr. Grundy's own tables. Thus we find on referring to the statement published in your issue of 4th inst., page 315, that on the "New All Day Circuit" 28 lamps have run for 480·5 hours with only one natural death, and as this occurred on the first day, we may fairly take a fresh start, and say the remaining 26 lamps (one having been accidentally broken) have been burning 456·5 hours *without a single death.* Using Mr. Grundy's formula we have—

$$\text{average life of lamps} = \frac{456{\cdot}5}{0} = \text{infinity.}$$

We believe that a few million years hence—

"The cloud capp'd towers, the gorgeous palaces,
"The solemn temples, the great globe itself,
"Yea, all which it inherit, shall dissolve!"

Yet these twenty-six immortals shall surely illumine chaos through the Æons, a glorious monument to the nineteenth century in general, and to the skill of the Edison-Swan Company in particular.

In conclusion, let me urge Mr. Grundy to lay to heart the old "saw" (slightly altered), "Don't reckon on the life of your lamps before they are dead."—Yours, &c., S. E.

SIR LYON PLAYFAIR'S ADDRESS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As a constant reader of your valuable journal I venture to offer you the following remarks, having reference to Sir Lyon Playfair's Presidential Address at the British Association meeting, as reported in your issue of the 11th inst.

After careful perusal it occurs to me that a point upon which the author might, perhaps, have been expected to enlarge has only very shortly been touched upon.

The subject of the address, as stated by the President, was "The Relations of Science to the Public Weal," and a large portion of it was occupied in considering the present attitude of the State with regard to scientific education.

Throughout the address, however, very little mention is made of those wonderful scientific discoveries by which such blessings and benefits have been conferred upon mankind, and which, I think, might with advantage have occupied a prominent place in the address, as serving to strengthen the cause for which the author was pleading.

The State apparently not being yet alive to the importance of scientific education, it is very necessary to lose no opportunity of strengthening its claim where possible, nor to allow it to be forgotten how much we are indebted to science for the present state of perfection to which we have arrived.

Digitized by Google

It cannot, I suppose, be expected that the nation's money will be advanced in furtherance of scientific education until it is made aware of what it is indebted to science for and what it may expect from her in the future.

As to the first, a glance around will furnish an ample answer.

Lord Macaulay has thus enumerated some of the services which have been rendered by science in promoting human welfare :—"It has lengthened life; it has mitigated pain; it has extinguished diseases; it has increased the fertility of the soil; it has given new securities to the mariner; it has furnished new arms to the warrior; it has spanned great rivers and estuaries with bridges of form unknown to our fathers; it has guided the thunderbolt innocuously from heaven to earth; it has lighted up the night with the splendour of the day; it has extended the range of the human vision; it has multiplied the power of the human muscles; it has accelerated motion; it has annihilated distance; it has facilitated intercourse, correspondence, all friendly offices, all despatch of business; it has enabled man to descend to the depths of the sea, to soar into the air, to penetrate securely into the noxious recesses of the earth, to traverse the land in cars which whirl along without horses, to cross the ocean in ships which run ten knots an hour against the wind."

With regard to the future progress of science, a learned professor has stated as his opinion that whereas the highest points in Literature and Art had been attained, the future developments of science would mark the continuous progress of knowledge in the world.*

Another subject of great importance which is mentioned in the address is the present system of examinations, and which, without confining the subject within the limits of Sir Lyon Playfair's remarks, may well claim attention at the present time, as in a few weeks the winter term of study will have commenced, and preparations for examinations next May will have begun.

Opinions have, I think, been expressed lately that the present mode of carrying out examinations is open to improvement, and there is much to commend itself in the system adopted by the late Prof. F. Jenkin, one argument in its favour being that it would very rarely happen that a student, when left to himself, would trust wholly to his memory, and at least would always have hand-books ready for reference and confirmation of his conclusions. In addition to this, the use of note-books at examinations would tend to urge a student to keep his notes in good order, a point to which I have found teachers always give great prominence, but which in many cases is not now done.

Lastly, objection will perhaps be raised (as, indeed, it is by *The Engineer*) to Sir Lyon Playfair's advice "to advance science for its own sake, and not for its applications;" but I think that in this must consist the argument in favour of the study of science for a large number of persons, as it cannot be expected that each individual student will, as the result of his studies, be enabled to confer a new blessing on mankind. One result, however, of the study of science (and which, I think, alone justifies Sir Lyon Playfair's views) is that the mind becomes occupied with high and worthy thoughts, to the exclusion of others, which materially tend to raise the whole life to a higher standard; and especially is this the case, I think, where the science studied proves interesting, as with that science to which your journal is devoted, and the other sciences which of necessity follow in its train.—Yours, &c.,

Westminster, Sept. 14, 1885. A. NEWMAN.

* Prof. Tomlinson at the Birkbeck Institution, 3rd October, 1883.

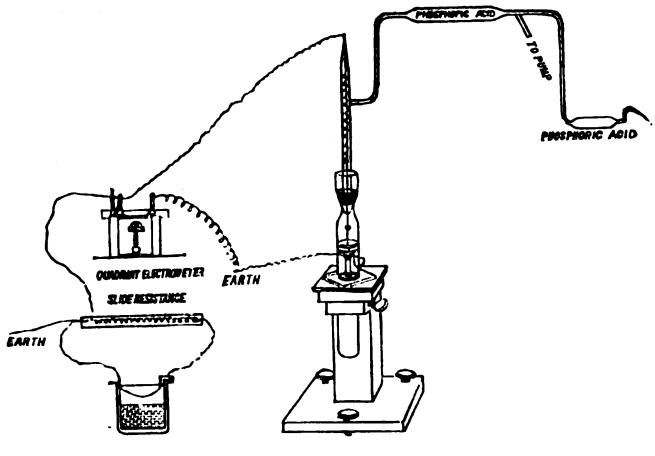
AN ELECTRIC CRANE.—An electric crane is in use in one of the foundries of M. Farcot, at St. Ouen. The generator is situated at a distance of 100 metres, the receptor being set up in the leverage apparatus, on the axis of which a force equal to 4 horse-power is developed. Whereas the crane was formerly worked by ten men, it is now attended to by one. The new crane has resulted in a considerable saving of hand labour.

ON CONTACT ELECTRICITY IN COMMON AIR, VACUUM, AND DIFFERENT GASES.*

BY. J. T. BOTTOMLEY, M.A., F.R.S.E.

The discussion at the British Association meeting at Montreal last year on the seat of electromotive force in the voltaic cell, the paper of Prof. O. Lodge which resulted from that discussion, and the subsequent discussion at the Society of Telegraph Engineers, must have brought forcibly before the minds of those interested in the subject the extremely unsatisfactory state of our experimental knowledge on some of the fundamental questions relating to contact electricity. Foremost among these, perhaps, is the question of the behaviour of various metals as to Volta contact effect in air and vacuum, and in gases different from common air. I have undertaken a series of experiments on this subject, and have already obtained some definite results, although the experiments which I have made up to this time are only to be considered as preliminary to a fuller inquiry.

The apparatus which I am using is shown in the diagram. The lower of the two plates to be experimented on is supported in the vacuum chamber by a small stand with a glass pillar; and the electrode from this plate passes through the side of the chamber, hermetically sealed into it. The upper plate is hung from the top by a long platinum spiral, the upper end of which is also hermetically sealed into the glass. To the lower end of the spiral is attached a long hook which carries the lower plate, and at the junction of the spiral with this hook there is a small globe of soft iron. It is by means of this small soft iron globe and a magnet applied outside the tube that the upper plate is lifted from the lower plate. The nature of the vacuum chamber and its connection to the pump will be readily understood from the diagram. The final adjustment of distance between the two plates when at their nearest is done at the top of the tube, by heating it and drawing out the glass carefully, or else letting it fall in, till the adjustment is satisfactorily made. The branch tube on the right hand side of the diagram, which is shown sealed off, is used for supplying gases to the apparatus. A small part only of the drying and purifying apparatus is shown in the diagram.



For determining the value of the Volta contact effect, I have used the quadrant electrometer and the compensation method of Sir William Thomson. The Daniell cell and slide resistance and the connections are shown in the figure. The method is so well known that it need not be described here. It was described in *Nature*, April 14, 1881, and has also been described in the paper of Prof. O. Lodge, which was printed in the British Association *Reports* and elsewhere.

The plates which I have used are zinc and copper discs a little larger than a shilling. Testing them first with full air pressure I found that the Volta contact difference was rather over 0·74 volt; which is as nearly as possible what has been found by previous experimenters, and by myself experimenting a few weeks ago with Sir William Thomson's old contact apparatus.

* Abstract of Paper read before the British Association at Aberdeen.

Digitized by Google

The air was then very carefully exhausted; the exhaustion being maintained for two days, and finally made exceedingly good with 2½ hours' work at the pump, just before testing. The pressure during the testing was not greater, and was probably much less than $\frac{1}{5}\frac{1}{2}\frac{1}{3}$ mm. of mercury, or 2·5 **M**. (2½ millionths of an atmosphere). The electrical test was then applied, and the value of the Volta contact effect was found to be *exactly the same as before*, a little over 0·74 volt. The final test, however, consisted in allowing the air to come back into the apparatus, and then testing electrically. This was done by breaking the point of the sealed tube to the right of the diagram, and as the air entered the electrometer test was rapidly applied. So far as the sensitiveness of the testing apparatus goes, there was absolutely no change in the Volta contact difference.

My experiments, therefore, are absolutely contradictory, so far as they have gone, to those of Dr. W. Von Zahn, quoted by Prof. Lodge, who experimented in a high vacuum, and found the Volta effect to be diminished, and to be represented by a potential difference of only half a Daniell.

I have also experimented on hydrogen and oxygen gases in this apparatus in a way precisely similar to that described above. The chamber was very carefully exhausted, and the Volta contact effect tested with the electrometer. Hydrogen was then admitted, and while it was entering, which it was forced to do slowly, the electrical testing was repeated several times.

A second and a third exhaustion were made, and hydrogen admitted a second and a third time. The same was subsequently done with oxygen, except that it was, of course, sufficient to admit the oxygen a single time. The result of my investigation, so far as it has gone, is that the Volta contact effect, so long as the plates are clean, is exactly the same in common air, in a high vacuum, in hydrogen at small and great pressure, and in oxygen. My apparatus and the method of working during these experiments was so sensitive that I should certainly have detected a variation of one per cent. in the value of the Volta contact effect, if such a variation had presented itself. To do away with all question as to the dependence of the Volta effect on "ancient air sheets," I propose to modify my apparatus by making the vacuum chamber much longer, and finally of combustion tubing. I shall then apply great heat to the plates while they are contained in a vacuum as high as I can command. If, then, there be any ancient air sheets existing, they must either be driven off or else absorbed into the plates. If any gas be driven off it will be removed by the pump. The plates will then be tested when they have perfectly cooled, and the value of the contact difference determined. That being done, the atmospheric air or some other gas will be admitted, and the contact difference will be again determined. The effect of the pressure of the atmosphere or other gas will, I think we may safely suppose, be thus ascertained. In conclusion, I have to express my indebtedness to Mr. J. Rennie, assistant to the Professor of Natural Philosophy in the University of Glasgow, for most valuable assistance during my investigation.

COOLING OF WIRES IN AIR AND VACUUM.*

BY J. T. BOTTOMLEY, M.A., F.R.S.E.

This paper gives a brief account of recent experiments on radiation of heat from the surface of metallic wires in air and in vacuum. A preliminary paper on this subject was communicated to the British Association at its meeting last year. Since that time the arrangements for experimenting have been greatly improved, and further results have been obtained. The object is to determine, in absolute measure, the loss of heat from the surface of small wires of various materials, both uncovered and when covered with various coatings, the wires being surrounded with different gases at various pressures down to the very lowest.

The chief experimenters on this subject in recent times have been Kundt and Warburg and Mr. Crookes. My method of experimenting, which is very different from that of other experimenters, consists in passing a current of known strength through the wire under examination, and determining the increase in the resistance of the wire due to heating of the current, when the wire has assumed a permanent temperature with the given current passing through it. When temperature of the wire has become constant, the heat generated by the current (which can be calculated in absolute measure) must be equal to that emitted at the surface of the wire, plus that lost at the ends of the wire. The temperature of the wire at the moment is also ascertained from its resistance (as was done by Siemens in his experiments in resistance of platinum wire at different temperatures, *Proc.* R.S. Vol. XIX., p. 443), and the emissivity of the surface of the wire can thus be determined in absolute measure.

My recent experiments have been directed to the determination of emissivities in very high vacuums. Using a Sprengel pump with five full tubes and a M'Leod gauge of improved construction due to Mr. C. H. Gimingham, I have obtained and measured a vacuum with air pressure as low as $\frac{1}{3}\frac{1}{0}$ **M**. (one thirty-millionth of an atmosphere).

The wire with which I am experimenting at present is a platinum wire half a metre long and 0·04 centimetre in diameter. It is contained in a glass tube about 0·6 centimetre in internal diameter.

A table of emissivities for metallic surfaces has not yet been completed, but one result obtained with high vacuum may be quoted. On passing a current of 1·18 ampere through this wire with full air pressure, the permanent temperature attained by the wire was 75°C., the temperature of the room at the time being 15°2·C. On exhausting down to $\frac{1}{1}\frac{1}{5}$ **M**.$\left(\frac{1}{19\times10^6}\text{ atmo.}\right)$, and passing the same current, the wire became heated to a good red heat.

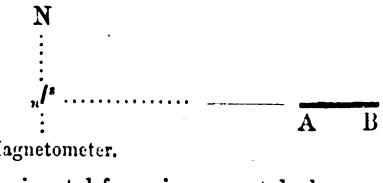
ON A SPECIMEN OF ALMOST UNMAGNETISABLE STEEL.*

BY J. T. BOTTOMLEY, M.A., F.R.S.E.

The author has examined a specimen of steel presented to Sir William Thomson by Mr. R. R. Eadon, of the firm of Moses Eadon and Sons, Sheffield. This steel is made under Hadfield's patent, and the specimen contains 15 per cent. of manganese. One side of the bar has been polished, and shows that the steel is capable of taking a very high finish. The present specimen has probably a tensile strength of 45 tons to the square inch.

To test it magnetically the bar was first "touched" with steel magnets; and such preliminary tests seemed to show that the magnets had not the slightest effect upon it. It was then placed between the poles of a powerful Rhumkorf electromagnet, which was excited by 40 large tray Daniells arranged in fours for quantity and ten in series; and the process for magnetising which is always used in the Glasgow University Laboratory, and which is very satisfactory, was proceeded with. It was very astonishing to find the bar of steel absolutely unaffected by the electro-magnet so far as could be perceived by the hand.

After magnetisation the bar was tested carefully by the magnetometer method, which consists in placing the magnet to be tested at a known distance from a very short suspended magnet in a known position, the suspended needle being in a



Magnetometer.

place where the horizontal force is accurately known, and by the deflection of the magnetometer comparing the force of the bar with that of the earth.

With the bar to the east or west of the magnetometer, the

* Abstract of Paper read before the British Association at Aberdeen.

* Abstract of Paper read before the British Association at Aberdeen.

Digitized by Google

formula for calculating the magnetic moment of the bar is as follows :—

$$\mu = H \frac{2d}{(d^2 - l^2)^2} \tan \theta.$$

Where μ is the magnetic moment,
H horizontal force,
d distance of centre of bar from centre of magnetometer,
$2l$ effective length of bar,
θ angle of deflection,

a mirror magnetometer being used, and the deflection being very small, $\tan \theta = \theta$, and θ is equal to half the number of scale divisions of the deflection divided by the distance in scale divisions of the scale from the magnetometer.

In the present instance the effective length of the bar has been estimated at 10 centims., the real length over all being 14·29 centims. The value of H is very accurately known at a certain place in the Glasgow University Laboratory. The experiment on the bar gave for the magnetic moment

$$\mu = 2{\cdot}55.$$

The weight of the magnet is 192·09 grammes. Hence the magnetisation per gramme of this specimen of steel is

$$\frac{2{\cdot}55}{192{\cdot}09} = 0{\cdot}013 \text{ C.G.S.}$$

per gramme.

To compare this with other specimens of steel, we find in many specimens that magnetisation of 40, 50, or even 60 C.G.S. per gramme can be obtained. In some specimens as much as 90 or even 100 C.G.S. per gramme has been obtained.

P.S.—The author has been informed that Dr. Hopkinson has already experimented on steel containing manganese, and has obtained similar results. He has not, however, seen Dr. Hopkinson's figures, and is unable to compare his own results with them.

DOMESTIC ELECTRIC LIGHTING.*

BY W. H. PREECE, F.R.S., ELECTRICIAN G.P.O.

After referring to the full details of the lighting installation of his house in Wimbledon, given to the Section at the meeting at Montreal, Mr. Preece spoke generally of the experiences he had gained during the past twelve months. The secondary batteries upon which he had mainly relied exceeded his expectations in the services they rendered. They returned 70 per cent. of the energy put into them without any apparent diminution whatever in their E.M.F. They showed no signs of deterioration, and gave no trouble whatever. He used his gas engine for charging only two days a week. He had experienced no fault with the wiring of his house. He had used only the very best materials, and had attended personally to the insulation of the system. It was periodically tested and found to be good. He condemned, in severe terms, the cheap and nasty wire which was so frequently and ignorantly used, and feared that the prejudice against the electric light would increase when failures from this cause arose. None but the very best materials should be used, and the joints should be seen to by experts. He had devoted considerable attention to the problem of distributing light, and had succeeded so far that while his rooms were beautifully illuminated the eye was not irritated by regarding a bright source of light. The lamp he used was a 50-volt 10 candle-power glow lamp, and it was, as a rule, so fixed that the eye never saw it. He had arrived at the use of these lamps after careful consideration and many trials of other lamps. They secured greater safety in the leads, and involved less capital in batteries through the use of low E.M.F.

Mr. Preece went on to say that he ran his lamps at an E.M.F. about 2 per cent. less than the normal E.M.F. He did this to secure long life to his lamps. The breakage had been very small. The E.M.F. and current which will give a lamp a normal life of 1,000 hours and a certain candle-power should be determined by every maker. The sixth power of the current will give the candle-power and the twenty-fifth power the life with any other current. The great advantage of batteries is that the proper current once determined can never be exceeded, and thus efficiency is ensured. If lamps are run too low there is a waste of power, if too high there is waste of lamps. We are, Mr. Preece thinks, now gradually acquiring a thorough knowledge of the number of watts which should be expended in each lamp to secure the maximum economic efficiency.

He had introduced into the charging lead, and into the discharging lead a Ferranti meter, so that he was able to record exactly the quantity of electricity passed through the batteries and that passed through the lamps. This beautiful meter is based on Ampère's laws, which determine the attraction and repulsion of currents.

A small phosphor-bronze vane is immersed in a bath of mercury, through which the current flows radially, fixed in a magnetic field. The mercury rotates and carries with it the vane. The rate of rotation varies directly with the strength of current, and the number of rotations are recorded by a counter, which can be read off directly. So far, he was perfectly satisfied with its performance.

As regards expense, excepting the first cost, Mr. Preece did not find much addition to his expenditure for illumination. His electric light was costing him about £50 a year for gas, wages, oil, and lamps. It was the cheapest luxury he indulged in. The greatest advantages were the comfort and cheerfulness it engendered, and as cheerfulness was the main element of health, he thought that the electric light would prove a serious rival to the doctor. There was no one who valued health and comfort who should neglect to apply the electric light to his home when it was brought, as it has been, by the success of the secondary batteries, within his means.

It was said that he, as an expert, could make things go which would fail in ordinary hands; but he mentioned several cases where coachmen, butlers, gardeners, and grooms had been found perfectly competent and intelligent enough to attend to everything.

* A Paper read before the British Association at Aberdeen

ON THE THERMODYNAMIC EFFICIENCY OF THE THERMOPILE.*

BY LORD RAYLEIGH, F.R.S.

During the last few years the thoughts of many electricians have turned to the question of the possibility of replacing the dynamo by some development of the thermopile; and it is, I believe, pretty generally recognised that the difficulty in the way is the too free passage of heat by ordinary conduction from the hot to the cold junction. The matter may perhaps be placed in a clearer light by an actual calculation, accompanied by a rough numerical estimate applicable to the case of German silver and iron.

If t, t_0 denote the temperatures of the hot and cold junctions respectively, e the electromotive force per degree centigrade, the whole electromotive force for n pairs in series will be represented approximately by

$$ne(t - t_0).$$

The magnitude of the current (C) is found by dividing this by the sum of the internal and external resistances ($R_0 + R$); and the useful work done externally per second is RC^2. It reaches a maximum when the external resistance is equal to the internal; and its amount is then

$$\frac{n^2 e^2 (t - t_0)^2}{4R_0}.$$

The value of the internal resistance R_0 depends upon the dimensions of specific resistances of the bars. Denoting the latter quantities by r_1, r_2, and taking σ_1, σ_2 to represent the areas of section, the common length being l, we have

$$R_0 = nl\left(\frac{r_1}{\sigma_1} + \frac{r_2}{\sigma_2}\right);$$

* Paper read at the Aberdeen Meeting of the British Association.

Digitized by Google

so that the external work per second is

$$\frac{ne^2(t-t_0)^2}{4l\left(\frac{r_1}{\sigma_1}+\frac{r_2}{\sigma_2}\right)}.$$

We will now compare this with the work dissipated by ordinary conduction of heat along the bars.

If Q be the amount of heat conducted by the n pairs, r'_1, r'_2 the *thermal* resistances, then

$$Q = n\left(\frac{\sigma_1}{r'_1 l}+\frac{\sigma_2}{r'_2 l}\right)(t-t_0).$$

The fraction of this heat, supplied at temperature t, which might be converted into work by a perfect engine working between the absolute temperature, t and t_0, is $(t-t_0)/t$; so that the work dissipated per second is

$$\frac{nJ(t-t_0)^2}{tl}\left(\frac{\sigma_1}{r'l}+\frac{\sigma_2}{r'l}\right),$$

where J denotes the mechanical equivalent of heat.

The ratio of this to the useful work is

$$\frac{4J}{te^2}\left(\frac{r_1}{\sigma_1}+\frac{r_2}{\sigma_2}\right)\left(\frac{\sigma_1}{r'_1}+\frac{\sigma_2}{r'_2}\right),$$

independent of $(t-t_0)$, of n, and of l. It is further evident that the ratio in question does not depend upon the absolute values of the sections, or of the electrical and thermal resistances, but only upon the *ratios* of these quantities. Thus the *efficiency* of the thermopile is independent of the absolute dimensions of the bars, and even of the difference of temperatures at the junctions. The *power* is increased by diminishing the length and increasing the sections to a limit not indicated by these expressions (in which the terminal temperatures are regarded as given), and probably determined in practice by the necessity of conveying the heat to the scene of action.

The resistances being given, the ratio of sections σ_2/σ_1 is to be determined so as to make our ratio a minimum. This happens when

$$\left(\frac{\sigma_2}{\sigma_1}\right)^2 = \frac{r_2 r'_2}{r_1 r'_1};$$

and thus we get

$$\frac{4J}{te_2}\left(\sqrt{\frac{r_1}{r'_1}}+\sqrt{\frac{r_2}{r'_2}}\right)^2.$$

To turn this into numbers for the case of German silver and iron, we have the following approximate numbers in C.G.S. measure* :—

$$r_1 = 2{\cdot}0\times10^4, \qquad r'_1 = 1{\cdot}0\times10^1$$
$$r_2 = 1{\cdot}0\times10^4, \qquad r'_2 = 5{\cdot}0\times10^0$$
$$e = 3{\cdot}0\times10^3.$$

The value of J is $4{\cdot}2\times10^7$, and for t we will assume 500 (absolute measure). The use of these gives, as the ratio of the work that would be obtained by a perfect engine from the conducted heat to that actually obtained from the thermo-electric force, the number 300; from which we may conclude that the steam engine and dynamo are not likely to be superseded by a German silver and iron thermopile, even though considerable allowance be made for the admitted roughness of the numerical estimate.

As regards other materials, it is interesting to note that the ratio contains as divisor the *square* of the electromotive force per degree.

* Everett's "Units and Physical Constants," Landolt's *Tabellen*.

ELECTRIC LIGHT SWITCHES.

We illustrate below two forms of switches lately designed by Mr. N. G. Thompson. The large switch, Figs. 1 and 2, has been constructed with a view to balancing the pressure generally found necessary to form good contact, and to compensate for wear and tear. In the majority of switches now made for heavy currents the requisite pressure is given by means of a spring acting on the spindle, which throws the wear and strain on that part. This is obviated in Mr. Thompson's switch by making the contact plates in the form of a cylinder cut into segments, a a a, and secured by a flange to the wood base b. Two plugs, c c, are fitted loosely into the cross tube d, and are forced out against the segments by means of the spiral spring e; a strip of metal in the form of a bow, f, is also secured to the plugs c c, and any convenient handle is attached to the tube d. It will thus be seen that the pressure on the segments is completely balanced, without in any way affecting the spindle and handle to which the tube is fixed. The bow-shaped piece of metal f conveys the current from one plug to the other, and at the same time aids the action of the spiral spring. The result of this balanced

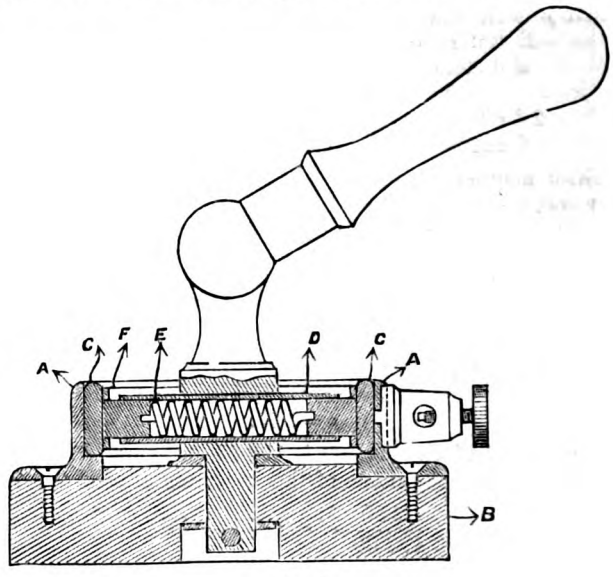


FIG 1.

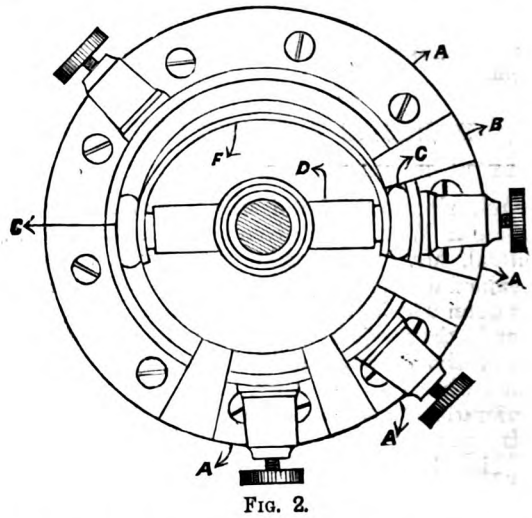

FIG. 2.

action is to make the switch remarkably free to move, and at the same time permits of the desired pressure.

Figs. 3 and 4 show a smaller form of switch, or, more properly speaking, contact breaker suitable for one or more incandescent lamps. Its construction is simple and its action certain. It consists of a short length of riband steel, a, maintained in a bow form by a stiff piece of metal of channel shape, b, with a spindle, c, carrying the handle passing through the spring a, and secured to a cylindrical plug, d, in such a way that the spring and plug move

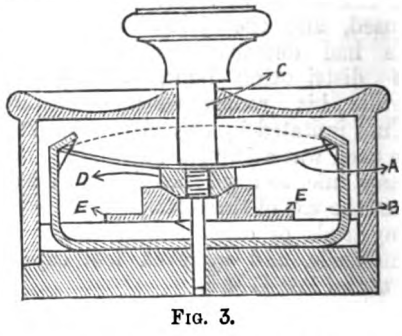

FIG. 3.

Digitized by Google

with the spindle, while at the same time the spindle and plug can revolve free of the spring. The plug, in the position shown, presses against two halves of a metal cylindrical base, *e*, to which the wires are attached respectively. The action is as follows:—

If the handle is pulled out from the switch, the plug and spring will pass into the new position, shown by dotted lines, and thus break the circuit, and the spring in passing through its intermediate positions will force out the ends of the metal base or holder *b*, which acts as a powerful secondary spring, maintaining the spring *a* in either of the two positions indicated. From this it will be seen that it is quite impossible to fix the plug and spring in any other or intermediate position, and that the action of making or breaking contact is exceedingly positive and sharp. The revolving play of the plug and handle gives facilities for grinding and cleaning the contacts.

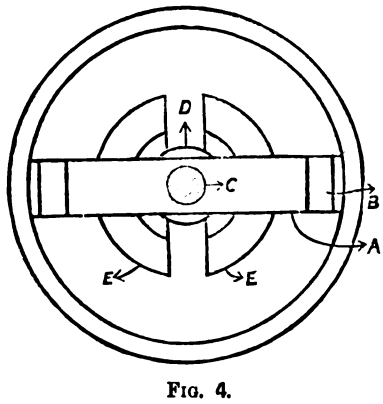

FIG. 4.

We understand that Mr. Thompson has entered applications at the Patent Office for each of these designs.

GREENOCK POLICE BOARD.

The following report by the Electric Lighting Committee to the Police Board was submitted and unanimously approved of at the meeting of the Board on September 10 last:—

"We have to report that the contract for the supply and fitting up of the electric lighting plant at Prospecthill entered into with Mr. E. W. Beckingsale on 10th and 13th October, 1884, was completed on 9th March last and certified by Prof. Jamieson as being in perfect working order. The electrical apparatus has been working successfully since the last date, and on 12th May Prof. Jamieson reported as follows:—

'College of Science and Arts, 38, Bath-street,
Glasgow, May 12th, 1885.

'To the Greenock Police Board Committee on Electric Lighting.

'Gentlemen: I have much pleasure in reporting that Mr. Beckingsale has carried out the electric lighting at Prospecthill in full accordance with your specification and contract. I frequently visited the work during progress, thoroughly tested the whole system upon completion, and again only last Friday, after the lamps had been in action for over 500 hours, I tested the system at work. All my tests are duly recorded in the official test book at Prospecthill. The high insulation resistance maintained in the underground cables and wires is due to great care in handling them, close superintendence during laying them, and a constant application of searching electrical tests. The dynamos and testing apparatus are all of the *best* make and suited for their work.

(Signed) 'ANDREW JAMIESON, Principal.'

"There are 20 street lamps regularly lighted in the area set apart under the provisional order; and three lamps in the machine-house and grounds. Mr. Beckingsale, by his contract, undertook to maintain the whole electrical apparatus for a period of six months after completion, and this period expired to-day (9th September, 1885). The work has been satisfactorily upheld during this period, and the contract is now at an end.

"During the month of August last, arrangements were made with the Roxburgh Street Refining Company, whose refinery is situated within the compulsory area, for a supply of electricity to light their char-house for a period of three years from date of commencement. The fitting up of the apparatus in the refinery was entrusted to Mr. Beckingsale, but the whole cost is payable by the Roxborough Street Refining Company. The rate to be charged for each lamp by the police board is £1 per annum for the time during which the ordinary street lamps are lighted; and the number of lamps is about ninety, which are to be maintained by the Refining Company. The charge will be from 8th September, as the lighting was commenced on that date.

"The total cost of the undertaking is as follows:—

1. Mr. Beckingsale's contract for apparatus, &c...	£873	9	2
Do. do. for maintenance ...	73	0	0
2. Cost of machine house, making trenches, &c...	386	7	6
3. Turbine pulleys and gearing	151	10	0
4. Consulting engineers	51	0	0
5. Expense of provisional order and printing	216	4	10
	£1,751	11	6

"ORDINARY WORKING.

"The maintenance having expired, two men are engaged in attending the machinery, at a total cost of £2. 10s. per week, which, it is expected, will be reduced during the summer months. The renewal of lamps will cost about 15s. per annum each.

"The revenue for the refinery contract and from the public lighting is expected to yield £133 per annum, which will almost meet the cost for wages and upkeep.—Reported by

"Greenock, 9th Sept., 1885." "JN. DUFF, convener.

THE ELECTRIC LIGHT AND ATMOSPHERIC ABSORPTION.*

(Concluded from page 364.)

Relative Intensities of Lights of Different Colours.—Various attempts have been made to assign to each portion of the spectrum its relative illuminating power, the result being a general agreement as to the strong illuminating power of yellow and orange yellow, and the weak illuminating power of blue rays, so that in sunlight, as we see from this table, the specially blue rays only give an illumination of 10 per cent., and in the electric light not more than 20 per cent., so that a cutting off of the blue rays will only cut off from 10 to 20 per cent. of the whole light. When attempts are made to measure more exactly the relative illuminating powers of various portions of the spectrum, we find very considerable differences in the percentage of light assigned to the same part by different observers. This is not remarkable, seeing that Helmholtz has declared that there is no possibility of comparing directly the intensities of two sources of light of different colours. The sensation produced is not in direct proportion to the intensity of the light, and for lights of different colours the sensation and the luminous intensity are differently related. In attempting to measure the intensity of a blue light by means of a standard light of a yellow colour, such as oil or gas, the number expressing the intensity varies with the conditions under which the comparison is made. We can to a certain extent compare differently coloured lights by the ordinary photometers by looking at the images or at the Bunsen disc through some coloured medium placed before the eye, and so determine the relative amounts of red, green, or blue light contained in the two sources of light to be compared. Taking, for instance, copper ruby glass for the red rays, and signal green glass for green and cupric ammonia sulphate for the blue rays, we can accurately compare the lights, determine the relative amounts of red or green or blue light in the two sources of light. The colour of the light depends upon the temperature of the source from which it is produced; a heated platinum wire just begins to give out red light when it reaches a temperature of about 525°C., and as the temperature rises the more refrangible rays gradually appear, until at 1,500°C. the wire gives out a brilliant white light. Carbon poles heated in a vacuum to 1,000°C. give a glow equal to about 30 candles, but on heating them to 4,500°C. the luminous intensity is increased to more than 4,000 candles, the carbons giving out not only light of a high degree of refrangibility and ultra-violet radiations, but being rich also in all kinds of light as well as in obscure heat rays. During the past year interesting experiments have been carried on at the South Foreland Lighthouse on the relative intensities of the most powerful artificial lights with which we are acquainted, and on the general absorption of their light by the atmosphere in different states of clearness. We have only to go back a few years in lighthouse illumination to find as our brightest oil lights either the Fresnel 4 wick lamp or the Trinity House 4-wick lamp of about 300 candles, giving a cylinder of orange-yellow light about 4in. in diameter. By the introduction of the electric light at the South Foreland fifteen years ago, under the advice of Faraday, a source of light of 1,200 candles was obtained within a circle half an inch in diameter. This concentration of the light within so small a space is of vast importance in its use behind a lens, and greatly increases the brightness of the light and the distance to which it can be seen. Its advantages to the mariner are shown from the reports of Profs. Faraday and Holmes on the comparison of these lights, and from a French report in 1870 of the electric light, which says:—"The advantages of the system have been highly appreciated by mariners, and the increase of range of the lights has been very marked in slightly foggy weather. It certainly enables mariners to continue their voyage and to enter a port at night, when they would not have been able to do so with oil lights." A comparison of electric and oil lights of the first order was made by M. Petit, hydrographer to the Belgian Government, some years ago, soon after the electric light was permanently established at the South Foreland. He estimates the relative efficiency of the electric light of 1,200 candles and the oil light of 300 candles, and finds that on 76 nights in a hundred the electric light was seen at a distance

* Evening lecture delivered by Prof. Grylls Adams, before the British Association, at Aberdeen, on Friday, Sept. 11, 1885.

Digitized by Google

of more than twenty miles, whereas the strongest oil lights then used were only seen twenty-nine nights in 100 in the same distance. Improvements have been made in oil lights by adding extra rings of wicks, bringing the candle-power of the 6-wick oil light up to 730 candles, and increasing the cylinder of flame to about 4½in. in diameter. In the meantime gas has also been introduced for lighthouse use, and by the addition of ring after ring of burners the largest gaslights regularly used consist of 108 jets, giving a light of 2,400 candles, and giving a cylinder of flame 11in. in diameter. The oil light, 4½in. in diameter, giving a light of 730 candles, and a gas light, 11in. in diameter, giving 2,400 candles, will give beams of light which are more and more divergent as the source of light is larger, and as seen from any point in the axis of the beam appear of equal brilliancy. When placed behind a very powerful lens they are nearly equal in brilliancy to the electric light of 1,200 candles in the permanent lighthouse, which for the last fourteen years have been supplied from the Holmes magneto machine, and in the observations made on the sea the three lights have been seen over the same range. Following M. Petit we may say, then, that both oil or gas have so improved that the practical efficiency has been raised to 76 per cent. But the efficiency of the electric light does not stop at 76 per cent. If we compare the practical efficiency of the permanent electric light supplied by the Holmes machine and the electric light from the De Meritens machine by means of the electric currents which they severally produce, we find in the first a current of 30 amperes, giving an illumination of from 1,200 to 1,500 candles, and in the second a current of from 120 to 150 amperes—ten times the power—giving the light of from 1,200 to 1,600 candles. The effect of this increase of light would be to render this light visible at sea at a distance of twenty miles, through hazy atmospheres, on from eighty-eight to ninety out of every 100 nights in the year. Thus the increase in the illuminating power which is possible with the electric light diminishes the risks to shipping, and raises the practical efficiency of lighthouse lighting from 76 per cent.—the best that can be done by any other means—to 90 per cent., leaving only 10 nights in a hundred when the light is not seen 20 miles away. By a proper arrangement, and more powerful lenses, the efficiency can be still more increased. Of the remaining 10 nights in a hundred there are some when even the strongest lights cannot be seen for a distance of two or even one mile, as has been shown on a few occasions at the South Foreland during the past year. On these occasions the coefficient of transparency of the atmosphere is so small that an increase of 100 fold in the source of light will hardly increase the distance to which the light is seen by 100 yards. Nor can we be astonished at this when a short time since we read that in a balloon enveloped in a cloud 400ft. in thickness, with bright sunshine all around, the observers were carried for long distances in absolute darkness, showing that about 100ft. of cloud is quite sufficient to absorb bright sunlight and cause total darkness. Now let me compare observations made on a very foggy night at the South Foreland (Feb. 12). A compact 6-wick oil light of 730 candles, and a large gas burner giving 2,400 candles, are only just perceptible at the distance of 1,060ft., and both disappear together. An electric light of 12,000 candles, with a smaller lens, is seen at a distance of about 1,350ft. On the same night the glare from the oil and gas was seen in each case to 1,500ft., and the glare from the electric light to a distance of 1,900ft. The lens for the electric light is smaller, and had the same lens been used as is used for oil and gas, other measurements have shown that the light given out from the electric arc would have been twelve times as great, or that an electric light of 1,000 candles with the large lens would have been seen at 1,350ft., and that an electric light of 100 candles would have been seen as far as the strongest oil or gas lights. That in this statement I am well within the mark will be seen by the fact that at the South Foreland a 50-candle incandescent lamp has given, at the distance of 6,000ft., an illumination equal to two-thirds of the illumination of the oil or gas. We have here facts which illustrate two very important principles, each bearing upon the efficiency of the electric light as regards its power of penetration of the earth's atmosphere when used behind a lens. The oil light of 730 candles gives a light which, because of its compactness, is equal in illumination at any point to the gas light of three times the intensity, and the still smaller and more compact electric light, giving a beam more nearly parallel, gives the same illumination. The question may well be asked—How is it that an electric light of 100 candles will penetrate a fog to a distance of 1,000ft., whilst ten times the light of the same kind will only penetrate 350ft. further? Let me try to make clear to you the law of absorption of light by the atmosphere or by any other absorbing medium. Take a beam of light in its course through successive portions of atmosphere of equal length, each successive portion will not absorb the same amount of light, but each successive portion will absorb a given fraction of the light which falls upon that portion, and the quantity absorbed by each portion will depend upon its distance from the source. If, for instance, the first portion absorbed one-half the light, the second portion will not absorb all the remainder, but only one half of it, *i.e.*, one-fourth of the whole; the next portion will not absorb the remaining one-fourth, but only one-half of it, *i.e.*, one-eighth of the whole; so that one-eighth of the whole will have passed through three portions. Take, for instance, a parallel beam of light, such as sunlight, there will be no diminution of this beam as it passes through a vacuum, but in passing through successive miles of an absorbing medium like the atmosphere, a given fraction of the light will be absorbed by the first mile. The same fraction of the remaining light will be absorbed by the second mile, and the same fraction of what still remains will be absorbed by the third mile, and so on, the fraction of any particular kind of light which passes through any mile depending upon the coefficient of transparency of the atmosphere for that particular kind of light. Now let us apply this law to the case of our electric light of 100 and 1,000 candles when the density of fog is such that the coefficient of transparency is ·556 for every 100ft. of thickness. The table I show will give us the quantities of light which pass through the successive layers, each 100ft. in thickness, and we see that in each 400ft. the quantity is diminished to about one-tenth of what it was before. Hence, according to the law of absorption, if a light of 100 candle-power will penetrate fog to a distance of about 1,000ft., then it will require a light of 1,000 candle-power to penetrate to a distance of about 1,400ft. Since the electric light does not give a truly parallel beam, the real distance will be somewhat less than this. Let me quote another instance from the results obtained at the South Foreland with two lights of precisely the same kind to show the rate of increase of light necessary to penetrate a very small extra distance. On one particular evening of dense fog, two gas lights of 2,400 candles each, one above another, are lost at a distance of 1,000ft.; on exactly doubling the amount of light, the light of 9,600 candles in four stages, one above another, was lost at a distance of 1,090ft., the extra 4,800 candles so arranged had only increased the distance by 90ft., showing that for short distances the source of light should be concentrated as much as possible. Let us take another instance which illustrates the advantage of using large lenses with the electric light. The light from the electric light when placed behind the smaller lens was seen to a distance of 1,200ft.; the same electric light behind the larger lens, of about twelve times the power, was seen to a distance of 1,450ft. The light was seen an extra distance of 250ft. when placed behind the larger lens. On May 17, 1884, in a thick and homogeneous fog, the gas lights were seen at a distance of 1,300ft., the oil lights were seen to a distance of 1,500ft., and the electric light at a distance of 1,900ft. On these occasions when the thickest fogs were experienced, we see that it requires a tenfold increase of the light to increase the distance to which it is seen by 300 or 400ft. The very fact that the strongest lights hitherto obtained cannot throw their light farther than 2,000ft. shows us that it is useless for the few nights in the year when such fogs occur to rely on any source of light. For these very exceptional nights it will be necessary to rely on the use of fog horns or on some other mode of guarding the sailor from the rocks, for no lights can penetrate far enough to do him service. Let us look at the reports in just a few cases where the difference in power of two lights may be of great importance. Take the case where a light of 720 candles pierces a fog to a distance of two miles, whilst it requires a light of 16,500 candles to pierce to a distance of four miles. These facts show us that the coefficient of absorption per mile is about ·4, and that about 72 candles would be required if it is to be seen to the distance of one mile, and about 4,000 candles to penetrate to a distance of three miles. On Sept. 6, the revolving lights were exhibited from 10:45 to 11:45 in thick rain; on a lightship at a distance of 10½ miles the electric light became visible at 11 o'clock, but the gas and oil lights at full power were not seen until 11:35 p.m. On Nov. 23, a hazy night, fixed lights were exhibited from 9:40 to 10:15, but at Ramsgate the electric light only was visible. On Dec. 1, the lights were exhibited revolving on a dark and hazy night. At Ramsgate, 11½ miles off, the gas and oil lights were not visible after 8:30 p.m., whilst the electric light was very powerful until it was put out at 12 o'clock. At the Gull Lighthouse, eight miles off, all the lights were seen throughout the evening. On Nov. 26 there is another instance which shows that at a distance, as well as near at hand, the most powerful gas light yet used in lighthouses, in four stages one above another, does not penetrate farther than the single permanent light of the South Foreland Lighthouse as set up by Faraday fifteen years ago. The gas and the permanent electric light disappeared together at a distance of 12½ miles, but the experimental electric light was visible as far as the vessel steamed, *i.e.*, up to 14½ miles. Or take again, as a last instance, the observations of January 24 of the present year, when at the Varne lightship, 12 miles from the lighthouse, the electric light was seen throughout the evening, but no other light was seen. All these cases of fog and partial fog are included in those 10 nights in 100 of which I have spoken, and we see that probably in half of them the new electric light would be sufficient to prevent disaster to our shipping, leaving only 5 per cent. of nights of thick fog when no light can be sufficient. In order to study the effects of very dense fogs in eclipsing powerful lights, steam was allowed to issue from the steam pipes introduced into the photometric gallery 380ft. in length at the South Foreland Lighthouse. The steam was let out at various points, so as to fill the gallery with a dense and fairly homogenous mass of condensed steam, the supply being kept up from points farther away from the lights than the observer was. Such a mixture of air and condensed steam may fairly be taken to represent a dense sea fog or genuine Scotch mist. Let me give you the results of some of my experiments made in this gallery. At one end of this gallery were placed a 108-jet gas burner, giving an illumination of about 2,500 candles, and a De Meritens arc lamp giving a light of about 12,000 candles. These were alternately eclipsed by placing a screen in front of first one and then the other. Such was the density of the fog which could by this means be obtained, that in the gallery when daylight was shut out, at a distance of more than 100ft. I could see no light at all, not even the slightest illumination of the fog, and the eclipsing or exposing either light made not the slightest change whatever in the state of gloom. No light sufficient to affect the eye penetrated the fog to a distance of more than 100ft. From 90 to 100ft., when the electric light was exposed there was just the faintest possible illumination of the fog in the general direction of the source of light, but when the gas was exposed not the slightest illumination could be seen. On approaching nearer, the illumination from the electric light became brighter, but when that was eclipsed there was no illumination whatever from the 108-jet gas until a point of 65ft. from the source of light was reached. From 60ft. to 65ft. there was just a faint illumination of the fog from the gas light; at this distance the fog was well illuminated when the electric light was exposed, but the source of light, the electric arc itself, could not be seen. On approaching nearer, at 50ft., the glowing 40-millimetre carbons became visible, not as a single point of light but of the full breadth of the car-

Digitized by Google

bons. On approaching still nearer the gas flames themselves were not seen, until at a distance of 36ft. the whole breadth of the flame came into view at once, and the direction of the source became accurately defined. In another series of experiments, on going away from the flames, the gas flames were seen up to a distance of only 30ft., and the glowing carbons of the electric arc went out at 40ft. In these experiments with the fog in the photometric gallery my observations agree with those made by Mr. Dixon, and taking the value which he gives for the relative distances to which the electric light and gas were seen, I have deduced the coefficient of absorption per every 100ft., and shown by a table the law of diminution with the distance. It is not right to assume, as some have done, that the light coming through different distances of fog varies inversely as the square of the distance, for this law does not apply. An interesting experiment was made with the electric light of 12,000 candles and the Douglass standard of one candle-power in the steam fog. It was found that the glowing carbons, 40 mm. or 1⅝in. wide, was seen to a distance of 80ft., and the one candle standard, ¼in. wide, was seen to a distance of 40ft., and with the same coefficient of transparency the 108-jet gas would have been seen to a distance of 60ft. Again, the glowing carbons in another experiment were seen to a distance of 117ft., and the standard one candle to a distance of 55ft., and with the same coefficient of absorption the 108-jet gas was seen to a distance of 80ft., and a single gas jet was seen to a distance of 70ft., showing that the distance to which a light is seen in fog depends on the intrinsic brightness of the flame, and that an increase in the size adds very little to the pentrative power. The observations made as to the *character* of the illumination in these dense fogs are very important, and directly illustrate the subject of my lecture. When first the faintest illumination from the electric light became visible at from 90 to 100ft. the illumination was not red or yellow but white, like moonlight (those who speak of a yellow light as white would call it blue), and at any and all distances there could be no question whatever as to the source which was giving the light. Whenever the electric light was exposed the illumination of the fog was white, but whenever the gas was exposed the illumination was yellow or orange yellow. The illumination of the fog was of the same colour as the source of light, showing that with a mixture of air and vapour in the form of steam, forming a cloud without the admixture of other substances, rays of different colours were absorbed, and scattered very nearly in the same proportions. Here also Mr. Dixon's observations agree with mine, for he says, "Long before the actual lights were seen, the fog was brightly illuminated by the lights, the *blue* tint of the electric light greatly predominating." In this case those blue rays, which some say are so readily cut out, can still be seen. This shows that the proportion of the electric light which is scattered by such a fog is no greater than the proportion of any other source of light. During these experiments with steam, a pocket spectroscope clearly revealed the rain bands in the yellow, near the sodium lines, and other rain bands in the yellowish green and blue, showing that the true selective absorption of the molecules of water vapour is not specially confined to the blue end of the spectrum. We may to some extent illustrate the action of a mixture of air and vapour upon a beam of light by experiments with tubes, into which the mixture may be introduced. Taking a beam from the electric arc, and sending it through a tube containing air which has been cleared of particles of dust by being filtered through cotton wool, we get a clear beam through the room, and by a lens we may get a clear image of the opening, or of a slit upon a screen. On introducing vapour of water by passing air through water there is no condensation, and the image is still clear, but when particles of dust are by any means introduced into the tube, the vapour becomes condensed into water around the particles of dust, and the masses of molecules so collected scatter and reflect the light in all directions without producing colour. What, then, may we gather from these experiments at the South Foreland as to the relative intensities of the electric light in lighthouses as compared with other lighthouse lights? The experiments have shown that, using the large Mew Island lens with the Wigham gas-light of 2,400 candles, and the smaller lens with the electric light of five times the power, or 12,000 candles, the electric light in clear weather was at least sixteen times as bright, and in foggy weather was about thirteen times as bright as the gaslight, the excess of absorption for the electric light being about 20 per cent. more in foggy than in clear weather. The experiments have also shown that the electric light is at least of twelve times the intensity with the large Mew Island lens as with the smaller lens; hence the illumination which would be given to the mariner from the electric light by using the same lens as for gas is from 150 to 250 times as great as is given by the gas. If we take lights of the two kinds of equal intensity, the electric light in thick weather will give the mariner thirty times the light and in clear weather about forty times the light which is given by the gas. By employing two De Meritens machines, giving a light of about 18,000 candles, the electric light in foggy weather will give the mariner more than 60 times the light which he has hitherto obtained from four Wigham gas burners of the largest type placed one above another. If we compare electricity with a single new Douglass 10-ring gas burner, the strongest light other than electric which has been tried for lighthouse work, and which has been seen at the Gull light vessel eight miles off when oil and 108-jet gas burners were obscured by fog, we find that the electric light in fog sends out a beam which is from 100 to 150 times as bright. As regards the question of the relative absorbing power of the atmosphere in different kinds of weather for the different lighthouse lights, the principles which I have attempted to explain as to the greater absorption of the atmosphere of blue rays than of red, and the fact that the electric light, while abounding in all, is especially rich in blue rays, would lead us to expect that the illumination from the electric light will be weakened somewhat more than gas or oil in foggy weather. Although this does not appear in the case of the steam fogs, yet the other measurements made at the South Foreland show a somewhat greater weakening of the electric beam.

COMPANIES' MEETINGS.

The Electric "Sun" Lamp and Power Co. (Limited).

The third ordinary general meeting of this Company was held at the Cannon-street Hotel on the 22nd inst. Mr. William Perkins presided.

The SECRETARY (Mr. F. R. Boardman) read the notice convening the meeting. In their report the Directors stated, *inter alia*:—"We are reluctantly compelled to come to the conclusion that until the Board of Trade adopt the modifications and changes in the Electric Lighting Act suggested by the Electric Lighting Act Committee in their report of March last, we cannot hope to succeed. We have found that the general public are unwilling to incur the heavy expense of separate private installations, however good the systems may be; and the restrictions of the present Act effectually bar the employment of capital for the installation of works for a general supply of electricity; and it is quite certain that had gas when first introduced been hampered with the same restrictions which have been imposed upon electric lighting, it never could have survived them or have attained its present great success. In fact our field for work is reduced to such a small compass that we regret to say we cannot see our way to make the undertaking sufficiently profitable to continue it."

The CHAIRMAN said: We have entered fully in our report upon the working of the Company in the past 18 months. We were appointed with the view of seeing whether we could bring this thing out of its despondent state at that time. Some of the Directors were anxious to wind up the Company at the last ordinary meeting, and others were anxious to go on. It was thought that if we had a fresh trial we could possibly make a success of the Company. At any rate, the trial was thought worth while making. As soon as we assumed office we went to work to curtail the working expenses of the Company. We gave up the offices at Westminster and removed to Ridinghouse-street, where the Company had premises; and altogether we reduced our working expenses to the extent of some £1,500 a year. We then appointed agents in every principal town of England, Scotland, and Ireland, with the view of seeing whether the Sun lamp could be introduced to the public. We improved upon the lamp and employed the inventor of the lamp himself, M. Clerc, who had some fault to find with the construction of the lamp as it then came under our notice. He made various improvements in it, and has so far succeeded that at the present moment we as Directors look on it as of very much more value than when we took it over. He has succeeded in making the lamp workable in parallel as well as in series—that is, that the dynamo in use for working other lamps can be used for working the Sun lamp. That is an enormous advantage over its original state. When we had appointed our agents in the country we also appointed a traveller and a manager. The latter had had very considerable experience in establishing at the outset the telephone work, and we thought he would be a valuable acquisition. We had very high testimonials and recommendations of him as to his energy; and he devoted quite a year to pushing the lamp, and endeavouring to introduce it among private individuals, and at picture galleries, theatres, music halls, and elsewhere. The traveller, whom we appointed on salary and commission, canvassed the country generally. We issued circulars to the public. We contracted to light a portion of the Health Exhibition, and now of the Inventions Exhibition, and since the last meeting we have taken two gold medals and one silver medal for the lamp. When, however, it came to a question of the public really adopting this or any other form of lamp we were met by this difficulty—that the late Government had placed such restrictions on the manufacture and supply of the electric current that we, like the other companies, found it would be madness to invest our capital, large or small, in establishing a central station for the supply of electricity. The whole of such capital as we had would have been absorbed in putting up one installation alone from the central station, and the Government, or the local authorities, would have had the right at the end of 15 years to take that from us at its then value. We considered that it would have taken nearly 10 or 15 years to have established the value. However, our money would have been sunk, and the value of our plant, after 15 years' wear and tear, would have been very small indeed, as compared with the cost to us. Therefore it would have been, and would be, madness to establish a central station, and it is a known fact that not one of the electric light companies have cared to or will incur the expenditure of a central station for supplying the current of electricity till the Government have modified the Electric Lighting Act, and placed electric light companies who go in for the production of the electric current for lighting purposes on an equal footing with gas companies. Many of the companies that were formed were formed simply for the purpose of supplying a special lamp. We were formed partly for that purpose, but at the same time for the purpose also of supplying the current necessary for the working that lamp. My own opinion is that the future of electric light companies will be that the producing company—that is, the company supplying the current—will be independent from the company that supplies the lamp, and that the companies which supply the electric current necessary for working the lamp will be in the same position as gas companies, the owners of special forms of lamps being in the position of chandelier makers, and makers of gas burners and fittings. The supply of electricity must be—and will be, I think—entirely independent of any special form of lamp. We have a special form of dynamo, which is well adapted for the production of the electric current for general supply, and doubtless when the Government give the necessary facilities for its production and distribution, the dynamo we have will be adopted by such producing companies, if not by ourselves. That our lamp has proved to be a practical success is demonstrated by its adoption at the Grosvenor Gallery, and by the high praise it has received at both the Health and the Inventions Exhibitions, and from every one, in

Digitized by Google

fact, who has seen it, no matter where. We have installations at the present time at the Grosvenor Gallery, at the Inventions Exhibition, at the *Manchester Guardian* office, and at two or three other places, but they are altogether insufficient to warrant us in continuing the working of the Company. Finding that we could not dispose of large installations, we turned our attention to canvassing London districts to see if we could get private individuals to adopt any system of electric light; but their reply was, "If you will supply the current we have seen sufficient of your lamp to induce us to adopt it; but we ourselves are not going to be producers of the necessary current of electricity to work the lamp. If we were to put a dynamo and engines on our premises, no matter where, if in a populous neighbourhood, we might be indicted." Therefore, they say, till you can take your manufactory away from a populous district, where there is no difficulty, and produce it as gas is produced, we decline to adopt it. Otherwise, even though it cost us double our present gas bill, we would adopt it, but we will not become producers ourselves. The Directors, therefore, have nothing but to admit that at present we do not see our way to carry on the business of the Company successfully. In fact, the proof of the last eighteen months is that it has cost £2,750 beyond what we have taken into stock. Our loss during the time we have been in office has been £4,147. That is over a period of eighteen months, and we have worked as economically as possible. We think the fairest and most candid manner to deal with the Company's assets at the present time is this—We have practically in hand and owing to us some £6,000 at the present moment, and at the present rate of expenditure we could go on for another year or two. It would, however, be useless to spend that money, and we have come to the conclusion that it would be more advisable to distribute the cash assets at once among the shareholders, retaining the patent till the Government see fit to remove the restrictions they have imposed on electric lighting. We also propose to retain the plant. We have plant sufficient for several installations, and we propose that an immediate division of the cash assets of the Company should take place, and that the realisation of the stock of lamps, dynamos, and engines, and the other apparatus necessary for the installation of electric lighting, shall be disposed of as the demand arises. In that way we shall not have to put up with the sacrifice which we should otherwise have to bear. If we went to a forced sale now, we should get a "mere song" for the plant we have, whereas, if you wait, I think the time is not far off when the Government will see the absolute necessity for granting facilities for electric lighting. We have in addition to that stock, as I have said, our patent, which may be sold to a company that may be formed to acquire it, or to any of the existing companies who require the form of lamp we have, or the liquidators may see fit to grant licences to the manufacturers of electric lighting installations and apparatus, with a view to their making and supplying these lamps, or this special form of lamp, to the public. We have done our best in trying to make a success of the Company, but we have failed—failed simply from no fault of our own. We have done, I believe, our best. The Government have not seen fit to give us any facilities to make a success of the electric lighting enterprise; the public will not become producers of the current necessary to light our lamps or any other lamp, and, therefore, we have reluctantly come to the decision to advise you to take the course suggested in the report, namely, to divide the cash assets, and to realise the plant and patent as opportunity arises. I now beg to move that the report and accounts be adopted.

Mr. M. I. F. BRICKDALE seconded the motion.

Mr. DUCHAMP said he thought that the course proposed by the Directors should be followed, but he thought that Mr. Henry de Grelle should be added to the liquidators.

The CHAIRMAN pointed out that the suggestion mentioned might be dealt with at the extraordinary meeting. He then put the motion, which was carried unanimously.

The SECRETARY next read the notice covening the extraordinary meeting, at which, it was stated, the following resolution would be submitted:—"That the Company be wound up voluntarily under the provisions of the Companies Acts, 1862 to 1883, and that William Perkins, of York Villa, Princes-terrace, Bayswater, Esquire, and Matthew Inglett Fortescue Brickdale, of 8, New-square, Lincoln's Inn, Barrister-at-law, be and they are hereby appointed liquidators for the purposes of such winding up."

The CHAIRMAN having proposed, and Mr. BRICKDALE having seconded the above resolution, it was agreed to unanimously.

Mr. DUCHAMP then proposed that Mr. De Grelle should be appointed one of the liquidators, a large number of the shares being held, he stated, by Belgian gentlemen.

M. CLERC seconded the motion.

The CHAIRMAN stated that the Directors had no objection to the proposal, and in reply to a question, he added that Mr. De Grelle was one of the Directors. The motion was carried unanimously.

A SHAREHOLDER inquired whether any decision had been come to as regarded the remuneration of the liquidators.

The CHAIRMAN replied that the solicitor had informed him that there was no regular scale for such services, and had suggested that it was a matter which would come before the shareholders at a future meeting. They were all in the same boat. Mr. Brickdale, who was the largest shareholder of the Company—holding £5,000 in the shares—was certainly likely to look after his own interests, and in doing so he would be looking after those of the other shareholders.

On the motion of Mr. THACKER, seconded by Mr. SIMPSON, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN acknowledged the compliment, and in reply to a question, said that the moment anything arose with regard to the disposal of the patent, the shareholders would certainly be called together. There would be another meeting to confirm the resolution which had been passed that day for the winding-up of the Company.

The proceedings then terminated.

COMPANIES IN LIQUIDATION.

We extract the following notices from the *London Gazette*:—

The Pyramid Electric Light Company (Limited).—Notice is given that a general meeting of this company will be held at the offices of Messrs. W. H. and F. S. Collins, St. Mary-street, Ross, Herefordshire, on the 16th day of October, 1885, at 12 o'clock at noon precisely, for the purpose of having the liquidators' accounts, showing the manner in which the winding up has been conducted, and the property of the company disposed of, laid before such meeting, and of hearing any explanation that may be given by the liquidators.—Dated the 11th day of September, 1885.—(Signed) F. W. T. Brain, liquidator.

Electric News Telegraph Company (Limited).—Notice is hereby given that a general meeting of this company will be held at 4, Ludgate-circus, E.C., on the 24th day of October, 1885, at two o'clock in the afternoon precisely, for the purpose of having the liquidators' accounts, showing the manner in which the winding up has been conducted, and the property of the company disposed of, laid before such meeting, and of hearing any explanation that may be given by the liquidator.—Dated the 12th day of September, 1885.—(Signed) Wm. J. Burnside and B. P. Daniels, liquidators.

Provincial Brush Electric Light and Power Company (Limited).—The creditors of this company are required, on or before the 3rd day of October, 1885, to send their names and addresses, and the particulars of their debts or claims, to William Henry Pannell, the liquidator of the said company, at the registered office of the said company, 38, Basinghall-street, in the City of London, or in default thereof they will be excluded from the benefit of any distribution of the assets of the said company made before notice of such debts or claims have been received by the said liquidator.—Dated the 15th day of September, 1885.—(Signed) Wm. H. Pannell, liquidator.

NOTES.

THE TANNERGRAM!—It is suggested that the new sixpenny telegram shall be called "Tannergram."

ATLANTIC CABLE COMPETITION.—It is expected that a rate-cutting contest is about to begin among the Atlantic cable companies.

CHEAP TELEGRAMS.—An article on cheap telegrams appears in this month's *Fortnightly Review* from the pen of Mr. Charles Cameron, M.P.

GERMAN ASSOCIATION.—The fifty-eighth meeting of the German Association of Naturalists and Physicists was held at Strassburg, Sept. 17—23.

THE ELECTRIC LIGHT IN TEXAS.—It is stated that the Edison Company is contracting to light the City of Dallas, Texas, with incandescents.

CHEAP TELEGRAMS AND THE PRESS.—The Postmaster-General notifies that no alteration is to be made in the mode of counting Press messages under the new tariff.

THE ANTWERP EXHIBITION.—Rumours are afloat as to the probable time of the closing of this Exhibition. In any case it will remain open, we are informed, until the 12th prox.

THE TASMANIAN DUPLICATE CABLE.—Advices from Tasmania state that the steamer "Sherard Osborn" was to leave Singapore immediately with the new duplicate cable for Tasmania.

THE CROYDON ACCIDENT.—On the occasion of the late accident on the South Eastern Railway at Croydon several telegraph poles were knocked down and the wires disconnected.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ended 11th, 18th, and 25th Sept. amounted to £2,388, £2,758, and £2,986 respectively.

FREEMASONRY.—On Saturday last the Electric Lodge held their last meeting of the year. Messrs. H. Crookes and J. E. Spagnoletti were raised, and Mr. W. H. Preece was elected Master for the ensuing year.

THE RIVER PLATE TELEPHONE AND ELECTRIC LIGHT COMPANY.—This company notify that coupons due on the 1st of October next will be paid, less income tax, on and after that date at the Alliance Bank, Bartholomew-lane, E.C.

THE CANADIAN NORTH-WEST.—The new railway will afford communication between the cattle ranches on the slopes of the Rocky Mountains and Manitoba and the East. A telegraph line has also been constructed in connection with it.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ended 18th and 25th Sept. were £1,780 and £1,201 respectively, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE TELEGRAPH REVENUE.—The Revenue returns for the past quarter show that the telegraph revenue has increased by £5,000 as compared with the corresponding three months last year, and has increased £20,000 for the year ending 30th September compared with the year ending September, 1884.

SARCASM.—At a recent meeting of the Bingley Improvement Commissioners, one of the members observed that he believed the Telephone Company had more regard to private property than the Board. If this be so, private property in Bingley, between Board and Telephone, must have a bad time of it.

THE ELECTRIC LIGHT AT LIVERPOOL.—At a recent meeting of the Mersey Docks Board it was resolved to accept the tender of Messrs. R. E. Crompton and Co. to supply the apparatus and lantern required in connection with the proposed adoption of the electric light upon the new lightship now being built for the Bar station.

A NEW CABLE FOR WESTERN AUSTRALIA.—The telegraph cable for connecting Breaksea Island with King George's Sound has been successfully laid. It was expected that the work of signalling vessels passing Breaksea Island, and reporting the fact by means of the cable would be inaugurated in the course of a short time.

A NEW ARC LAMP.—An arc lamp, constructed for the purpose of projecting a single ray of intense brightness, was recently described by the *Elektrotechnische Zeitschrift*. This is the invention or rather design of Mr. R. Ruhlmann. Those interested in search lights might do worse than look at this new model of the arc lamp.

THE BESSBROOK AND NEWRY TRAMWAY.—The official report of the Board of Trade inspectors who inspected the Bessbrook and Newry Electrical Tramway last week, has been received. The inspectors speak in high terms of the line, which was to be opened for traffic yesterday. It is the second electrical tramway constructed in Ireland.

THE EARTHQUAKES.—It is stated by the Russian *Official Messenger* that repeated shocks of earthquake have been experienced all through the summer in the town of Namangan, in Ferghana. The most violent of the shocks occurred in the months of April (the 17th) and August (4th), but were not attended with any very serious consequences.

THE FRENCH TELEGRAPHS.—By the decree of the Minister of Posts and Telegraphs, dated the 7th ultimo, the opening of telegraph offices is authorised in the following communes:—Cognac-Lyonne (Allier), Praixan (Aude), Parsenans (Jura), Saint-Germain l'Espinasse (Loire), La Recousse-Zouafques (Pas-de-Calais), and Argenton-l'Eglise (Deux-Sèvres).

ELECTRIC TRAMWAYS ON THE CONTINENT.—In the collieries of La Peronnière, near Rive-de-Gier, Thibault, near Saint-Etienne, and Saint-Claude, near Blanzy, in France, electric tramways are in full and satisfactory operation. Tramways on the same principle have also been laid down in German collieries, and Belgium is soon to possess a similar line.

THE TELEGRAPH IN EASTERN ROUMELIA.—The postal and telegraphic tariff in Eastern Roumelia has been assimilated to that in Northern Bulgaria, and the authorities have apprised the International Bureau at Berne of the fact. Telegrams to both of these countries, however, are at present subject to considerable delay, owing to the disturbance in political affairs.

TESTIMONIAL.—The following testimonial, dated the 16th February, 1885, has been received by the Kinetic Engineering Company from the Imperial Austrian Ministry of Commerce:—"The last tests made by the Department of Posts and Telegraphs at Insbrück have proved that the cables which you have furnished for the Arlberg Tunnels remain, both as regards conductivity and insulation, in a condition completely satisfactory."

ELECTRIC LIGHTING AT EXETER.—At a recent meeting of the Town Council the tender of the Consolidated Electric Company for the installation of the electric light at the new asylum at Digby's was accepted, and the Town Clerk was instructed to communicate with several electrical engineers unconnected with any company, and ascertain the terms upon

Digitized by Google

which they each would act as consulting engineer to the Corporation.

TELEGRAPH WORK ON THE CONTINENT.—During the interview between the Emperors of Russia and Austria, at Kremsier, the local telegraph office forwarded, on the 29th of August, 295 messages, representing 27,700 words ; on the day following 338 messages (33,400 words) were sent, and on the 26th 390 messages (26,700 words), making a total of 1,023 messages and 87,800 words for the three days. These were all sent on a single Hughes type writer.

BOTTOMLESS AMBITIONS.—Amongst the more remarkable of the attempts of recent years to set the Thames on fire the following should be remembered and credited to the year 1885 :—The "French International light tower, Paris all there and the rest nowhere." "Oceanic Telegraphy with a vengeance ; cable stations every two miles across the Atlantic." "A Federation of Nations to purchase the Submarine Cables ;" and "Unlimited Telephony, or round the world by telephone for two pence."

THE PULUJ INCANDESCENT LAMP.—The filament in the Puluj incandescent lamps, now manufactured at Steyr, in Austria, is apparently of Manila fibre, and is arranged in the somewhat curious form of a hand having three fingers. This carbonised filament is said to present a remarkably uniform surface and to be of great strength. The average resistance of the lamp is about 214 ohms (cold presumably), giving, with a difference of potential of 20 volts at the terminals, 20 candle-power. Their life is fixed at 1,000 hours.

REWARD FOR GALLANT CONDUCT.—On Wednesday morning the Mayor of Dover presented a young man named M'Cudden, a telegraph clerk, with the bronze medal and certificate of the Royal Humane Society. M'Cudden was engaged at the Dover Telegraph Office recently, when he saw a private of the Royal Irish Regiment fall into the harbour. One of the soldier's comrades jumped in after him, and M'Cudden ran from the office and plunged into the harbour after them, rescuing both men, neither of whom could swim.

THE TELEPHONE IN SWITZERLAND.—Direct telephonic communication will before very long be established between Berne, Thun, and Solothum. The Telephone Exchange at the Lake of Geneva has already a list of 1,272 subscribers. Zurich alone has some 1,350 instruments connected to two central stations. There are in the town 1,100 subscribers, the remainder being distributed through nine suburban villages, the latter also, of course, being in direct communication with the central stations. In comparison with Bâle, Zurich possesses twice the number of subscribers.

THE BLACKPOOL ELECTRICAL TRAMWAY.—On Tuesday last the inauguration of the Blackpool electrical tramway—the first street tramway of the kind in England—was celebrated. The Mayor of Manchester guided an electrically propelled car for a considerable distance over the line, which is some two miles in length, amid considerable applause. The inaugural ceremony was followed by a banquet, at which Colonel Stanley, M.P., Mr. Tomlinson, M.P., the Lord Mayor and Lady Mayoress of York, and some forty Mayors and Mayoresses of Lancashire, Cheshire, and Yorkshire were present.

THE TELEPHONE IN RUSSIA.—It is somewhat a matter of surprise that the telephone contrives, commercially speaking, to live in Russia, let alone to flourish. The rules and regulations which govern the formation of telephone companies in that country are, to say the least of them, rigorous, in that the Treasury lays claim to 10 per cent. of the private subscriptions and 5 per cent. of those of municipal and Government corporations. The revenue derived from this source amounted in 1883 to some 22,000 roubles, and that for 1885 is confidently expected to realise no less than 40,000 roubles, or about £6,500.

TELEGRAPHIC COMMUNICATION WITH SOUTH AFRICA.—The following letter has been written to *The Times* by Mr. W. J. Tyler, the secretary of the India Rubber, Gutta Percha, and Telegraph Works Company :—"With reference to the letter in *The Times* from 'X,' in which letter we are referred to as the Silvertown Company, we beg to say that we have completely manufactured and are now shipping cables to be laid from the Cape Verd Islands to the West Coast of Africa, in accordance with concessions from the Governments of Portugal and France, and these cables can easily be connected with the possessions of other Governments in West Africa if so desired."

PERSONAL.—We are informed that Mr. Townsend, lately district manager in Inverness for the National Telephone Company, has been appointed district manager of the newly-formed Scottish South Central District. The district embraces the counties of Fife, Kinross, Clackmannan, and Stirling, with head-quarters at Kirkcaldy, and from the extent of the circuit must in its management of necessity prove much more responsible than the position which Mr. Townsend has resigned. Mr. R. C. Bennett, who has been assistant at Inverness since the opening of the Exchange, and who thoroughly understands the work, will take charge in Inverness, and under his management the Exchange will no doubt be carried on as successfully as hitherto.

NOTICE OF REMOVAL.—The following companies have removed from 66, Old Broad-street, E.C., to Winchester House, 50, Old Broad-street, London, E.C. :—The Eastern, the Eastern and South African, the Eastern Extension Australasia and China, the Submarine Cable Trust, the Globe Telegraph and Trust Company, the London Platino-Brazilian Telegraph Company, the Black Sea Telegraph Company, the German Union Telegraph and Trust Company, and the German Union Telegraph Company of Berlin. The London telegraph stations of the Eastern and the Eastern and South African Companies remain unaltered, viz. :—No. 11, Old Broad-street ; No. 3, Great Tower-street ; No. 8, Leadenhall-street ; No. 41, Parliament-street, S.W.

A PHENOMENON IN ARC LAMPS.—Mr. Levett, in the *Electrical World*, describes a curious phenomenon which was noticed upon the negative carbon of an ordinary arc lamp being replaced by a piece of copper filed to a blunt point. Instead of fusing, there was merely a slight melting of the point on first starting, after which no further melting of the copper took place. There seemed to be a deposition of carbon particles carried from the positive electrode of carbon to the negative electrode of copper which tended to shield the copper. Mr. Levett had a piece of copper taking the place of carbon for three weeks without perceptible diminution in weight. His experiments were conducted on a circuit of 20 amperes, and length of arc of $\frac{1}{32}$in.

DIVIDENDS.—The directors of the Eastern Extension, Australasia, and China Telegraph Company announce an interim dividend of 2s. 6d. per share for the quarter ended 30th June last together with a bonus of 2s. per share, both free of income-tax, payable on 15th inst.—The directors of the Globe Telegraph and Trust Company, at the board meeting held on the 29th September, declared the payment of an interim dividend on and after the 23rd inst. of 3s. per share on the preference shares, less income tax, and of 1s. 6d. per share on the ordinary shares (income tax having already been

Digitized by Google

deducted) for the quarter ending the 18th October. The transfer books were ordered to be closed from 15th October to 23rd October, both days inclusive.

THE MEXICAN TELEGRAPHS.—The Government telegraphs in Mexico do not seem to be in a very flourishing condition, if the following figures may be taken as a criterion. The estimates for this year are :—

	Fr. ct.
Salaries	3,066,709.50
Maintenance	2,100,000.00
Construction of new lines	750,000.00
Total	5,916,709.50

The last annual report gave the receipts as :—

Ordinary messages	1,115,854.65
Official messages	3,084,829.20
Total	4,200,683.85

The mileage is about 21,000 kilometres (13·02 miles).

KISSING GOES BY FAVOUR!—This is a remark that was perhaps never more *apropos* than of certain events which took place in connection with the late meeting of the British Association at Aberdeen. Tickets for anything special were not to be had by the smaller fry of electricians and journalists for love or money. Several of the latter, in the interests of the papers they represented, became associates for the mere purpose of accompanying the members on certain of their perambulatory visits. These gentlemen, however, were frowned upon ; and those who here in London have approached Royalty in the ordinary course of their business were rigorously forbidden even to mention the name of Her Gracious Majesty in the hearing of autocratic Aberdeen. Hoot, mon !

SOUTH AUSTRALIAN TELEGRAPHS.—Mr. Charles Todd, Postmaster-General of South Australia, has written as follows to *The Times* Berlin correspondent :—"I have read your telegram in *The Times* with much interest ; but I trust you will allow me to call your kind attention to two omissions, no doubt caused by want of full information, viz., that with a view to a reduced through rate of 8s. 8d. on private messages South Australia will reduce her rate for transmission over the land line between Port Darwin and Adelaide from 1s. 3d. to 1s. 1d. per word ; and to effect a reduction on Press messages to 2s. 8d. per word she will reduce her rate from 1s. 3d. to 4d. per word. In connection with these reductions I should mention that South Australia has expended £500,000 in the first erection and subsequent re-poling with iron poles of the line across Australia, and that she sustains an annual loss of about £25,000, including interest on outlay."

CONTINENTAL NOTES.—The electric light in the Theatre de l'Eldorado at Paris continues to give great satisfaction. It will be remembered that the installation was put down by M. Cance.—The exhibitors at the Palais de l'Industrie are said to be preparing a petition with the object of obtaining the electric light in the Exhibition during the evening.—Great success has attended the experimental lighting of the Palais Royal, Paris. At present the number of incandescent lamps in the installation is 150. The Theâtre Français, Theâtre du Palais Royal, and the Council of State have, however, now approved of the deed of agreement signed by the tradespeople, so that a large number of lamps may reasonably expected to be in operation at an early date. Extensive experiments are now being carried out with the object of determining the best lamp to be used.—It is announced that the new branch of the Thomson-Houston Company will commence operations in Liège next month.—At the request of M. Déroulède a telegraph office has been opened in the Camp de Vincennes.

THE MEDITERRANEAN SQUADRON.—A correspondent, writing from Malta, under date Sept. 21, says: "H.M.S. ship 'Alexandra,' with Admiral Lord John Hay on board, accompanied by the 'Superb,' 'Dreadnought,' and three first-class torpedo boats, left the harbour on Tuesday last for a cruise. A night attack was made on the 'Alexandra' when anchored in the Comino Channel by the other ships and the torpedo boats, three second-class ones belonging to the 'Superb' and 'Dreadnought' being also hoisted out for the occasion. The attacking vessels left St. Paul's Bay at seven o'clock in the evening, and with the boats in company steamed slowly round to where the 'Alexandra' was supposed to be. At nine o'clock all lights on board the ships and boats were extinguished, and they were cleared for action. A rocket from the 'Superb,' about half an hour later, was the signal that the flagship was discovered, and the engagement soon became general, lasting half an hour. One torpedo boat came to grief during the attack, as, blinded by the electric search-lights of the vessels, she was run ashore with the loss of her propeller and damage to her plates. She was towed into harbour next morning by the 'Superb.'"

A MODIFICATION IN THE BRUSH ARC LAMP.—Amongst the distinguishing features which separate the dynamos and lamps of the Brush system from those of its many competitors, one of the most striking is the constancy of type which marks them. During the seven years of their existence both dynamos and lamps have naturally been modified and improved in various ways. The improvements effected have been those of detail, gradually introduced, and in every case the modification entailed has been one that has been easily and cheaply grafted on to the original pattern. Amongst these may be instanced the new laminated armature, which, although it increased the output of the Brush machine by 50 per cent., yet did not entail any alteration in or even removal of the machine frame, and enabled the earlier solid form, whose place it took, to be kept as a reserve in cases of emergency. So with the Brush lamp, which is one of the few lamps which can be relied on to work continuously without getting out of order. The object has been always to avoid any kind of addition to the working parts, its hardiness and endurance far outweighing, in the opinion of some practical men, any slight inconvenience from occasional flickering. Recent experiments in another direction have, however, shown that without any such addition to the working parts, but simply by a modification in the winding, the slight unsteadiness referred to may be effectually removed.

"ELECTRIC LIGHTING AND THE LAW."—This was the title of a paper read before Section G at the British Association meeting. The paper was merely a diatribe against the Electric Lighting Act, and contained no new argument or any old arguments in a new light. It was useful, however, in that it recalled attention to a subject which is not yet settled. The value of any changes made in the Act and what the effect will be upon the electric light industry are questions for the future, while it may even now be disputed whether progress is as slow as is supposed. The field is not vacant—it is already occupied ; and the capital expended upon existing illuminants will not be shunted because a new and better illuminant is in the market. Railways did not replace coaches in a year, nor should it have been expected that the introduction of the electric light would differ materially from the introduction of other improvements. We have never looked upon the Act as altogether useless—rather in the shape of a violent medicine, which had the effect of bringing many men to their senses. The existing caution of investors is not favourable to specu-

Digitized by Google

lators and swindlers, but it leads to a closer examination of evidence; it will lead to a calmer spirit of investment rather than the feverish spirit of speculation. The time was not ripe for combined street and house lighting in 1882, nor we fancy is it now upon a very large scale. Better to walk first and run afterwards than to begin by galloping.

AN ELECTRO-MECHANICAL CLOCK.—An electro-mechanical clock is being exhibited by Mr. B. Watkins, of Leadenhall Buildings. It is apparently of an ingenious and simple mechanism, winding itself automatically, and maintaining a continuous action from year to year. It is said to require a small spring but little larger than the main-spring of a watch, which is kept at a uniform tension, and acts directly on the hour-wheel. This spring is wound in six seconds, and offers no interruption to the time while winding. It is kept only at a tension sufficient to run the clock one hour. It is then wound again by means of a small rotary electric motor, which is connected with the mechanism. An ordinary battery is concealed in the frame or case of the clock, and has, it is claimed, sufficient power to wind the clock two years without attention. The hour wheel, each hour of its revolution, switches the electric current through the motor, which rapidly revolves for six seconds, and communicates its rotary motion, by a gear-wheel, to the barrel on the centre arbour containing the spring. This barrel (in one revolution) imparts sufficient tension to the spring to run the clock one hour, stops the motor by breaking the electric current, and the battery rests for an hour, or until it is necessary to wind the clock again. This process is automatic and continuous from year to year, and the battery is used six seconds each hour, or less than fifteen hours in a year. The inventor is Mr. C. H. Pond, of New York.

THE COST OF OVERHEAD WIRES.—Mr. David Brooks, in a letter to one of the American papers, makes the following calculation with regard to the cost of overhead wires in Philadelphia:—"On September 22nd, 1884, the total number of miles of overhead wire, as reported to the city authorities, was something short of 4,000 miles, and this embraced the whole city. This sum is that reported by the different companies and the owners of private lines. It is presumed that it falls short of the actual amount, inasmuch as these reports were made up for the purpose of taxation, of which they got clear. But say there are 4,000 miles within the thickly built-up portions of the city, and that 80 dols. per mile would be required for putting them under ground, the cost would be 320,000 dols., and the interest on this sum at 6 per cent is 19,200 dols. Dr. Jacques states that not a repairman is employed by the Paris Telephone Company. There are at least one hundred employed in this city. Say that there are fifty for the thickly built-up portions before mentioned at 2·50 dols. per day, this is one hundred and twenty-five dollars per day, and counting three hundred working days in the year, there are 37,500 dols. for wages alone, not counting the expense of poles, wires, house-top fixtures, insulators, &c., and this sum for repairmen is the interest upon 625,000 dols. at 6 per cent. These figures and suggestions are made for the benefit of the overhead wire people, and I ask them if Mr. Preece has not reason to say: 'Why you have neglected this matter so long I cannot make out.'"

THE DESIRE TO BELIEVE.—An author—now, alas, too much neglected—wrote of criticism in this strain: "Grant me patience, just Heaven! Of all the cants which are canted in this canting world, though the cant of hypocrites may be the worst, the cant of criticism is the most tormenting." Sterne was not a reader of the papers devoted to the gas interests, or he would probably have written differently. From the birth of the electric lighting era till now the *Journal of Gas Lighting* has consistently and persistently traduced statements made about electrical progress. Such a policy serves no interest, but on the contrary, creates a feeling of unrest in the minds of gas shareholders that, while ostensibly ridiculing the progress of electricity, there exists in the minds of these writers a real undercurrent of fear that there is danger ahead. Our contemporary will do well to study facts, and ascertain whether gas in the first four years of its history made the real progress that electricity has done during the last four years. Is it, as the journal says, "romance" that electric lighting is making great and successful strides? We are of opinion that there is little of the romantic in the matter, and that such a statement is a plain unvarnished truth. It may justly be argued, however, that electric lighting has not yet had four years of life. Its capabilities were shown at Paris in 1881, and afterwards at the Crystal Palace, and it was not till the close of that Exhibition that any real work in electric lighting commenced. All prior work had been more or less tentative, and principally of the nature of an advertisement. Much, indeed, of the later work has been of the same character, but any statement that electric lighting is not making great strides is false.

THE AMERICAN ASSOCIATION.—It is quite evident that peripatetic science does not flourish in America as it does in England, for while the B.A. meeting had a plethora of papers, its American *confrère* had too few. So far as reports have reached us the electrical papers were not important. Our American contemporary, *Science*, says Prof. H. S. Carhart presented a paper "On Surface Transmission of Electrical Discharges," which was an ingenious revision of work by Prof. Henry. Prof. E. L. Nichols presented some further notes "On the Chemical Behaviour of Magnetic Iron," a continuation of work described at the Philadelphia meeting. Prof. Mendenhall called attention to the modifications and improvements already made or desired in electrometers, especially with reference to their use in observations on atmospheric electricity. Observations of this kind have been regularly made for the last year or two, but the meaning of the variations recorded is still a mystery. Prof. Dolbear read three papers. In one he described a method of studying the contact theory of electricity by means of the telephone. He has found that a click is produced in the telephone every time the circuit is broken between two heterogeneous materials, as copper and zinc. In a second paper he referred to the success obtained in using a Bernstein incandescent lamp for projection purposes; and in the third he described a new battery of high E.M.F. and great constancy, consisting of carbon in a saturated solution of bichromate of potash and sulphuric acid, and zinc in a saturated solution of ammonia chloride; nitric acid can be used instead of sulphuric. Mr. A. T. Rogers read a paper "On the Electrolysis of the Salts of the Alkaline Earths." Two papers by Dr. J. W. Moore were devoted to an "Explanation of Apparatus for Class Room Demonstration of Electrodynamic Phenomena."

THE TELPHERAGE SYSTEM.—A telpher line is to be opened at Glynde on the 10th inst. In view of this fact it may be interesting to glance at the general objects of the telpherage system and the advantages claimed for it by its promoters. The object of the invention, as is now well known, is to convey goods easily divisible into parcels of from 2cwt. to 5cwt., at a speed of about five miles per hour, and at a cost greatly less than that of cartage. It will probably find its application in all cases where the traffic is sufficient to pay interest on a small

Digitized by Google

outlay, and is insufficient to pay for the construction of even the cheapest form of railway. The road and trucks closely resemble the road and trucks already employed for overhead wire rope tramways; but instead of dragging the trains along by means of a wire rope, they are driven by very simple electrical arrangements. By employing electricity the following advantages are gained:—The road is simpler and cheaper, as there are no pulleys or working parts, and no second rope is required; the maintenance is cheaper; there is nothing to oil, and no working parts to wear out; the direction of the electrical road can be changed as often as is desirable, so as to follow a winding direction, an object difficult of attainment even to a moderate extent with rope haulage; the gradients in the electrical road may be as heavy as one in eight, and these gradients may vary as frequently as is desired, which is not possible, except with complicated arrangements, in rope haulage; finally, the power required will be less, except in the simplest cases of rope haulage. As compared with light steam railways, the telpher lines may be said to possess the following advantages:—They are cheaper, requiring less metal than the lightest rails. No earthworks, bridges, culverts, drains, or fences are required. No land need be purchased. Much sharper curves can be employed. No attendant is required to accompany the trains; while telpher lines crossing a farm will not materially interfere with the cultivation of the land.

Domestic Lighting made Easy.—Our excellent contemporary, the *Spectator*, commenting in a recent issue upon Mr. Preece's paper, "Domestic Electric Lighting," read before the British Association at their late meeting in Aberdeen, says:—"There is no mystery about the electric light, and nothing in its management which an instructed gasfitter could not learn in a month; yet there is nothing in which small experiment is so difficult, or about which it is so hard for ordinary men to get information. If a man with a large house wishes to burn 40 colza lamps, he can learn in five minutes what his expenditure will be; but if he wants 40 electric lights, the only information he can acquire as to his expenditure is a feebly vague statement, which at once, unless he owns Eaton Abbey, induces him to recede. Why should not the exact method and cost and trouble of lighting a house with electricity be made as familiar to the public as similar details about gas lighting, and hundreds of gasfitters be taught carefully all that is needful for that new development of their trade? There is no need to teach them science. They are not to be like Mr. Preece, but like Mr. Preece's gardener, able to go round and set small engines at work, and repair wire fittings in separate and ordinary houses. The companies are too greedy and too pompous, and do not see that if little groups of houses could once be easily supplied by ordinary tradesmen, the demand for the thing they sell would become almost limitless. People would become habituated to their light, and as it is the best and most convenient, would soon be discontented with any other." In the last issue of the *Spectator* the following letter from a correspondent points to a satisfactory solution to the problem of domestic lighting:—"I have read your article on Electric Lighting with interest, and fully agree that the charges of the various companies at present prevent its more general adoption. I wanted an installation of thirty lamps, fifteen or twenty to be in use at once. The lowest estimate I received was over £150. This was, to my mind, too much. I therefore bought a dynamo, lead, lamps, &c., at various places, and put it in myself, following directions I obtained from several books on the subject. It cost me £41 complete, with driving-power and everything. It is now running, and has been running for eight months, with complete success, and has cost me 6d. only in repairs during this time. If companies would charge reasonable sums I am sure they would soon have more work on hand than they could do." We repeat, this gentleman has solved the problem. It only remains now for him to tell us where we can all procure a dynamo, lead, lamps, &c. (does the &c. mean "engine?") at the price he mentions, and we will immediately go and do likewise.

Sixpenny Telegrams.—We cull the following from *The Globe* of last evening:—

You may write them, dear public, in German or Dutch,
In French, or Italian, or Spanish,
In Latin, or English—it don't matter much—
In modern Greek, even, or Danish;
But Cryptographs, Arabic, Hebrew, are barred,
Aramaic and Syriac; likewise
All systems of shorthand—it seems very hard—
And cuneiform characters spikewise.

You cannot make use of Turanian—no,
Its dialects rich are excluded;
Siamese, Polynesian, don't get a show,
Malay must be never obtruded;
Nomadic-tribe languages are all tabooed,
Though people of moves undecided
Are those most addicted to "wiring," and you'd
Have imagined their wants were provided!

A message in Zend you're forbidden to scratch,
To avoid Attic Greek you're requested,
Unless you are willing to have the despatch
Into lengths of five letters digested;
Nay even that solace is out of your reach
If your lettering be not the Roman;
And *this* in a country where freedom of speech
Is the birthright of man and of woman!

Why should strict regulations make *repertoire* scant,
Deny us Phœnican and Finnish?
In the Postal Department it argues a want
Of the latter our scope to diminish;
And are we expected to offer them thanks
For reducing the price to a tanner,
While they meanly object to our writing in Manx,
Or after the Japanese manner?

Nay, rather, let's vote their conditions absurd—
A clumsy and meaningless jingle—
Whereby we are free to count "cannot" one word,
But cannot count "can't" as a single!
I am bound to admit that in "mother-in-law"
They grant us a lavish immunity,
But *that* word conveys the one notion of "jaw,"
And hence its numerical unity.

If you write "N. E. R.," that is reckoned as three,
With an optional "ner;" the beginner
Might haply conjecture the latter to be
The fag-end of "dinner" or "sinner."
But "ner" is entitled to "collar the bun,"
For, to show you its true valuation,
It's classed with those "words of five letters in *un-Intelligible* combination!"

Don't sport your initials, or yield to a taste
For the affix of ordinal numbers,
If you do, many spaces you'll foolishly waste
On a garnish that only encumbers;
Remember that those who are dealing this dole
Are full of economy's rigour,
And even intend to count ½ as a whole
Word, and "0" as a taxable figure!

Oh! do not write "don't," or they'll count it as two,
And don't venture "do not," but win a
Braw Scotian triumph, and dupe of its due
The Telegraph Office with "dinna!"
Ne'er give them a chance for extortion, in fine,
But try to plant thorns in their pillows
By dating your message "Newcastle-on-Tyne,"
Or "Oldham-cum-Newton-le-Willows!"

ALTERNATING CURRENTS.

BY THOMAS H. BLAKESLEY, M.A., M. INST. C.E.

(Concluded from page 155.)

Upon the Use of the Two-coil Dynamometer with Alternating Currents.

The dynamometer as usually constructed consists of two coils destined to transmit the same current, and for that purpose placed in series with one another by a maker's connection between the end of the first and the beginning of the second. The user of the instrument has access only to the beginning of the first coil and the end of the second. The torsion to be applied to the suspension of the moving coil to bring it into some constant relative attitude towards the other coil (usually but not necessarily the rectangular position) measures with constant current the square of it, with harmonic current the half of the square, where the maximum value of the current gives the denomination to the current. In this sense I have called the function $\frac{I^2}{2}$ of the harmonic current I, the dynamometer reading. But suppose that the employer of a dynamometer has access to the final terminal of the first coil, and to the first terminal of the second coil, as well as to the two usually free terminals; and, further, suppose that he sends one harmonic current through the first coil, and another harmonic current through the second coil, the only ruling condition being that the two currents shall have the same period. What in such a case will be the reading of the instrument? What will be the torsion necessary to bring the coils to the standard relative attitude? It will be as follows: The reading of the dynamometer will measure the quantity $\frac{I_1 I_2}{2} \cos\theta$, when $I_1 I_2$ are the currents as usually defined by their maximum values, and θ is the angle of the phase difference between the currents, *i.e.*, $\theta = \frac{\pi t}{T}$ when t is the interval of time at which the phases of one current follow the same phases of the other.

The truth of this statement appears at once by applying the first geometrical proposition (see first Article), when the two magnitudes there considered represent I_1 I_2 respectively.

I propose to call the reading of a dynamometer under such circumstances the *Force Reading*, and the function $\frac{I_1 I_2}{2} \cos\theta$ will receive the same name. The propriety of this depends upon the instrument being so graduated that when a direct unit current flows in each coil the angle of the index shall be taken as the unit angle.

This is the same condition under which $\frac{I^2}{2}$ is called the dynamometer reading, under the usual circumstances of connection.

The instrument can be converted into a dynamometer of usual construction by placing a stout wire between the final terminal of the first coil and the first terminal of the second, in fact by making a series arrangement of the coils.

It is clear, therefore, that such an instrument is capable of giving in the first and second place the two dynamometer readings of the two currents—viz., $\frac{I_1^2}{2}$ and $\frac{I_2^2}{2}$, and in the third place the force reading, or $\frac{I_1 I_2}{2} \cos\theta$. A comparison of these three readings will therefore furnish the important angle θ, the angle of phase difference, and, by inference, *all the quantities upon which its value depends.*

Let the three readings be a_1 a_2 a_3, so that

$$\frac{I_1^2}{2} = a_1, \quad \frac{I_2^2}{2} = a_2, \quad \frac{I_1 I_2}{2} \cos\theta = a_3$$

$$\therefore I_1^2 I_2^2 = 4 a_1 a_2 \quad \therefore \cos\theta = \frac{a_3}{\sqrt{a_1 a_2}}.$$

The final formula, viz., $\cos\theta = \frac{a_3}{\sqrt{a_1 a_2}}$ will not be changed even if the instrument is not graduated, as I have supposed, but in any uniform manner, including of course the usual degree graduation.

Before proceeding to examine the application of this method to particular cases, it will be well to point out the following peculiarity. Whereas, when a dynamometer is employed to take a *dynamometer reading* the twist to be given to the suspension is always in the *same direction*, still when used for *a force reading* the twist may have to be applied in either direction. This will merely depend upon the value of $\cos\theta$. If in any case the tendency were in the unusual direction, it may be reversed, should the mechanical arrangement of the suspension or the direction of graduation demand it, by simply making the terminals of one of the coils change places with reference to the main circuit.

The previous chapters have been mainly devoted to tracing the effect of self and mutual induction and of condensers, local or distributed, upon the values and phases of the resulting currents of the system. All currents in the systems considered have the same period. If, therefore, in the dynamometer we have an instrument capable of measuring the various currents and of detecting their phase differences, it is clear we possess the means of calculating the values of coefficients of self and mutual induction and the capacities of condensers.

To take as an example the case of a harmonic source of E.M.F. operating in a primary coil, which in its turn acts by induction upon a secondary coil. First, let the dynamometer readings for the two currents be taken separately, and suppose them to be a_1 and a_2 respectively. Then let the force reading be taken, and let it be a_3. Then the cosine of the angle of phase difference will be $\frac{a_3}{\sqrt{a_1 a_2}}$.

But a reference to Fig. 5 shows that this angle is B C F or C E A, whose cotangent is equal to $\frac{L'\pi}{rT}$, L' being the coefficient of self-induction of the secondary coil.

But $$\cot^2\theta = \frac{\cos^2\theta}{1-\cos^2\theta}. \quad \therefore \left(\frac{L'\pi}{rT}\right)^2 = \frac{a_3^2}{a_1 a_2 - a_3^2}$$

$$L' = \frac{rT}{\pi} \frac{a_3}{\sqrt{a_1 a_2 - a_3^2}}.$$

Therefore the coefficient of self-induction of the secondary coil is determined, the period and resistance being of course supposed known.

The value of M, the coefficient of mutual induction, may be found without further observation, thus.

$$\frac{CA}{CE} = \sin\theta \text{ and } \frac{CE}{CF} = \tan CFE = \frac{M\pi}{RT}.$$

Hence $$\frac{CA}{CF} = \frac{M\pi}{RT} \cdot \sin\theta.$$

But $$\frac{CA}{r} = I_2. \quad \therefore CA = r\sqrt{2a_2}.$$

Similarly $$\frac{CF}{R} = I_1. \quad \therefore CF = R\sqrt{2a_1}.$$

Hence $$\frac{r}{R}\sqrt{\frac{a_2}{a_1}} = \sqrt{\frac{a_1 a_2 - a_3^2}{a_1 a_2}} \frac{M\pi}{RT},$$

and therefore $$M = \frac{rT}{\pi} \cdot \frac{a_3}{\sqrt{a_1 a_2 - a_3^2}}.$$

or the coefficient of Mutual Induction is determined.

If the coefficient of self-induction in the primary coil is desired, it may be determined by making it temporarily the secondary coil, and pursuing a similar course to that already described. A second determination of M will result from the second series of observations serving as a check upon the former series.

It may be pointed out in passing that in the determinations of L' and M the resistance R in the primary coil need not be

Digitized by Google

known, for its symbol does not occur in the formulæ for those magnitudes. Hence any change in the value of the resistance in the primary coil will not affect the relative values of a_1, a_2, and a_3, upon which M and L′ are calculated, for they are independent of R.

Therefore, the insertion of a resistance in the primary coil may be used to bring all the readings within the range of the instrument, by pairs in turn. Thus, suppose a_1 a_2 a_3 are in descending order of magnitude. It might happen that when the resistance in the primary is such as to allow a_1 to be read, a_3 might be so small as to be untrustworthy. In this case let a_2 be read. Then take resistance out of the primary circuit. All the readings will go up, a_1 would be off the scale at the high end, but a_3 would reach a reasonable value, and may be compared with a_2. Now a_2 will be found to have gone up in a certain proportion. It will now only be necessary to reduce a_3 in this proportion to obtain a value which, with the former values of a_1 and a_2, will serve for immediate use in the equations.

In investigating the capacity of a condenser by means of an alternating current, we may bridge over a circuit by means of the condenser at points dividing the circuit into two portions, r containing the generator, and R beyond the terminals of the condenser. It may be convenient to avoid a coefficient of self-induction in that part which is remote from the generator, a matter easily accomplished. The coefficient for that part which contains the generator cannot in practice be avoided, but fortunately will not appear in the calculations. For a little consideration will show that if there is no coefficient for the remote section the construction of the diagram upon the rules given for Fig. 11 will coincide with those given for Fig. 7 up to and including the construction of the lines giving the effective electromotive forces in the two sections. So that we need contemplate only the construction of Fig. 7.

The procedure will be as follows:—

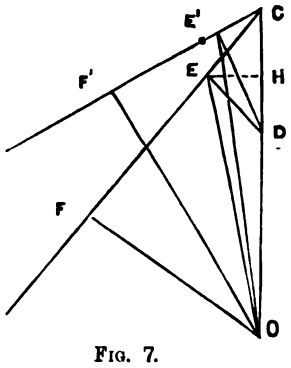

Fig. 7.

(1.) Take the dynamometer readings for the two sections.

Let them be a_1 for the generator's section.
a_2 for the remote section.

(2.) Take the force reading between the two sections.

Let this be a_3.

Then, taking I_1 and I_2 as the currents in the two sections, near and remote, respectively, we must have

$$\frac{OE}{r} = I_1. \quad \therefore \quad OE = r\sqrt{2a_1}.$$

$$\frac{EC}{R} = I_2. \quad \therefore \quad EC = R\sqrt{2a_2},$$

and $\frac{a_3}{\sqrt{a_1 a_2}}$ will be the magnitude of the cosine of the angle C E O, or the sine of the angle D E O.

Now, from the geometry of the figure,

$$\tan^2 OCF = \frac{OF^2}{FC^2} = \frac{OE^2 - FE^2}{FC^2}.$$

But $$FE = \frac{r}{R} EC = r\sqrt{2a_2},$$

and $$FC = \frac{R+r}{R} EC = \overline{R+r}\sqrt{2a_2}.$$

Hence $$\tan^2 OCF = \frac{2r^2 a_1 - 2r^2 a_2}{2\overline{R+r}^2 a_2} = \left(\frac{r}{R+r}\right)^2 \frac{a_1 - a_2}{a_2}.$$

Therefore $$\tan OCF = \frac{r}{R+r}\sqrt{\frac{a_1 - a_2}{a_2}}.$$

But by the construction $$\frac{C\pi Rr}{T\cdot(R+r)} = \tan OCF.$$

Hence $$\frac{C\pi R}{T} = \sqrt{\frac{a_1 - a_2}{a_2}}.$$

or C, the capacity of the condenser, $= \frac{T}{\pi R}\sqrt{\frac{a_1 - a_2}{a_2}}$,

thus determined by the dynamometer observations. It will be noticed that this formula does not involve the force reading a_3, but this if taken can be used in the place of a_2, for the values can be shown to be identical.

To prove this point, consider that F E O is the angle of phase difference; therefore, its cosine is equal to $\frac{a_3}{\sqrt{a_1 a_2}}$. But cos F E O is also equal to $\frac{FE}{EO}$

$$= \frac{ECr}{R}\frac{1}{EO} = \frac{r}{R}\frac{R\sqrt{2a_2}}{r\sqrt{2a_1}} = \sqrt{\frac{a_2}{a_1}}.$$

Hence $$\sqrt{\frac{a_2}{a_1}} = \frac{a_3}{\sqrt{a_1 a_2}},$$

or $$a_2 = a_3.$$

This is an important fact in employing the method to measure a condenser, for in practice it would be desirable to have as little self-induction in the remote section of the coil as possible. In this investigation it has been assumed at zero. But the self-induction in the near section has no effect upon the operations. Hence it would be desirable to have the coil in the remote section of no more than a very few turns of wire, while the sensitiveness of the instrument might be furnished by having very many turns in the other coil; *i.e.*, that in the near section. For the same reason it would be well to make the standard position of the coils the rectangular one.

If it be necessary to take the self-induction of the remote section into consideration, we may contemplate the construction of Fig. 11 down to the fixing of the point O.

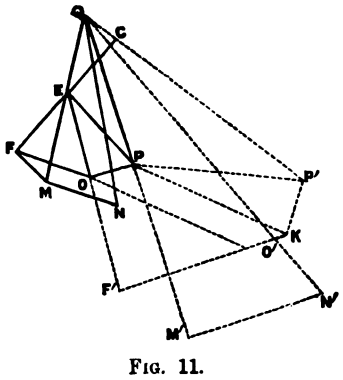

Fig. 11.

In this case the observations may be expected to furnish not only the value C of the capacity of the condenser, but also the value of the coefficient of self-induction of the remote section, as in fact they will be found to do. If a_1 a_2 a_3 are the three observations, we have

$$OE = r\sqrt{2a_1} \quad EC = R\sqrt{2a_2}.$$

$$\therefore \text{ also } EF = r\sqrt{2a_2}, \quad \text{and} \quad \cos FEO = \frac{a_3}{\sqrt{a_1 a_2}}.$$

For brevity call the angle F E O θ, and the angle C E Q β. Then also F E M $= \beta$. Because E M is perpendicular to F O, and

$$EF\cos\beta = EO\cos\overline{\theta - \beta}.$$

$$\therefore \cos\beta = \frac{EO}{EF}\cdot\cos\overline{\theta-\beta} = \sqrt{\frac{a_1}{a_2}}\cos\overline{\theta-\beta}.$$

Digitized by Google

Hence $$\tan\beta = \frac{1-\sqrt{\frac{a_1}{a_2}}\cos\theta}{\sqrt{\frac{a}{a_2}}\sin\theta} = \frac{a_2-a_3}{\sqrt{a_1a_2-a_3^2}}.$$

But $$\tan\beta = \frac{L_1\pi}{TR}. \quad \therefore L_1 = \frac{TR}{\pi}\frac{a_2-a_3}{\sqrt{a_1a_2-a_3^2}},$$

or the coefficient of self-induction is determined in terms of the dynamometer observations.

This formula also demonstrates the equality of a_2 and a_3 when there is no self-induction.

To find the capacity. From the above value of tan β we may obtain $$\cos^2\beta = \frac{a_1a_2-a_3^2}{a_2(a_1+a_2-2a_3)}.$$

Further, $$\tan^2 MQN = \frac{MN^2}{QM^2} = \frac{R^2FO^2}{R+r^2QE^2} = \left(\frac{R}{R+r}\right)^2\frac{FO^2}{CE^2}\cos^2\beta$$

$$= \left(\frac{R}{R+r}\right)^2\frac{FE^2+OE^2-2FE.OE.\cos\theta}{CE^2}.\cos^2\beta.$$

$$= \left(\frac{R}{R+r}\right)^2\frac{2r^2a_2+2r^2a_1-4r^2a_3}{2R^2a_2}.\cos^2\beta$$

$$= \left(\frac{r}{R+r}\right)^2\frac{a_1+a_2-2a_3}{a_2}.\frac{a_1a_2-a_3^2}{a_2(a_1+a_2-2a_3)}$$

$$= \left(\frac{r}{R+r}\right)^2\frac{a_1a_2-a_3^2}{a_2^2}.$$

Hence $$\tan MQN = \frac{r}{R+r}.\frac{\sqrt{a_1a_2-a_3^2}}{a_2}.$$

But by construction $$\tan MQN = \frac{C\pi Rr}{TR+r}.$$

Hence $$C\frac{\pi R}{T} = \frac{\sqrt{a_1a_2-a^2}}{a_2}.$$

and $$C = \frac{T}{\pi R}.\frac{\sqrt{a_1a_2-a_3^2}}{a_2}.$$

Hence the capacity is determined in terms of the dynamometer observations.

Similarly, alternating currents and dynamometers may be employed to investigate the rate at which capacity is distributed along a cable.

THE PROPER METHOD OF OBTAINING THE AVERAGE DURATION OF AN INCANDESCENT LAMP.

BY J. A. FLEMING, M.A., D.SC.

Recent statements on the average life of incandescent lamps and other general practice agree in indicating a certain absence of clearness in many minds on the proper principles by which the desired average quantity can be obtained from the experience of observations. It seems desirable, therefore, to call attention to the proper method by which alone any figures at all useful can be obtained. To do this we shall adopt, what is always best when possible, graphic illustrations instead of symbols. Let us suppose that there is an incandescent lighting plant set up for continuous or intermittent use, and that the person in charge desires to arrive at some correct notion as to what is the mean duration of the carbon filament under any condition of working. On a line, $o\,x$, mark off equidistant points, each one of which represents a working lamp. Draw vertical lines through these to represent time or duration, and the crosses represent the times or dates at which lamps are replaced. Thus in the diagram, lamp 2 is replaced at three periods, represented by the crosses a, b, c; the first lamp burnt for a time $2a$, the second for a time $a\,b$, the third for a time $b\,c$, and the fourth lamp is yet burning.

Now, suppose that a trial period of time is taken, represented by the distance between the horizontal lines through A and X. The distance A X represents the duration of this trial run. Suppose it is desired to obtain the average life of the lamps during this period, then the *usual* mode of arriving at this quantity would be to divide the total lamp hours by the number of replaceals, and deduce (perhaps to a decimal) the average life of the lamp. If matters could be so managed that if the lamps all

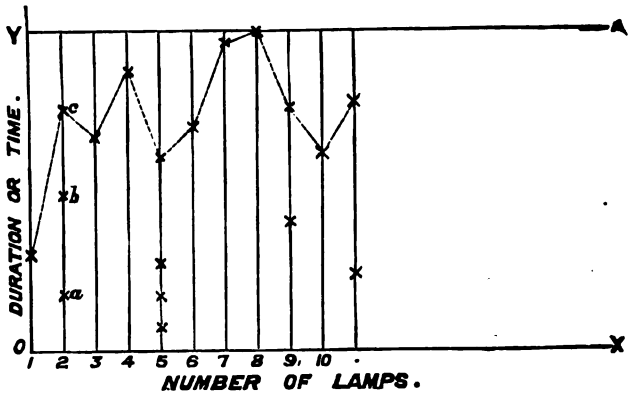

FIG. 1.

gave out at once, and that the trial run finished exactly with the expiry of all lamps, it is obvious that the above mode of procedure would be correct; also, if the lamp hours of every separate lamp were taken from the beginning of the trial up to the end of the duration of a life, the same having been replaced 1, 2, 3 or n times. Then it is also obvious that the average life would be the average of the average deduced by dividing the whole lamp hours of *each* lamp separately by the number of times that lamp has been replaced. But neither of these two processes is practicable in a general way, and accordingly we can deduce no accurate average from any trial in which there remain at the end of the trial unexhaused lives, or lamps which have in them yet lamp hours of potential working. Referring once more to the diagram above, we see that the diagram may be divided into two parts, one above the dotted line formed by joining all the last crosses and one below. The united lengths of all the vertical lives included between the dotted line and the horizontal O X represent the lamp hours of burnt out lamps. The united lengths of all the parts of vertical lines between the dotted line and the upper horizontal A Y represent the lamp hours burnt by lamps yet alive and likely to live.

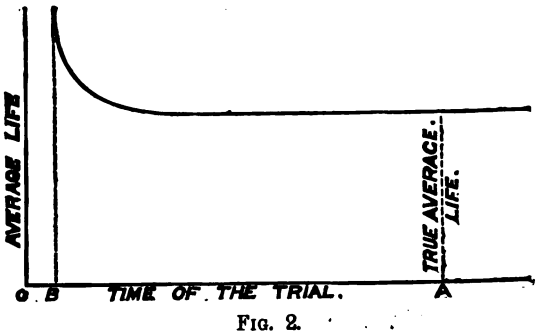

FIG. 2.

Now let us call these two parts the total exhausted lives, and the total unexhausted lives.

If the lamp hours of unexhausted lives form an appreciable or moderate fraction of (much more if it exceeds) the lamp hours of exhausted lives, then the application of the common rule only leads to ridiculous results. And the only circumstances under which the quotient of total lamp hours by replaceals gives a correct approximation to the average life is when the total unexhausted lamp hours is small or negligible in comparison with the total exhausted lamp hours. And under the former supposition the average life is always over-estimated. Accordingly, the moral of this is, no trial tests or experimental

Digitized by Google

runs are of the least use for the purpose of averaging the life of incandescent lamps which do not last for a period at least four or five times the average duration of a lamp, that is for 5,000 or 6,000 hours, and the longer the better.

If a given number of lamps be set up and run continuously, and replaced as they fail, and the ordinary rule applied at stated intervals, it would be found that as the trial run extends in time, the average life deduced would diminish towards a fixed minimum, which is the real average.

It is easily seen that the ordinary rule makes the average life of a lamp infinite for short trials, which, as Euclid would have observed, "is absurd."

If we plot down the results of applying the common rule as ordinates along a scale of time representing the time of the trial, then it is easily seen that for time zero, life is infinite; and as the time of the trial increases, we eliminate more and more the respective proportion of unexhausted lives as compared with total lamp hours of exhausted lives, and approximate to a horizontal position in the life curve, which gives the true average life by its distance above the horizontal line. These considerations if weighed will, it is to be hoped, prevent those in charge of installations from rushing into print with statistics derived from one or two hundred hours of burning. Although, as the results of such too limited experience will always be to bring out the average life of the lamp too high, it is, perhaps, hardly likely that lamp manufacturers will refrain from quoting them in their own favour, or come forward to instruct the publisher of them in the true principles which should control the collection of observations intended to furnish an approximate estimate of the mean duration of incandescent lamps properly used.

One further remark suggests itself in connection with the statistics which have given rise to discussion on this subject, and it is this, the vital importance of working all lamps at the proper E.M.F. necessary to make the expenditure of energy in them equal to the proper watt mark of the lamp. And knowing as we do what serious variation is made in the average life by a difference of one or two volts (considered by many of small importance), it is obvious that the careful and systematic use of known accurate voltmeters should be a matter of consideration with every one who has the care of incandescent lighting.

THE LATE MR. JOHN MUIRHEAD.

On Tuesday, September 22nd, the remains of Mr. John Muirhead were interred in the Cemetery of Lower Norwood.

The deceased was in many respects a remarkable man; but such was the quietude and modesty of his character, that few except the members of his own family had any real knowledge of the good and sterling qualities he possessed. Mr. Muirhead was one of the last survivors of the early days of the electric telegraph. He was the colleague and fellow-worker of nearly all the men whose names are indissolubly associated with the introduction of that great invention; and very interesting were his reminiscences of the old times. But he was a man not much given to talking; and most of his recollections have ended with him.

Born at Gifford, in Scotland, in the year 1807, his life has extended over what will probably be considered one of the most progressive periods in the world's history. The more material part of this progression has been the development of the railway and the telegraph; and in the latter of these great works the late Mr. Muirhead played an honourable part.

The electric telegraph, under Cooke and Wheatstone, had begun to take a practical form in this country in the year 1837; but it was struggling with many difficulties. When in 1846 the original Electric Telegraph Company was formed, Mr. Muirhead, who even as a young man showed a decided talent for construction, joined this company, and remained in its service until the system was transferred to the Post Office in 1870. From his first connection with the telegraph until within a few years of his death, Mr. Muirhead devoted himself continuously to the work of extending the system, building the lines, and perfecting the appliances.

The tubular bracket of annealed iron which he introduced in place of the solid cast-iron one previously employed was rapidly adopted, and is now in general use. The hollow iron pole, which under various improvements is now so common, was also, we believe, one of his ideas. The early metropolitan lines were laid by him, and the pneumatic system for collecting messages from the local telegraph stations to the central transmitting station in London and other provincial towns was first installed under his supervision. Mr. Latimer Clark and the late Mr. Cromwell Fleetwood Varley did much to introduce and perfect this novel system of communication, which is now employed in all the important telegraphic centres.

In the absence of manufacturing facilities such as exist now for the supply of telegraphs to the world at large, Mr. Muirhead, in conjunction with Mr. Latimer Clark and Mr. W. M. Warden, of Birmingham, founded the house now known as Messrs. Latimer Clark, Muirhead and Co., a firm which, in the course of its career, has planted the telegraph in every corner of the world, and doubled the carrying power of nearly all the great submarine cables, by the duplex system, which is the invention of Mr. Muirhead's sons. It was from this manufactory that Mr. Muirhead introduced the form of battery which bears his name, a form so eminently portable and practical that it has become the model for most of the existing batteries, while continuing itself to be largely employed. This battery includes the use of rectangular earthenware vessels, containing flat porous pots, the whole being removable from the box for cleaning purposes.

Other improvements and innovations of Mr. Muirhead might be mentioned, such, for example, as the introduction of teak for telegraphic apparatus in hot countries; but the greater part of his time was devoted to the practical execution of telegraphic work. His ordinary duties took him to every part of the country, and left him very little leisure time. Nevertheless, he was a well-read man; and on retiring from business a few years ago, his favourite amusement was reading works of history, a study in which he was extremely well versed. His knowledge of events and their dates was unusually accurate and comprehensive.

Endowed with a very strong and robust frame he hardly knew a day's illness, except at rare intervals when overwork or exposure had told upon his constitution. His natural vigour was sustained by sober habits, both of mind and living.

A few months before his death the health which he had hitherto enjoyed began to break down, and the tranquil leisure he had earned so well was interrupted by a serious illness. He rallied, however, to some extent from this, but on Thursday, the 17th September, while conversing quietly with his doctor in the library of his residence at Oakwood, he suddenly fell back and expired. Thus died a faithful servant; one who had done his work ungrudgingly and taken his reward.

Mr. Muirhead was unquestionably a successful man, and his success was due rather to the influence of character than to the possession of genius. One discerned in him some of the best traits of the old Scottish type—a natural truthfulness and sincerity, intolerant of duplicity and humbug; a plainness of speech for which the times are perhaps a little too fine; a directness of action which led him straight to the end in view. Frugal and industrious he was also economical; but it was the economy of principle and honest independence. He could not be induced to do an unscrupulous action in order to profit by it. He did the thing which he believed to be right, and left the consequences to be dealt with when the time came. Mr. Muirhead always took a great interest in his work. He loved good material to work with, and took a pride in turning out a piece of thorough workmanship. If one of his men was doing a job in a slovenly or clumsy fashion he would take the tool out of the man's hands and show him how it should be done. The workmen liked and respected him because of his practical knowledge of the business and his kindly interest in them and their affairs. His very presence in the shop was sufficient to make the work go on with diligence. If he had occasion to rebuke a workman he did so privately, and not before his fellows in a way calculated to pain the man's self-respect. He forebore to scold or brow-beat him, and imposed no fines. His method was to point out the faults of the work, and appeal to the better nature of the man for an improvement in it. Under a somewhat rugged exterior he concealed a warm and kindly heart. But such was his dislike of anything approaching to ostentation that most of his benevolence was strictly private, and perhaps only known to the recipient. He had a sympathy with struggling men, especially artisans, and enjoyed giving them a helping hand in his own works. Some of these turned out badly, others well, and a few have even become notable. He believed firmly in education for the masses. A good education, he was wont to say, is much better than money; a man cannot spend it. He was also very tolerant of the opinions of other persons in political and religious matters, believing that they held them in perfect honesty, and considering that they had as much right to their opinions as he had to his own.

Living an upright and faithful life, he has left few or no enemies behind him. He was one of those who never sought to shine, and most of his work was of that silent order which is its own praise. He was one of the labourers who seek to do with all their might the work that is put into their hands.

"Without them, how could laws or art
Or towered cities rise?"

EDUCATION AND EXAMINATION.

Next to the Presidential Address in general interest, and before it perhaps in practical utility, was the paper read by Prof. Chrystal to the Mathematical and Physical Section of the British Association, on the Diffusion of Scientific Knowledge. So far as title goes, there was a close correspondence between this and the subject chosen by Dr. Playfair; but in treatment they widely differed. The President's method of diffusing scientific knowledge would be, as we pointed out at the time, to bribe the people with a subsidy out of the public exchequer, and so virtually to convert Science into a State Establishment. Prof. Chrystal has no such suggestion or any other for diffusing science knowledge; his complaint is rather that it is too much diffused already—diffused, in fact, to such an extent that he finds it hard to discover substantial trace of it. Of crammers' knowledge there is an abundance, and of text-books adapted to the crammed no lack; of examinations, too, which incontestibly prove the universal prevalence of knowledge thus diffused, there is more than enough; but as evidence of the spread of scientific knowledge, which is not the same thing as a knowledge of science, Prof. Chrystal cannot accept these signs without misgiving—nay, speaking as an examiner as well as teacher, he roundly asserts that the net result of modern scientific teaching is the filling up of examination papers with lifeless words reproduced from dead text-books. By dead the worthy Professor does not mean that they are out of date—on the contrary, they are in this respect very much alive—but they are stuffed with inanimate fragments unfit for wholesome food, and are good for nothing but the show case. All men practically engaged in teaching, says Prof. Chrystal, are agreed that it is the absurd prominence given to written competitive examinations that works all the mischief. Yet this competitive examination system is primarily due to the State's interference, and is mainly fostered by its patronage. A more damaging commentary upon Dr. Playfair's Presidential Address could hardly he imagined.

The condition into which the educational system is drifting, and more especially the scientific portion—which is peculiarly adapted for the crammer's methods—is graphically set forth in a single passage of Prof. Chrystal's discourse. It is now argued, he alleges, that professional lectures should contain nothing but what is to be found in every text-book; lectures are therefore superfluous; examinations should touch nothing that is not in the text-books, because that would be unfair; and similarly there should be nothing in the text-books not likely to be set in examination, because that would tax the candidate's memory unnecessarily. For our part we see nothing surprising in this description; it is the natural and logical outcome of a system which has grown up for many years under our very noses, with our eyes wide open, with consequences predicted over and over again, and with results which obtrude themselves upon us at every turn. The end of all education having been to fit the pupils to be examined, and the end of every examination to pass a goodly number of badly taught pupils, it is no marvel that both educators and educated "are left more and more to wander in primeval darkness." It may be true that specialists, into whose hands true science has exclusively fallen, are "soaring higher and higher into the light of day." But if so the fact is phenomenal; the tendency is to stop their flight, to tie them down to the level of competitive exams, and to entice them with the rewards of successful passes. In a few years' time we may hope to have achieved for English learning what the Chinese long ago accomplished for theirs. In China the competitive examination has prevailed in every branch of life for centuries; and unless they are greatly maligned the Chinese are at once the most ingenious liars and most learned idiots the world has ever seen. The excuse of the English teacher, otherwise honest and well meaning, is, says Prof. Chrystal, that he does so and so, knowing it to be vicious, "because of the examination." No Heathen Chinee could wish for a better excuse.

It is here, when we approach the moral aspect of the subject, letting alone its practical aspect, that we feel disappointed with Prof. Chrystal's otherwise sensible address. The description he gives us of that solemn, national farce, a great public competitive examination and its ridiculously misleading results, would, one might suppose, arouse some indignation, some stern resolve to remedy the evil, or—well, let us say, turn specialist, soaring "higher and higher," though the pay may be lower and lower. But we are rather asked to pardon the system, chiefly because it is an outlet from the old one of patronage; as if patronage ever wrought such mischief as this is doing. Patronage had always the strongest motive for patronising the best available material, and at its worst it never systematically pretended to be what it was not. Prof. Chrystal says that the cure for all this evil—the evil of pretending to be educating when we are only examining—is "simply to give effect to a higher ideal of education in general, and of scientific education in particular." Our own view, we feel constrained to say, is, that to give effect to a high ideal you must first have a high ideal of moral duty in general, and that of scientific men in particular. They still enjoy in the non-scientific world the reputation for self-denying integrity in the pursuit of their calling; yet here we have a

Digitized by Google

confessedly vicious and abortive system carried on by them, under the guise of education, costing the country a vast deal of money, which is pocketed chiefly by scientific men, and which they admit might just as well be thrown in the school fire for all the good it does. They have had this system virtually under their control for more than a generation past, and they are almost the only people who profit by it. If not to them, to whom are we to look for a remedy? But we do not discover one in Prof. Chrystal's paper, nor is it inspired with anything more energetic than the plaintive wail of well-deserved failure. The most vigorous attacks on the system in recent times, so far as our memory serves, have come from quite another class—from journalists and men of letters. It is time that men of science bestirred themselves to remove this discreditable sham—the parent of many other shams in the sphere of scientific education—and although the task may not be easy it is in one sense simple. Let them unite in protesting against it under threat of washing their hands of the business altogether. But to do this effectually they must first disabuse their minds of the prevailing delusion that any good can come of diffusing knowledge that is only coveted for the sake of a pass. It would be much nearer the truth to say that nobody is worth teaching who does not love to learn.

SIXPENNY TELEGRAM DAY.

From all accounts received to the time of our going to press, the first day of the Sixpenny Telegram era passed off very satisfactorily. By this we mean there was no untoward rush, no panic, and no pressure which the telegraph service was not quite competent to deal with in a satisfactory way and without unusual delay. A considerable extra force of telegraphists, and of course a very large increase in the number of messengers, were provided at most of the head offices; but so far as the former is concerned there was no urgent need for them, as the traffic on the whole, although vastly increased in point of numbers, was far from being proportionately augmented in bulk. It is calculated that there has been an increase of fifty per cent. in the number of messages, but this of course is largely conjectural; whereas the decrease in the length of the messages is represented by the fact that forty per cent. of the traffic passing through the principal centres consisted of messages containing not more than twelve words each. If this percentage is maintained throughout the country, conclusive proof will be afforded that the cutting down of the maximum number of words by more than fifty per cent. has been attended with no public inconvenience. The new tariff is so low that if nearly half the messages can be compressed within the twelve words' limit, there need be no hesitation about taxing the rest.

As regards the great Central Telegraph Station in London, thanks to the admirable provisions made by Mr. Fischer, the Controller, and his excellent staff of assistants, the first day's business was disposed of with the customary smoothness and celerity; and a visitor to the gallery could mark no perceptible change in the aspect of affairs, except perhaps that both male and female operators were in stronger force than usual. We were informed that although the addresses have experienced a curtailment amounting to forty or fifty per cent., no inconvenience has yet arisen with regard to the deliveries. This matter, however, has been greatly facilitated, no doubt, by the registration of addresses, which has latterly gone on at the rate of some hundreds daily in anticipation of the reduced limit. Perhaps the most notable effect of the new tariff was felt in the metropolitan part of the establishment, where the number of local messages was immensely greater than usual. No small proportion of these, however, were of the facetious character peculiar to such inaugurations. The honour of first place was obtained, we are told, by one of these, sent by some midnight prowler, who relieved his feelings at the small cost of sixpence by telegraphing from one part of London to another that it was "all on account of Eliza." Another telegram of a more practical kind, to improve the occasion, was forwarded by the clerks of a provincial office to the Postmaster-General wishing success to the Sixpenny Telegram scheme, *and* payment for Sunday duty. We hope they may have their reward.

CORRESPONDENCE.

THE PNEUMATIC SYSTEM FOR TELEGRAPH PURPOSES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the interesting description of the pneumatic system which was read at the British Association, and which appears in your journal of yesterday, it is stated that "the system was first introduced by Mr. L. Clark in 1854, who employed vacuum;" and, later on, "about the year 1866 Mr. C. F. Varley applied compressed air for propelling the carriers in the opposite direction," &c. These statements are perfectly correct, and they appear in almost all descriptions of the pneumatic system, but they would seem to imply that Mr. Varley first suggested the use of both pressure and vacuum, which is not the case. The fact is that, succeeding me in the position of engineer to the company, it was only in his day that the company's requirements were such as to justify the expense of a double system of engines and pumps.

A single extract from my patent, No. 1,641 of 1857 (nine years before Mr. Varley's application of the system) will be sufficient to show this:—"In working telegraphs of this description I have found that a saving of cost may be effected by so arranging the apparatus that the packages are propelled in one direction by exhausting the air from the pipe in front of the package, and in the other direction by admitting behind it air under a pressure exceeding that of the atmosphere. When the apparatus is arranged in this way one pumping engine only is necessary, and this engine works to produce a partial vacuum in one vessel and a pressure in another vessel."

The constant association of Mr. Varley's name in connection with the application of the double system conveys the idea that I had overlooked so obvious an employment of pneumatic pressure. So far as I am aware the only real advance made upon the system since I left it is the introduction of the "Pneumatic double sluice valve," described in Mr. Willmot's paper, which is an admirable invention and appears to act most efficiently.—Yours, &c., LATIMER CLARK.

6, Westminster-chambers, Victoria-street,
London, 26th September, 1885.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you allow me the privilege of your space to bring the following phenomenon under the notice of electricians—though I ask this with the consciousness, first, that the phenomenon may possibly be already known; and, secondly, that it may be a phenomenon not of induction generally, but merely due to some defect in the instrument I was using at the time, though I do not think this was the case?

Whilst engaged with a small induction coil six or seven inches long, with a spring make-and-break, I noticed, as often as I completed the secondary circuit, that the humming note caused by the vibrations of the spring rose somewhat in pitch, remaining constant at that pitch as long as the secondary current continued to be closed, and falling again to the lower pitch when an interruption was made. My chain of inferences drawn from the result was as follows:—The

Digitized by Google

higher pitch, or increased frequency of vibrations in the spring, means increase of magnetism; and increase of magnetism means increase of current in the primary coil, an effect of completing the secondary circuit. In this way I was led to think that completing the secondary circuit *relieved* the primary coil. But let me hear what others say who have had a wider experience in the matter before I develop any private explanations, which might be very wide of the mark. I will only add that those who wish to investigate the *fact* must either have or borrow a good musical ear, or, still better, a registering instrument. It is not difficult to anticipate that different varieties of pitch for the closed circuit might be attained by varying the resistance of the secondary circuit externally.—Yours, &c., E. ALDRED WILLIAMS.

37, Burlington-road, W., Sept. 28, 1885.

A SELENIUM PHOTOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In his lecture on the "Electric Light and Atmospheric Absorption," Prof. Adams stated that "selenium gives a very delicate mode of *measuring* the illuminating power or the energy of the visible radiations by the increase in the electric current, as shown by the deflection of the galvanometer." He exhibited among others a selenium cell received from Mr. Fritts, of New York, the resistance of which was reduced from 75,000 ohms on exposure to one candle at a distance of one foot, and he then said that "in this change of 32,000 ohms for an illumination of one candle we see that we have a means of *measuring* very small differences of illuminating power, and therefore a means specially adapted to measure small differences due to absorption of light by the earth's atmosphere." In the year 1876 I made many attempts to construct a selenium photometer, but I had to give it up because I could not construct or procure a selenium cell which possessed the two qualities which are essential in a measuring photometer, viz., constancy in its resistance when illuminated, and when illuminated the exhibition of a diminution of its resistance accurately proportional to the variation in the illumination. Since then I have carefully studied all the published accounts of experiments with selenium in the hope of finding that this difficulty had been overcome; but, as far as I am aware, no experimenter has yet succeeded in constructing a selenium cell which fulfils these requirements. The experiments of such careful observers as Siemens, Graham Bell, Shelford Bidwell, and others, all indicate that a selenium cell is very unstable and variable in its behaviour, and therefore the more fact that a particular cell exhibits an enormous diminution in its resistance or illumination by one candle, if not supplemented by conclusive evidence that it possesses the other requisite qualities, does not warrant the conclusion that such a cell could be employed as a delicate measuring photometer. If these cells possess these qualities, then I think an account of them would be as interesting to many of your readers as it certainly would to—Yours, &c., R. E. DAY.

CONSTANT GRAVITATIONAL INSTRUMENTS

FOR MEASURING ELECTRIC CURRENTS AND POTENTIALS*.

BY SIR WILLIAM THOMSON.

The instruments, the author stated, were parts of two series of electrical measuring instruments, for current and potential, which he was now working out. In the two current instruments—the milliamperemeter and the hecto-amperemeter—the mode of effecting the measurement was founded on Faraday's law that a ferro-magnetic mass placed in a variable magnetic field experiences forces tending to make it move from places of weaker to places of stronger force. The essential parts of the milliamperemeter are shown in the sketch diagram (Fig. 1). It consists of an electro-magnetic coil, fixed with its axis vertical, and a little bar of soft iron hung from one end of a light balanced lever so as to be free to move up and down in a circular arc, deviating but little in its middle and at its two ends from the axis of the coil.

The measurement is given by the deflections indicated on a scale by the end of the balanced lever when a weight of known amount is hung on the ring below the iron mass. To screen the iron from the effects of the earth's magnetism the coil is enclosed in an iron box. In the hecto-amperemeter the variable magnetic field is obtained by a suitable disposition of the metallic conductor conveying the current to be measured.

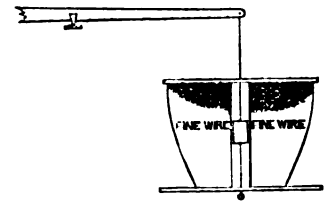

FIG. 1.

The conductor may be taken as consisting of two thick copper plates shaped according to the sketch Fig. 2, supported in a vertical position parallel to each other, say one centimetre apart, and metallically connected at the place indicated by B; A is fixed at a suitable electrode. The course of the current is therefore from A to B, and from B through the other plate to the part of it corresponding to A, which forms the other electrode. In this way two similar varying magnetic fields are produced, and the balanced lever, capable of motion in a plane situated midway between the plates, carries two masses of iron, one in each field. In other respects the instrument is similar to the milliamperemeter.

The electrometer consists of an air condenser with one of its plates capable of a to-and-fro motion so as to vary the capacity of the condenser.

The fixed brass plates are supported so as to be accurately parallel to each other and in metallic connection, while they are thoroughly insulated from the case of the instrument. The movable plate is of aluminium, of the shape shown at B B of the accompanying sketch, and is supported in a vertical position on a knife edge, the plane of its motion being parallel to the fixed plates and situated midway between them. The upper end of this movable plate has a fine prolongation which serves as a pointer for indicating the deflections on the scale of the instrument, and at its lower end is fixed a knife edge having its length perpendicular to the plane in which the plate moves.

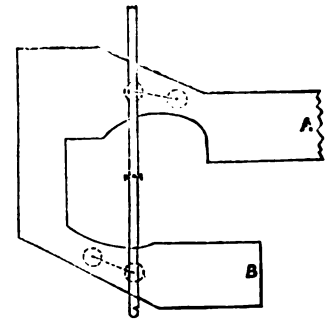

FIG. 2.

When the fixed and movable plates are connected respectively to two points of an electric circuit, between which there exists a difference of potential, the movable plate tends to move so as to augment the electrostatic capacity of the instrument, and the magnitude of the force concerned in any case is proportional to the square of the difference of potential by which it is produced. In the use of the instrument this force of attraction is balanced by the horizontal component of a weight of any convenient amount hung on the knife edge at the bottom of the movable plate.

AN ELECTRIC SAFETY LAMP FOR MINERS.*

BY F. WILSON SWAN, M.A.

I wish to bring under the notice of the Section the latest result of an attempt to adapt electric light to the requirements of coal mining. The object is to obtain greater security from the danger of the lamp causing an explosion of fire-damp. The principle of the Davy lamp is no doubt very beautiful, and I am not prepared to say that that principle, applied as it is with great ingenuity of detail in the construction of the modern safety lamp, is incapable of giving safety under the ordinary normal conditions of coal mining; but I do say that a well grounded doubt and suspicion rests upon lamps of this class when placed under certain exceptional but not improbable conditions. So long as the lamp, be it the Davy, the Clanny, the Geordy, the Mueseler, or any of the newer designs, is not subject to a strong gust or abnormally swift current of inflammable gas, it is, if well made, probably quite safe even in a highly explosive atmosphere; but it is more than doubtful if the best of these lamps is safe in such an atmosphere in a state of abnormally rapid motion, or when subject to a rush of air, such as a blast or the accidental swing of a lamp may occasion. The fragile partition of wire gauze which alone presents a barrier to the passage of flame from the lighted wick inside the lamp to an explosive mixture of gas outside is too slight a defence against the danger of explosion. The widely-entertained belief that a certain degree of danger is inseparable from the employment in fiery mines of this species of lamp, has naturally led to the inquiry whether it is not possible to get absolute immunity from the danger I have described by resorting to a different principle of construction.

When it was demonstrated that a small and steady light could be produced in a completely enclosed glass bulb by means of the incandescent electric lamp, imagination instinctively turned to electricity as the agent through which complete safety might be secured. The essential fitness of such a light, totally isolated by a gas-impervious covering from the smallest contact with the outer air, was obvious, and indeed it seemed at the first blush of the matter, and in the enthusiasm born of a new invention, that the problem was already completely solved. No sooner, however, was the attempt made to realise this attractive idea than many difficulties presented themselves, and these, on close encounter, proved to be so serious, that what at first seemed easy of accomplishment, began to wear the aspect of total impracticability. One of the chief difficulties was to bring the lamp, and the power to light it, within the limits of portability. The first electric safety lamp evaded this difficulty by requiring that there should be a general source of current supply, from which, by means of strong flexible conducting cords extending between the lamps and fixed main wires, a great number of lamps could be fed. Here is a lamp such as would be used under those circumstances, and which has been used, to a small extent, in one or two pits. It consists of a bell of strong glass defended by a cage of wires enclosing a small incandescent lamp. The connection of the lamp with the flexible conductor is so arranged that the enclosure is completely air-tight.

It is obvious that this kind of lamp, whether fixed or tethered by a flexible conductor, does not meet all the requirements of coal mine lighting. The passages can, perhaps, to some extent, be lighted by fixed lamps of this type, and some of the workings by movable lamps—that is, movable to a limited extent, through their connection with the fixed main wires by flexible conductors. But the cost of such a system of partial lighting by electricity would be great. The electric mains would be difficult to maintain in the presence of frequent stone falls and other inevitable accidents, and there would be great waste of light if the system were thoroughly carried out to the exclusion of detached hand-lamps, because it would be necessary to constantly light many passages in which there was little traffic. A hand-lamp, detached and portable—more or less like the ordinary safety lamp—is therefore an absolute necessity. It is a lamp of this kind that I have striven to put into a practical form, and am about to show you. It consists of two parts, the lamp proper and the battery. The great difficulty was to make the battery small enough and light enough. But these requirements were complicated with others equally imperative. The battery must not be too expensive either to make or to charge. The last-named considerations excluded some combinations, which, in point of bulk and lightness, might perhaps have had advantages over the kind of battery I have chosen to adopt. The trouble and cost of every day emptying, refilling, and generally keeping in order several hundred cells of even the simplest and least troublesome of any known type of *primary* cell appeared to me to put that class entirely out of the question. I was thus forced to consider whether any form of *secondary* cell which would not require emptying and refilling could be so constructed as to meet the necessities of the case. It seemed to me possible, without excessive trouble or expense of any kind, to charge several hundred *secondary* cells by day. This presented little or no difficulty; but to reduce within practical bounds the bulk and weight of a battery of this kind, possessing sufficient power to maintain the necessary amount of light during the required length of time, was a thing by no means easy of accomplishment.

I found by comparing the weight and storage capacity of the most efficient of secondary combinations, namely, the spongy lead and lead oxide combination, which, fundamentally, is that of Planté, that I must be content with a moderate amount of light—with a candle or even less, and the lamp must be so made as to give this light with few cells and small current. By the help of a new kind of filament of exceeding fineness, and at the same time of great strength, I have obtained a lamp which probably requires less current than any lamp hitherto made, viz., ·14 of an ampere. With this current, and an electromotive force of about 12 to 13 volts, the light of half a standard candle is produced; and the energy necessary to sustain this small amount of power during ten or twelve hours can be stored in a set of cells neither too bulky nor too heavy for easy carriage in one hand. Here is the combined apparatus of battery and lamp. Its weight is 6¼lbs., the cylindrical case containing the cells measures 8 by 4 inches. Each of the seven cells composing the battery is constructed in this way:—The core is a lead wire surrounded by peroxide of lead. This is covered by a wrapping of cloth, outside which, and filling the space between the oxide cylinder and the interior lead lining of the containing tube, is a packing of lead filament—a beautiful material invented and manufactured by Mr. Cookson, of Newcastle. The lead filament is in contact with the lead lining, and that, with a strip of lead which forms one of the outward conductors, the lead wire forming the core of the oxide cylinder being the other conductor. The electrolyte is as usual dilute sulphuric acid; adhesion to the lead filament prevents the liquid from spilling if the battery is inclined to one side. The terminals are attached to two elastic strips of brass, and these hold the little lamp between them with a slight end pressure, and in such a simple manner that it is removable in a moment. The lamp is protected against external injury by a very thick glass bull's-eye, and light is economised by a silver reflector behind the lamp. Two sockets within the case provide the means of connecting the battery terminals with the charging circuit. There is also a switch of simple construction which enables the current to be turned off or on the lamp; the object of this is to avoid waste of current by keeping the circuit uncompleted until light is required. Contact is made and broken within a small cavity in the switch plate containing a single drop of oil. Even without this precaution, there is not the slightest danger of ignition of explosive gas by a spark produced at the switch on opening the circuit. The spark, on breaking the circuit, is exceedingly minute, so minute, indeed, as to be quite invisible to the naked eye; even in absolute darkness the aid of a lens is required to see it. But, as I have explained, the switch is so arranged that in turning the current off the lamp this minute, invisible spark will not be produced in contact with the atmosphere, but within a covering of oil, or rather there will be no spark, for it will be entirely suppressed. The switch

* Paper communicated to the Aberdeen Meeting of the British Association, September, 1885.

Digitized by Google

is perhaps a superfluous appendage, for if electric lamps were regularly used in a colliery they would be on the charging circuit until required for use, and might remain lighted until put on the charging circuit again. After charging the cells the lid, which has attached to it a carrying handle, is screwed on and locked in the usual way, and then there is no access to the battery without uulocking. A battery of this size, having an aggregate weight of nearly 5½lb., will yield a current of nearly ·14 of an ampere during 12 hours, with an average available potential of about 12 volts. There is a slight gradual fall of potential, the result of which is that the lamp is a little brighter when first lighted than after it has remained lighted some hours. I do not venture to count upon a greater amount of light from this current and potential than half a standard candle.

By reducing the time of lighting to eight hours, the current may be increased to $\frac{2}{10}$ths of an ampere, and with this current, $\frac{3}{4}$ of a standard candle can be obtained without raising the filament to too high a temperature, and, of course, by increasing the size and weight of the cells, still more light can be had. The arrangement for charging, say five hundred lamps, would neither be complicated nor costly. A dynamo of very moderate size, absorbing three to four horse-power, would be sufficient. The cells would be ranged on benches in front of fixed wires from the dynamo, and these would be so fitted with coupling plugs, that the connecting of several hundred batteries would be the work of a very short time. The cost of the renewal of the electric lamps would probably be about the same as the cost of filling, cleaning, and keeping in repair Davy lamps, and that I believe is about 2d. per lamp per week. The supply of oil for ordinary safety lamps costs another 2d. per week, and I think that sum would fully cover the cost of charging the batteries for the electric light. Here, then, is a miner's lamp to which the appellation of safety may be given without any reservation. Whatever its faults, and I am not so partial a judge as to be incapable of seeing them, this electric lamp possesses at least the capital merit of being absolutely safe; free, I believe, from even the suspicion of a possibility of causing an explosion of firedamp. If it is neither so light nor so cheap as the ordinary lamp, it is in both respects at least practicable, and especially is it to be noted that the working cost will probably not be more than that of the ordinary lamps. As regards weight, I am not without hope of being able to reduce it.

Besides its safety, there is one other advantage of occasional importance which this lamp possesses over oil lamps. Oil lamps require air more or less pure to support the combustion of the oil. This lamp requires no air; and there are, unfortunately, times after an explosion of firedamp, when the air of a pit is so foul that no oil lamp will burn in it. With a Fleuss apparatus for breathing, and the electric safety lamp for lighting, the work of exploration, which could hardly be otherwise accomplished, might be carried on, and this, it is reasonable to hope, would be attended with the saving of life.

CHEAP TELEGRAMS.

In anticipation of heavy work yesterday, owing to the coming into operation of sixpenny telegrams, special preparations had been made by the Postal Telegraph Department. An exceptionally large staff had been arranged for, and the two floors comprising the instrument rooms at St. Martin's-le-Grand were peopled by some 1,500 operators—male and female. The first sixpenny telegram came through at 12:4 yesterday morning, containing a congratulatory message, and telegrams of a similar nature were received by the Postmaster-General, the ex-Postmaster-General, Mr. Lamb (secretary of telegraphs), Mr. Fischer (comptroller), and a number of other gentlemen. Among the first telegrams despatched were a number of a highly-amusing character, some evidently the result of much thought on the part of the senders. Among the most amusing were "*Toujours à toi*, you can't expect more for sixpence," and "Awake this October morn, for tanner telegrams are born;" while one sender anxiously inquires, "Can you lend me sixpence?" and another, wiring to a telegraph clerk, hopes "the public won't come it too strong." One riddle, the answer to which has not yet been received, has also passed over the wire—"Why's a sixpenny telegram like a new-born child?" A large number of telegrams arrived in the course of the morning, each claiming to be the first sixpenny telegram from that place, while several consisted of "slangisms" hardly intelligible to the uninitiated. A notable feature of the occasion is the introduction of a new "phraseogram," which is not looked upon with great favour by the authorities. The most simple and expressive is "tannergram," and will doubtless come into equal popularity with "cablegram," which has for many years held its own.

By midday it was evident that the lowering of the tariff had attracted a large number of new patrons to the telegraphic wires. The increase in messages over the number ordinarily received was considerable. There can be no question that but for the extensive preparations made the staff would have been insufficient for the work to be done. The number of operators, however, was ample, and the large amount of work coming in was dealt with more rapidly perhaps than usual. The numerous new hands who have been recently taken on from the Telegraph School well maintained their reputation, and throughout the vast floors devoted to telegraphic instruments there was not a single person idle. Between the hour of twelve and one the increase was most heavily felt in the metropolitan district, where an increase of no less than 53 per cent. over the number of messages sent the day previous was experienced. An interesting feature was the proportion of messages which did not exceed the sixpenny rate, this being out of 1,000 messages 33 per cent. One point noticeable was the number of telegrams with insufficient addresses, a lesson to the public not to cut this important item too short. One message, having no fewer than twelve addresses, had five undeliverable ones, while numerous missives addressed to "Miss Jones, London," or "Mr. Smith, Birmingham," had to be laid aside. One energetic firm in the Midlands issued a telegram with numerous addresses, consisting of a request to "do something to support sixpenny telegrams and the sender." Throughout the morning the operating rooms were visited by a number of gentlemen experienced in telegraphy, among others Mr. F. E. Baines, C.B., Inspector-General of Mails, who viewed with evident interest the establishment of the proposal he made before Parliament some years ago to grant a sixpenny rate for telegrams. It may be mentioned that a large number of code addresses have been registered, three hundred applications having been received yesterday alone.—*The Globe.*

BRITISH ASSOCIATION MEETING, 1885.

ADDRESS TO THE CHEMICAL SECTION, BY PROF. HENRY E. ARMSTRONG, PH.D., F.R.S., SEC. C.S., PRESIDENT OF THE SECTION.

In the Chemical Section of the British Association for the Advancement of Science the advancement of chemistry throughout the British Empire must be a subject of commanding interest. Signs of such advancement are not wanting—the rapid establishment of science colleges in one after another of our large towns; the establishment of the Society of Chemical Industry, which now, only in the fifth year of its existence, numbers over 2,000 members; the granting of a Royal charter to the Institute of Chemistry; the changes introduced at the London University in the regulations for the D.Sc. degree; the report of the Royal Commission on Technical Education, in which the value to chemical manufacturers of advanced chemical knowledge is so fully recognised; the important conference on education held at the Health Exhibition last year; the recent agitation to found a teaching university in London with adequate provision for research—surely all these are signs that the value of higher education must and will, ere long, be generally recognised.

The neglect of chemical research in our British schools has often been forcibly commented upon—of late, especially, by an eminent past-president of this section, Dr. Perkin, whose opinion is of peculiar value, as he is not only world renowned as a chemist, but also as a manufacturer; indeed, as the founder of two distinct important chemical industries. There can be no doubt of the fact and of the dire consequences to our country of such neglect. How is it, then, that such pronounced complaints have been so coldly received; that hitherto they have produced comparatively so little effect, and such slight encouragement is being given to those who, notwithstanding the many difficulties in their way, have steadfastly devoted themselves to research work? I question whether the value of such work has yet been brought home to teachers generally, let alone the public. The *cui bono?* cry is almost invariably met by pointing to some discovery of great pecuniary value as the outcome of research. This argument educationalists very properly refuse to recognise. Too little has been said as to the cause of the neglect so bitterly and properly complained of. Hence it is that I propose again to take up what many may regard as a somewhat threadbare theme.

Everyone will agree with Prof. Sir Henry Roscoe, who in his address last year to this section said "that those who are to become either scientific or industrial chemists should receive as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than they should be *forced prematurely*"—the italics are mine—"into the preparation of a new series of homologous compounds, or the investigation of some special reaction, or of some possible new colouring matter, though such work might doubtless lead to publication." We must also all cordially agree with him that the aim should be, as he tells us his has been, "to prepare a young man by a careful and fairly complete general training to fill with intelligence and

Digitized by Google

success a post either as teacher or industrial chemist, rather than to turn out mere specialists, who, placed under other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained." If it were necessary to show that Sir Henry Roscoe is a believer in research in its proper place, ample proof would be afforded by his statement, "that, far from underrating the educational advantages of working at original subjects, he considers this sort of training of the highest and best kind, but only useful when founded upon a sound and general basis."

But I venture to think that something has to be added in order to completely define the position of those who deplore the slight amount of original work which is being done in British laboratories. We maintain that no one can really "*fill with intelligence and success* a post either as teacher or industrial chemist" who has not been trained in the methods of research; and that, owing to the neglect of research, the majority of students are of necessity trained in a narrow groove. The true teacher and the industrial chemist are daily called upon to exercise precisely those faculties which are developed in the course of original investigation, and which it is barely possible—many would say, perhaps with justice, it is impossible—to sufficiently cultivate in any other manner. In a works the *chemist* is scarcely required as long as all goes well. The quality of the materials used or produced can be controlled by purely routine processes of analysis by the works analyst, or by well trained laboratory boys. But things never do go well for any long period of time. Difficulties are always arising; obscure points have to be investigated; and, if the manufacturer understand his business, improvements have to be effected, which cannot be done unless the conditions under which he is working be understood, as well as the character of the changes which are taking place. Investigation is therefore necessary at every step. No amount of instruction, such as is ordinarily given, in the mere theory and practice of chemical science will confer the habits of mind, the acuteness of vision and resourcefulness required of an efficient chemist in a works, any more than the mere placing of the best tools in a workman's hands will make him a skilful operator.

Such being our position, we maintain that it is essential to make research an integral portion of the student's course in every college which pretends to *educate chemists*. It will not suffice occasionally to set a promising student to investigate, but a number of students, as well as the staff, must always be engaged in original work; in fact, *an atmosphere of research must pervade the college*. It cannot be too clearly recognised that it is this which characterises and distinguishes the German schools at the present time. The student does not learn so much from the one special piece of work with which he is occupied, but a number of his fellow students being also similarly engaged, the spirit of inquiry is rife throughout the laboratory; original literature is freely consulted, and they thus become acquainted with the methods of the old masters; vigorous discussions take place, not only in the laboratory, but also at the most useful institution, the "Kneipe;" the appearance of each new number of the scientific periodicals is keenly welcomed—in fact, a proper spirit of inquisitiveness is awakened and maintained, until it gradually becomes a habit. Probably there is less actual routine teaching done by the staff in the German schools than in our own. I am proud to own my indebtedness to one of them, and I can without hesitation say that I never truly realised what constituted the *science* of chemistry until I came under its influence.

But to realise the state which I have pictured—*to create an atmosphere of research in our science colleges in order that it may be possible for our students to obtain complete training in chemistry*, several things are required. In the first place, it will be necessary that the students come to them better prepared than they are at present; as a rule they are so ill prepared that it is very difficult, if not impossible, in the time at disposal to give such preliminary instruction as is indispensable before higher work can be attempted. Their mathematical knowledge is so ill-digested that it is more often than not necessary to begin by teaching simple proportion, and they look aghast at a logarithm table. They cannot draw—so far have we advanced in our civilisation that the subject is more often than not an "extra" in our schools. They understand a little French; but German, which may almost be called the language of modern science, is indeed an unknown tongue to them. I do not complain of their want of knowledge of science subjects, but of the unscientific manner in which they have been trained at school, and especially of the manner in which their intellectual faculties have become deadened from want of exercise, instead of developed and sharpened. Too many have never acquired the habit of working steadily and seriously; they have not learnt to appreciate the holiness of work*, so that they render the office of teacher akin to that of slave driver instead of to that of friend. What is perhaps worse is their marked inability, often amounting to downright refusal, either to take proper notice of what happens in an experiment or to draw any logical conclusion from an observation. Man is said to be a reasoning being, but my experience as an examiner and teacher would lead me to believe that this fact is altogether lost sight of by the average schoolmaster, who appears to confine himself almost exclusively to the teaching of hard dry facts, and makes no attempt to cultivate those very faculties which are supposed to characterise the human race; or he is so ill-prepared for his work that he fails to understand his duty. These are harsh words, but the evil is of such magnitude that it cannot be too plainly stated; those who, like myself, are brought full face to it fail in their duty if, when opportunity occurs, they do not take occasion to call attention to its existence.

Probably the only remedy—certainly the most effectual, and that which can be most easily applied—is the introduction of a *rational system* of practical science teaching into all our schools, whatever their grade; one effect would be that all the school subjects would of necessity soon be taught in a more scientific manner. I am not one of those who would eschew the teaching of classics, and I do not wish to see science teaching introduced into schools generally, in order that the students who come to me may already have gained some knowledge of science. Under existing circumstances I prefer that they shall not; but I desire its introduction because the faculty of observing and of reasoning from observation, and also from experiment, is most readily developed by the study of experimental science; this faculty, which is of such enormous practical value throughout life, being, I believe—as I have said elsewhere—left uncultivated after the most careful mathematical and literary training. No one has stated this more clearly than Charles Kingsley. We are told that, speaking to the boys at Wellington College, he said:—"The first thing for a boy to learn, after obedience and morality, is a habit of observation—a habit of using his eyes. It matters little what you use them on, provided you do use them. They say knowledge is power, and so it is—but only the knowledge which you get by observation. Many a man is very learned in books, and has read for years and years, and yet he is useless. He knows *about* all sorts of things, but he can't *do* them." This is precisely our complaint—the average schoolboy may know a good deal *about* things, but he can't *do* them. The ordinary school system of training does not, in fact, develop the "wits," to use a popular and expressive term for the observing and reasoning faculties; but it is certain that the wits require training. It is because the teaching of experimental science tends to develop the wits that those among us who know its power are so anxious for its introduction. This cannot be too clearly stated, the popular view—to judge from newspaper discussions—being apparently that science is to be classed with "extras;" that it is good for those who can afford it, but can be dispensed with by those who cannot. This undoubtedly is true of the "science" which is taught the specialist, and I fear even of much of the "science" which is at present taught in schools; let us hope that ere long other views will prevail when the object which it is sought to gain by teaching science is made clear.

While blaming the schoolmaster for his neglect, it must not be forgotten that the teaching of sciences in schools meets with comparatively little encouragement at the hands of our examining bodies and the universities. Again, examinations are too often entrusted to those who have no educational experience, and with most unfortunate results; in no case, probably, is inexperience so inexcusable as in an examiner. Too often, also, the examinations are in the hands of pure specialists, who take too formal a view of their duty, and expect from boys and girls at school as much as from their own students, who are older and devote more time to the work. Such examiners are prone to discourage science by marking too severely; and as their questions govern the teaching, instruction is given in schools without due reference to educational requirements, and in a purely technical style; this, I fear, is the effect of some of the universities' local examinations.

I have it on good authority, that the recent changes in the scheme of the examinations for admission at Sandhurst have forced one large school, well known for the attention paid in it to the teaching of science, to cease to give instruction in science to those of its pupils who propose to compete at these examinations, at once on their deciding to do so. Then, not only are the science scholarships at the universities few in proportion, but the great majority of students pass through their university career without being called upon to gain the slightest knowledge of physical science; yet, more often than not, the teachers are chosen from these. A large proportion become clergymen, and considering the demands upon them and the unbounded opportunities which they have of imparting useful information, there cannot be a doubt that to no other class of the community is a knowledge of natural science likely to be of more value.* Let us hope that the time is near when our universities will no longer be open to this reproach.† Whatever steps they may elect to take, it is before all things important that it be not forgotten that their main purpose must be to influence the schools, so that experimental science may be used as an educational weapon at the most appropriate time, and not when the faculties to be fashioned by it have become atrophied through neglect, as I fear is too often the case, ere the university is reached.

We must carefully guard against being satisfied with the mere introduction of one or more science subjects into the school curriculum; some of those who strenuously advocate the introduction of science teaching perhaps do not sufficiently bear this in mind. Chemistry, physics, &c., may be—and I fear are, more often than not—taught in such a way that it were better had no attempt whatever been made to teach them. I hold that it is of no use merely to set lads to prepare oxygen, &c., or to make experiments which please them in proportion as they more

* In my experience, the behaviour of ordinary day male students is, in this respect, particularly striking in comparison with that of female and evening students. The evening students come with a desire to learn, and the female students are invariably most attentive, and make the fullest use of the opportunities afforded them.

* "I sometimes dream," said Kingsley, "of a day when it will be considered necessary that every candidate for ordination should be required to have passed creditably in at least one branch of physical science, if it be only to teach him the method of sound scientific thought."

† I learnt with the most lively satisfaction, but a few days ago, that Dr. Percival, the late head-master of Clifton College, speaking at a meeting of Convocation at Oxford last term, said:—"If twenty years ago this university had said, from this time forward the elements of natural science shall take their place in responsions side by side with the elements of mathematics, and shall be equally obligatory, you would long ago have effected a revolution in school education." This remark elicited some warm expressions of approval. Dr. Percival, I am sure, has the cordial approval of all science teachers, and he will earn their gratitude, and deserve that of the public at large if he can succeed in inducing his university to take action in accordance with his enlightened views.

nearly resemble fireworks; and it is not the duty of the schoolmaster to train his boys as though they were to become chemists, any more than it is his duty to fit them to enter any other particular profession or trade; the whole of the science teaching in a school should be subservient to the one object of developing certain faculties. Unfortunately, two great difficulties stand in the way at present—viz., the want of suitable books and of a rational system of teaching science from the point of view here advocated; and the requirements of the universities and other examining bodies. Both books and examinations are of too special a character; they may suit the specialist, but do not meet educational requirements. I have already somewhat fully expressed my views on this subject in a paper read at the Educational Conference in London last year. Although much more might be said, I will only now call attention to the important service which we may render in removing these difficulties.

The reform most urgently needed, in which, as members of the community, not merely as chemists, we are all most interested, is the introduction of some system which will ensure a proper training for teachers. Engineers, lawyers, medical men, pharmacists, have severally associated themselves to found institutions which require those who desire to join the profession to obtain a certain qualification; even chemists are seeking to do this through the Institute of Chemistry. But schoolmasters, although members of what is probably the most responsible, onerous, useful, and honourable of any of the professions, have as yet neither made, nor shown any inclination to make, a united effort to ensure that all those who join their profession shall be properly qualified. Surely the time has come when the subject must receive full public attention; the country cannot much longer remain content that the education of all but those of its sons and daughters who come within the province of the School Board should be carried on without any guarantee that it is being properly conducted.

Glaring as are the faults in the existing school system, and although it rests with the universities and other teaching and examining bodies—if the public do not intervene—to prescribe a proper course of instruction for potential schoolmasters, and to enforce a rational system of training all the mental faculties, we science teachers may meanwhile do much by introducing more perfect methods into our own system of teaching. The students attending our courses belong to various classes; some will become chemists, and require the highest and most complete training; others will be teachers in colleges or schools; many will occupy themselves as consulting chemists or analysts; many others will have to take charge of manufacturing operations in which a knowledge of chemistry is of more or less direct importance and value; not a few will become medical men; and a large proportion, let us hope, will be those who have no direct use for chemistry, although the knowledge will be of great service to them in many ways. Among such we may include architects and builders, engineers, farmers, and even country gentlemen. Have we sufficiently considered the several requirements of all these various classes? I submit, with all due deference, that we have not! Our attention has been too exclusively directed to the training up of the future analyst; the instruction has been of too technical a character.

I know it is rank heresy to say so, but I maintain that in future far less time must be devoted to the teaching of ordinary qualitative and quantitative analysis, and that *technical instruction* as now given in these subjects must find its place later in the course. Our main object in the first instance must be to fully develop the intellectual faculties of our students—to encourage their aspirations by inculcating broad and liberal views of our science, not an infinite number of petty details. We must not merely teach them the principles and main facts of our science, but we must show them how the knowledge of those facts and principles has been gained; and they must be so drilled as to have complete command of their knowledge. The great majority will not be required to perform *ordinary* analyses, either qualitative or quantitative; it will be sufficient for them to have gained such an amount of practical experience that they thoroughly understand the principles of analysis; that they shall have learnt to appreciate the sacredness of accuracy; and that they shall have acquired sufficient manipulative skill to be able when occasion requires to carry into execution the analytical process which their text-books tell them is applicable, and even, if necessary, to modify the process to suit circumstances.

Chemistry is no longer a purely descriptive science. The study of carbon compounds and Mendeljeff's generalisation have produced a complete revolution. The faults in our present system are precisely those which have characterised the teaching of geography and history, and which are now becoming so generally recognised and condemned; in fact, no better statement of the manner in which I conceive chemistry should be taught could be given than by broadly applying to the teaching of chemistry what was said by Professor Seeley, at the International Conference on Education last year, in an important paper on the teaching of history.

The necessity for some change must, I venture to think, be patent to all thoughtful teachers, and especially to those who are called upon to fulfil the painful duties of an examiner. The railway book-stalls have made us acquainted with "Confessions" of all sorts, but if the "Confessions of an Examiner" were to be written they would be far more heart-rending than any. The examiner in chemistry, let him go where he will, scarcely dare ask a question to which the answer cannot be directly read out from a text-book. He will be told "that such and such a compound is formed by the action of so and so upon so and so," but he will usually find blank ignorance of the phrase "by the action of," and as to the mode of performing the operation. The examiner would, however, be bound to agree with the teacher that it is almost impossible to induce students to seek information outside the lecture room, and except in the ordinary cram text-books, and that it is hopeless to expect them to devote attention to anything unless it will pay in a subsequent examination; in fact, that the old university spirit of acquiring knowledge for its own sake is almost unknown among our science students. Herein lies one of the teacher's most serious difficulties, as he is more often than not bound to teach in a particular way, or to teach certain subjects, in entire opposition to his own views, in order to qualify his students to pass a particular examination. For example, many of our colleges now distinctly state that their courses are intended to qualify students to pass the examinations of the London University, and hence they are governed by the requirements of that university, which vary more or less as the examiners are periodically changed. The examiner, on the other hand, is often placed in a difficult position. It is clear to him that the system under which the students he is called upon to examine have been taught is a bad one; yet he feels that he has no right to set questions such as he honestly believes should direct the teaching into proper channels, because he knows that the teacher is immovable, and it is not fair to make the examinees the victims of a system for which they are not responsible. Hence, perforce, the teacher goes on teaching badly and the examiner examining badly. Difficulties of this kind are bound to make themselves felt at a transition period like the present, and will only disappear if we recognise the grave responsibility which rests upon ourselves and improve our methods of teaching and our text books. These, in too many instances, are unsuited to modern requirements, and are being made worse by stereotyping, and the practice which is gradually creeping in of merely changing the date on the title-page and the numeral before the word "edition," thus engendering the belief that the information is given up to date.

Both in teaching and examining two important changes ought forthwith to be made—our students ought at the very beginning of their career to become familiar with the use of the balance; and the imaginary distinction between so-called inorganic and organic compounds should be altogether abandoned. I do not mean that students should be taught quantitative analysis as ordinarily understood, but that instead of endeavouring to make clear to them by explanation only the meaning of terms such as equivalent, for example, we should set them to perform a few simple quantitative exercises in determining equivalents, &c. It can easily be done, and terms which otherwise long remain mythical acquire a real meaning in the student's mind. That the elements of the chemistry of carbon compounds do not find a place at a very early period in the course of instruction is one of those riddles connected with our system which it is impossible to answer. Attention was once pithily directed to the fact in my hearing by a scientific friend—not a chemist—who said he had often felt astonished that, although he had learnt a good deal of chemistry, the chemistry of the breakfast-table was practically a sealed book to him, common salt being the one object of which he felt he knew something.

I may here urge that there is one great error which we *must* avoid in the future, that of overworking our students, in the sense of obliging them to pay attention to too many subjects at a time. This is done more or less, I believe, in all our science schools, and medical students are peculiarly unfortunate in this respect. It is to some extent necessitated by the deficient preliminary education of our students; but I believe that I am justified in stating that it is also partly, perhaps mainly, due to the fact that the curriculum is too often imposed by lecturers who are directly interested in the attendance of students at their lectures. This is one of the great difficulties in the way of higher education, and the continuance of the evil is probably in a measure due to inappreciation of what constitutes higher education and culture; neither consist in a smattering of knowledge of a variety of subjects such as is too often required at present.

The more general appreciation of the value of science undoubtedly depends to a considerable extent on improvements such as I have indicated being introduced. When such is the case, we may hope that a large number of students will enter our chemical schools, not with the intention of becoming chemists, but because it will be recognised that the training there given is of high educational value, and that a knowledge of chemistry is of distinct service in very many avocations.

We may also hope that it will be possible ere long to teach chemistry properly to medical students. Seeing that the practice of medical men largely consists in pouring chemicals into that delicately organised vessel the human body, and that the chemical changes which thereupon take place, or which normally and abnormally occur in it, are certainly not more simple than those which take place in ordinary inert vessels in our laboratories, the necessity for the medical man to have a knowledge of chemistry—and that no slight one—would appear to ordinary minds to stand to reason; that such is not generally acknowledged to be the case can only be accounted for by the fact that they never yet have been taught *chemistry*, and that the apology for chemistry which has been forced upon them has been found to be of next to no value. No proof is required that the student has ever performed a single quantitative exercise; and I have no hesistation in saying that the examinations in so-called practical chemistry, even at the London University, are beneath contempt. After more than a dozen years' experience as a teacher under the system, I can affirm that the knowledge gained is of no permanent value, and the educational discipline *nil*. Here the reform must be effected by the examining boards. It is for them to insist upon a satisfactory preliminary training, and they must so order their demands as to enforce a proper system of practical teaching; and if chemistry is to be of real service to medical men more time must be devoted to its study. Physiological chemistry is taught nowhere in our country, either at the universities or at any of our great medical schools; let us hope that the publication of works like those of Gamgee and Lauder Brunton may have some effect in calling attention to this grievous neglect of so important a subject.

Having dealt with the educational aspect of the question, let me now briefly refer to some other difficulties which seriously hinder research. It has been more or less openly stated that the teachers in our chemical schools might themselves do far more. Is this the case? I do not think so. I believe it is not the staff, in most cases, who are primarily in fault.

Digitized by Google

Under our peculiar system of placing the government of science schools in the hands of those who have little, if any, experience as educationalists and a little knowledge of or sympathy with science, the appointments are sometimes made without the slightest reference to capability of inciting and conducting original investigation, and without any proof having been given even of a desire to promote higher education in the only possible way—by research; nevertheless, experience shows that, as a rule, fair use is made by teachers of their opportunities. The opportunities afforded us are indeed few. In the first place, the amount of actual routine teaching we are called upon to perform is very considerable, many of us having to conduct evening as well as day classes; and the work is often of the most harassing description, owing to the want of interest displayed by the students. The assistance provided is also too often inadequate, and much which should be done by assistants is therefore thrown upon the principals. Higher work under these conditions is practically out of the question, not so much because it is impossible to snatch at intervals a few hours per week, but because the attention is so much taken up in the preparation of lectures and laboratory and tutorial teaching that it is impossible to secure that freedom of mind and concentrated attention which are essential to the successful prosecution of research. Bad, however, as is often the position of the principals, that of the junior staff is usually far worse. During official hours they are entirely occupied in tutorial work, and what little energy remains must more often than not be devoted to coaching or literary work, to supplement the too modest income which the salary attached to their official position affords. Under these circumstances, it is remarkable that so much enthusiasm should prevail among them on the subject of research. The tradition which prevails in the German schools, that the junior staff are bound to find some time for original work, is almost unknown in this country, and too often difficulties are raised, rather than facilities afforded, when the desire is manifested; we do not, in fact, sufficiently honour the assistant as the potential professor. It has also often struck me as remarkable, and it must have struck others who understand the German system, that in this practical country we have not adopted that cheap luxury—the Privat-Docent, who costs nothing and exercises a most important function in promoting higher education. The explanation of this and many other anomalies lies in the fact that very few among us realise what a university is; a clear exposition of the Scotch and German systems would be of great value in these days of new universities and university colleges.

I believe that in most, if not all, of the German chemical schools a private research assistant is placed at the disposal of the professor. Will this ever be the case here? The want of material assistance is not only felt in this respect, however; few of our chemical schools are really efficiently equipped; most of them are seriously in want of larger and more expensive apparatus, of suitable specimens, &c.; the annual grant barely suffices for the purchase of the ordinary chemicals and the payment of unavoidable current exposnes, so that, as a rule, nothing remains to meet the expenses of research work, *i.e*, of higher education. In point of fact, nearly all of those who are engaged in research are doing so at their own expense; important assistance, for which we cannot be too thankful, is indeed received from the various research funds, but the proportion which the grants bear to the total sum expended is not large. I am sure we all recognise that each one of us is bound, according to his abilities and the opportunities he has, to add to the stock of knowledge, and that the keenest intellectual pleasure is derived therefrom; but it must not be forgotten that the results we obtain are very rarely of immediate practical value, and that as a rule *we* reap no pecuniary advantage. I venture to think, in fact, that it is remarkable that so much, not that so little, is done, and that reproach rests very lightly upon the profession in this matter. Whether our national pride will prevent our being much longer beholden to foreigners for by far the greater number of new facts in chemistry is a difficult question to answer, and must rest with the public.

The occasions on which we teachers of science subjects are able to bear witness in public are of necessity few. Deeply sensible, not only of the honour, but also of the responsibility of my position as President of this Section, I felt that it was my duty to avail myself of this opportunity. Being a teacher who is interested in teaching; being convinced of the existence of most serious faults in our educational system; feeling that the present is a most critical period, I have not hesitated to speak very freely. Some of the difficulties to which I have referred might soon disappear if science teachers generally would agree to consider them together, and I believe that it would be a very great advantage if an association for the discussion of educational questions were formed of the staffs of our science colleges throughout the country. The special difficulties which surround our science colleges, and prevent them from exercising their full share of influence upon the advancement of our national prosperity might also be removed at no distant date; but I see only one way of accomplishing this, and I fear it will hardly find favour—it is by their all becoming vested in the State. In this country we like to do things in our own way, and the objection will at once be raised that this would deprive all the colleges of their individuality, and would tend to crush originality and to stereotype teaching. If I thought so, I should never make the suggestion. But it would not, provided that complete academic freedom were secured to the staff, and each college were left to adjust itself to local requirements; efficiency would be maintained by the competition of the various colleges. Local enterprise, which has hitherto been trusted to, is clearly breaking down under the tremendous strain of modern educational requirements; some change must ere long be made.

I now pass to the consideration of a subject of special interest in this section, which I think requires the immediate earnest attention of chemists and physicists combined—that of *Chemical Action*. In his Presidential Address to the Association last year, Professor Lord Rayleigh made only a brief reference to chemistry, but many of us must have felt that his few remarks were pregnant with meaning, especially his reference to the importance of the principle of the dissipation of energy in relation to chemical change. A year's reflection has led me to think them of peculiar weightiness and full of prophecy. I would especially draw attention to the closing paragraph of this portion of his address:—"From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some foreshadowing, will come on this side. And if I might, without presumption, venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena."

Chemical action may be defined as being any action of which the consequence is an alteration in molecular constitution or composition; the action may concern molecules which are of only one kind—cases of mere decomposition, of isomeric change and of polymerisation; or it may take place between dissimilar molecules—cases of combination and of interchange. Hitherto it appears to have been commonly assumed and almost universally taught *by chemists* that action takes place directly between A and B, producing AB, or between AB and CD, producing AC and BD, for example. This, at all events, is the impression which the ordinary average student gains. Our text-books do not, in fact, as a rule, deign to notice observations of such fundamental importance as those of De La Rive on the behaviour of nearly pure zinc with dilute sulphuric acid, or the later ones of Faraday ("Experimental Researches," Series VII., 1834, 863 *et seq.*) on the insolubility of amalgamated zinc in this acid. Belief in the equation $Zn + H_2SO_4 = H_2 + ZnSO_4$ hence becomes a part of the chemist's creed, and it is generally interpreted to mean that zinc *will* dissolve in sulphuric acid, forming zinc sulphate, not, as should be the case, that *when* zinc dissolves in sulphuric acid it produces zinc sulphate, &c. In studying the chemistry of carbon compounds, we become acquainted with a large number of instances in which a more or less minute quantity of a substance is capable of inducing change in the body or bodies with which it is associated without apparently itself being altered. The polymerisation of a number of cyanogen compounds and of aldehydes, the "condensation" of ketonic compounds and the hydrolysis of carbohydrates are cases in point; but so little has been done to ascertain the nature of the influence of the contact-substance, or *catalyst*, as I would term it, the main object in view being the study of the product of the reaction, that the importance of the catalyst is not duly appreciated. Recent discoveries, however—more particularly Mr. H. B. Dixon's invaluable investigation on conditions of chemical change in gases, and the experiments of Mr. Cowper with chlorine and various metals, and of Mr. Baker on the combustion of carbon and phosphorus—must have given a rude shock, from which it can never recover, to the belief in the assumed simplicity of chemical change. The inference which I think may fairly be drawn from Mr. Baker's observations—that *pure* carbon and phosphorus are incombustible in *pure* oxygen—is indeed startling, and his experiments must do much to favour that "more minute study of the simpler chemical phenomena" so pertinently advocated by Lord Rayleigh.

But if it be a logical conclusion from the cases now known to us, that chemical action is not posssible between any two substances other than elementary atoms, and that the presence of a third is necessary, what is the function of the third body—the catalyst, and what must be its character with reference to one or both of the two primary agents? In the discussion which took place at the Chemical Society after the reading of Mr. Baker's paper, I ventured to define chemical action as *reversed electrolysis*, stating that in any case in which chemical action was to take place it was essential that the system operated upon should contain a material of the nature of an electrolyte ("Chemical Society *Proceedings*," 1885, p. 40). In short, I believe that the conditions which obtain in any voltaic element are those which must be fulfilled in every case of chemical action. There is nothing new in this; in fact, it practically was stated by Faraday in 1834 ("Experimental Researches in Electricity," Series VII." §§ 858, 859*); and had due heed been given to Faraday's teachings we should scarcely now be so ignorant as we are of the conditions of chemical change.

The questions—What is Electrolysis? What is an Electrolyte? are all important to the chemist, if my contention be accepted. Moreover, the

* "Those bodies which, being interposed between the metals of the voltaic pile, render it active, *are all of them electrolytes*, and it cannot but press upon the attention of everyone engaged in considering this subject, that in those bodies (so essential to the pile) decomposition and the transmission of a current are so intimately connected that one cannot happen without the other. If, then, a voltaic trough have its extremities connected by a body capable of being decomposed, as water, we shall have a continuous current through the apparatus; and whilst it remains in this state we may look at the part where the acid is acting upon the plates and that where the current is acting upon the water as the reciprocals of each other. In both parts we have the two conditions, *inseparable in such bodies as these*, namely, the passing of a current and decomposition; *and this is as true of the cells in the battery as of the water-cell*; for no voltaic battery has yet been constructed in which the chemical action is only that of combination; *decomposition is always included*, and is, I believe, an essential chemical part.

"But the difference in the two parts of the connected battery—that is, the decomposition or acting cells—is simply this; in the former we urge the current through, but it, apparently of necessity, is accompanied by decomposition; in the latter we cause decompositions by ordinary chemical actions *(which are, however, themselves electrical)*, and, as a consequence, have the electrical current; and as the decomposition dependent upon the current is definite in the former case, so is the current associated with the decomposition also definite in the latter."

Digitized by Google

consideration of chemical action from this point of view almost of necessity obliges us also to consider what it is that constitutes chemical affinity. I will not presume to offer any opinion on this subject; but I would recall attention to the prominence which so great an authority as Helmholtz gave in the last Faraday Lecture ("Chemical Society *Transactions*," 1881, 277) to the view held by Faraday, and which is so definitely stated in a passage in his "Experimental Researches"* (Series VII. 918, also 850 and 869).

Helmholtz used the words: "I think the facts leave no doubt that the very mightiest among the chemical forces are of electric origin. The atoms cling to their electric charges, and opposite electric charges cling to each other; but I do not suppose that other molecular forces are excluded, working directly from atom to atom." In the passages which immediately follow, this physicist then makes several statements of extreme importance, which directly bear upon the subject I desire to discuss, and which, therefore, I quote.†

The interpretation of Faraday's law of electrolysis which Helmholtz has brought under the notice of chemists is of the most definite and far-reaching character. Does it, however, at all events in the form in which he has put it forward, accord sufficiently with the facts as these present themselves to the chemist's mind? All will recognise that the chemical changes effected by a current in a series of electrolytic cells are equivalent to those which take place within the voltaic cells wherein the current is generated; but in neither case is the action of a simple character; in both a variety of chemical changes takes place, the precise character of which is but imperfectly understood, and we are unable to assign numerical values, either in terms of heat or electrical units, to most of the *separate* changes. Moreover, many compounds are not electrolytes, while others which are regarded by the chemist as their analogues are very readily decomposed by a current of low E.M.F., although no great difference is to be observed in their "heats of formation;" liquid hydrogen chloride on the one hand, and fused silver chloride on the other, may be cited as examples. Again, how are we to interpret on this theory such changes as that involved in the conversion of stannic into stannous chloride? The former, I suppose, is to be regarded as consisting of an atom of quadrivalent tin charged with four units of, say, positive electricity, and of four atoms of univalent chlorine, each carrying a unit charge of negative electricity; on withdrawal of two of the chlorine atoms, the residual $SnCl_2$ will have two free unit charges of positive electricity. We know that when the temperature is sufficiently lowered two such residues unite, forming Sn_2Cl_4, and it is not improbable that crystalline stannous chloride represents a still later stage of condensation. Is this compatible with the theory? That cases of this kind are contemplated would appear from the reference to "unsaturated compounds with an even number of unconnected units of affinity," which we are told may be charged with equal equivalents of opposite electricity; and also from the allusion to the existence of molecules of elementary substances composed of two atoms. It is more than probable that these anomalies would disappear on fuller statement of his views by the author of the theory; I have ventured to call attention to them in the hope of eliciting such statement.

Helmholtz tells us that electrolytes belong to the class of typical compounds, the constituents of which are united by "atomic affinities," not to the class of "molecular aggregates." Is this the fact? Before chemists can accept this conclusion many difficulties must be removed which appear to surround the question. In the first place, it is in the highest degree remarkable that, with the one single exception of *liquefied* ammonia, *no known binary hydride is in the liquid state an electrolyte*, liquid hydrogen chloride, bromide and iodide, for example, withstanding an E.M.F. of over 8,000 volts (8,040 De la Rue cells; Bleekrode). Water, again, according to Kohlrausch's most recent determinations, has an almost infinite resistance. Yet a mixture of hydrogen chloride and water readily conducts, and is electrolysed; an aqueous solution of sulphuric acid behaves similarly, although the acid itself has a very high resistance.* Very many similar examples might be quoted, but it is well known that aqueous solutions generally conduct more or less perfectly, and are electrolysed.†

(To be continued.)

* "All the facts show us that that power commonly called chemical affinity can be communicated to a distance through the metals and certain forms of carbon; that the electric current is only another form of the forces of chemical affinity; that its power is in proportion to the chemical affinities producing it; that when it is deficient in force it may be helped by calling in chemical aid, the want in the former being made up by an equivalent of the latter; that, in other words, *the forces termed chemical affinity and electricity are one and the same.*"

† "Several of our leading chemists have lately begun to distinguish two classes of compounds—viz., molecular aggregates and typical compounds, the latter being united by atomic affinities, the former not. Electrolytes belong to the latter class. If we conclude from the facts that every unit of affinity is charged with one equivalent, either of positive or of negative electricity, they can form compounds, being electrically neutral, only if every unit charged positively unites under the influence of a mighty electric attraction with another unit charged negatively. You see that this ought to produce compounds in which every unit of affinity of every atom is connected with one, and only one, other unit of another atom. This, as you will see immediately, is the modern chemical theory of quantivalence, comprising all the saturated compounds. The fact that even elementary substances, with few exceptions, have molecules composed of two atoms makes it probable that even in these cases electric neutralisation is produced by the combination of two atoms, each charged with its full electric equivalent, not by neutralisation of every single unit of affinity. Unsaturated compounds with an even number of unconnected units of affinity offer no objection to such an hypothesis; they may be charged with equal equivalents of opposite electricity. Unsaturated compounds with one unconnected unit, existing only at high temperatures, may be explained as dissociated by intense molecular motion of heat, in spite of their electric attractions. But there remains one single instance of a compound which, according to the law of Avogadro, must be considered as unsaturated even at the lowest temperature—namely, nitric oxide (NO), a substance offering several very uncommon peculiarities, the behaviour of which will be perhaps explained by future researches." The popular mistake is here made of assuming that elementary substances, with few exceptions, have molecules composed of two atoms. We now know considerably over seventy elements, but of these the molecular weights in the *gaseous* state of only thirteen have been satisfactorily determined. The gaseous elements hydrogen, oxygen, nitrogen and chlorine, and also bromine, iodine and tellurium, have diatomic molecules; phosphorus and arsenic have tetratomic molecules; those of sulphur are hexatomic, and selenium molecules are probably of similar constitution, but more readily broken down than those of sulphur; lastly, cadmium and mercury molecules are monatomic. It is more than probable that carbon, and also silicon and boron form highly complex molecules. Of the remaining undetermined elements, the greater number are metals, and it is not unreasonable to assume that many of these will be found to resemble cadmium and mercury in molecular composition. It is clear, however, that at present we have no right to say that the elementary molecules are, as a rule, diatomic. It would assist in removing this error if chemists would consistently place *after* the symbol the numeral indicating the "atomicity" of the elementary molecule—thus, Hg_1, Cd_1, O_2; and if in all cases when a numeral is absent, or is placed *before* the symbol, it were understood that advisedly no indication of the molecular state is afforded.

* It is more than probable that the most nearly pure sulphuric acid which can be obtained is not homogeneous, but is at least a mixture of H_2SO_4, $H_2S_2O_7$ and "hydrated compounds" in proportions depending on the temperature, and hence that (pure) sulphuric acid, H_2SO_4, like water, would behave as a dielectric.

† On the other hand, it is remarkable that, whereas liquefied ammonia may be electrolysed, an aqueous solution of ammonia is a most imperfect conductor (Faraday, F. Kohlrausch), although solutions of ammonium salts compare favourably in conductivity with corresponding sodium and potassium salts. This fact serves *somewhat* to allay the suspicion that Bleekrode did not take sufficient precautions to dry the ammonia; but his result cannot, I think, be accepted as final, on account of the relatively high E.M.F. required, and the repetition of the experiment, with every precaution to ensure purity of the gas, is most important. Faraday regarded the decomposition of ammonia on electrolysis of its solution as merely the result of secondary action.

The Anglo-American Brush Electric Light Corporation

(Limited). Offices and Works: 112, BELVEDERE ROAD, LAMBETH, S.E.

TELEGRAPHIC ADDRESS: "MAGNETO," LONDON.

PATENTEES AND MANUFACTURERS OF APPARATUS FOR THE

BRUSH System of "Arc" Lighting, which is the only one which has stood the test of years of hard work, and by which an extended and economical lighting is rendered possible.

BRUSH-VICTORIA Compound-Wound Self-Regulating Dynamos, as supplied to Her Majesty's Naval, Military, and Civil Departments.

BRUSH-VICTORIA Incandescence Lamps, with the new pure homogeneous filament.

BRUSH-SELLON "Arc" Lamps, for outdoor and indoor lighting, to give a pure, steady, and unvarying light.

BRUSH CARBONS have been further reduced in price, and are now not only the cheapest carbons to burn but the cheapest to buy in the market.

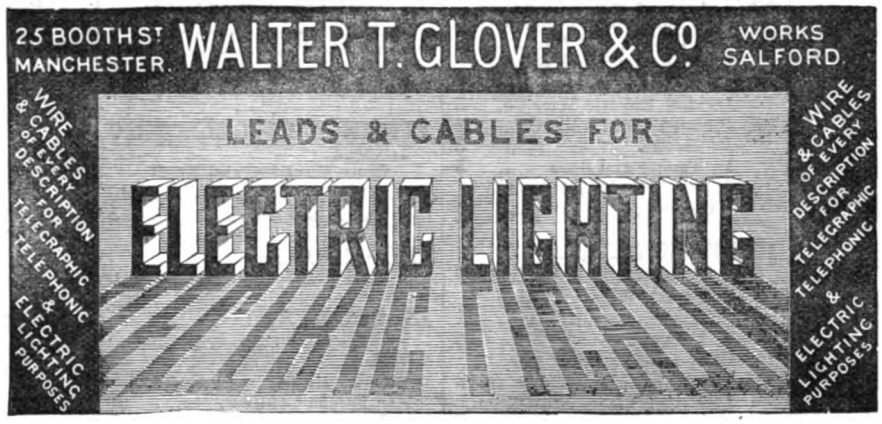
WIMSHURST Influence Machines, for the absorption and deposition of fumes and dust. Manufactured under the personal supervision of the Inventor.

The process of manufacture known as COMPOUND WINDING is covered by Patent No. 2003 of 1878, granted to Mr. H. J. Haddan as agent for Mr. Charles Francis Brush, which patent is the property of the Anglo-American Brush Electric Light Corporation. The public are warned against purchasing any compound wound dynamo electric machines other than those manufactured by the Corporation or their licensees.

The Corporation are prepared to furnish, on application, estimates for Electric Lighting of every description, public and private, and also to carry out complete installations of the Electric Light in the Metropolis and elsewhere.

SILVER MEDAL INTERNATIONAL ELECTRIC EXHIBITION. 1882.

ESTABLISHED 1868.



25 BOOTH ST MANCHESTER.

WORKS SALFORD.
LEADS & CABLES FOR
ELECTRIC LIGHTING
WIRE & CABLES OF EVERY DESCRIPTION FOR TELEGRAPHIC TELEPHONIC & ELECTRIC LIGHTING PURPOSES
WIRE & CABLES OF EVERY DESCRIPTION FOR TELEGRAPHIC TELEPHONIC & ELECTRIC LIGHTING PURPOSES

ESTABLISHED 1868.

Contractors to H.M. Postmaster-General, the Indian Government, the principal Railway, Telephone & Electric Light Companies.

MANUFACTURERS, BY PATENT PROCESSES, OF

GLOVER'S PATENT COVERED IRON WIRE FOR AËRIAL LINES.

Glover's Patent Covered Gutta Percha Wire for Leading-In, Tunnel, and Underground Work. Fancy Telephone Wire and Terminal Cords. Silk and Cotton Covered Wire of all classes. Special Makes of Electric Light Leads, Cable and Multiple Wire for the Various Systems.

All Classes of AËRIAL AND UNDERGROUND CABLES, AND SPECIAL ANTI-INDUCTION CABLES FOR THE TELEPHONE.

WALTER T. GLOVER & CO.,

ELECTRICAL WIRE AND CABLE MAKERS,

SALFORD, MANCHESTER.

WORKS: { Bridgewater Street, Broughton Road. / Salford Electric Wire Works. / Springfield Lane Cable Works. } SALFORD.

ELECTRICAL POWER STORAGE COMPANY, Lim.

Offices: 4, GREAT WINCHESTER STREET, E.C. Works: MILLWALL, E.

Telephone Nos.—Office, 338; Works, 5,116. Registered Telegraphic Address—"STORAGE," LONDON.

Sole Manufacturers of } **THE "E.P.S." ACCUMULATORS** { Sole Manufacturers of

(Faure, Sellon, Swan, Volckmar, and other Patents),

FOR ELECTRIC LIGHTING ON INCANDESCENT OR ARC SYSTEM, OR FOR MOTIVE POWER.

The only GOLD MEDAL awarded for improvements in ACCUMULATORS at the International Inventions Exhibition was given to this Company.

Manufacturers of Electrical Tramcars, Launches, and Hoists, Motors and Propelling Gear; also Main Distributing Switch Boards, Fittings, and Automatic Switches for Installations.

ELECTRIC LIGHTING FOR BALLS, DINNER PARTIES, &c.

CONTRACTORS FOR THE COMPLETE INSTALLATION OF THE ELECTRIC LIGHT IN PRIVATE HOUSES.

THE INTERNATIONAL INVENTIONS EXHIBITION.

Dynamo-Electric Machinery.

BY W. M. MORDEY.

The Brush Dynamo.—About eight years ago, when this well-known dynamo was designed, electric lighting may be said to have been in its infancy. At that time public attention had not been seriously drawn to the subject in its practical and commercial aspects. The supply of electricity and what was called the "subdivision of the electric light" had not become burning questions, even to electricians. Men very prominent in physical science—even specially in electrical science—were to be found who knew practically nothing about it. When an arc light was required it was nearly as likely to be supplied by a Grove or Bunsen battery as by a dynamo or magneto machine. And if supplied by the latter it was thought a very fine thing when a fair arc light was kept in operation for a whole evening. Electric arc lamps or "regulators," as they were called, existed in no great variety, and few possessed qualities demanding admiration. The importance of the great principles of the economy of high tension working had not been perceived—the principles themselves had not been formulated. It was a time when scientists convinced themselves and others, by the aid of abstruse calculations, that copper conductors of enormous thickness would be required to electrically transmit a few hundred horse-power from Niagara to New York. The incandescent lamp had not taken practical shape. Edison was still experimenting with platinum and iridium, and Swan was making no outward or visible sign. But chaos was soon to give place to comparative order. Much useful work was being done quietly in laboratory and workshop by many men. Among them, Brush in America, and Jablochkoff in France had developed their arc light systems, which, although entirely differing in general principles as well as in details, each succeeded in producing for the first time, from one machine, a considerable number of arc lights of moderate power. We need not compare these two systems. Their relative values may fairly be estimated on the basis of the success each has achieved. In one respect these earliest arc light systems resembled each other—they were launched on the world in a state of completeness which allowed of immediate application.

In the system which, in its most important part, the dynamo, we have to consider, there was a singular absence of variation or development as years went on. Brush saw clearly that in order to make arc lighting successful and practical a wide distribution of arcs of moderate power from a common centre was necessary, and that this could only be economically effected by the use of high tension and small current. He saw that it was most important that the dynamo should possess such qualities as certainty of action, the power to run continuously, accessibility, and ease of partition, and that highly skilled labour in connection with this and every other part of the plant should not be necessary. Consequently, he gave the dynamo a sound mechanical character, reduced the necessity for attention to a minimum, and designed the commutator—the only wearing part—in such a way that the wearing segments could be immediately replaced when required. This done, he designed machines of different sizes, all on the same lines, capable of supplying various numbers of lamps. An arc lamp which would work under almost any conditions, and which was eminently adapted to meet the conditions of the circuits, was added, and the system was at once a technical success. Brush was satisfied for the time with having the most perfect mechanical generator of electricity, and at having arrived at an economy of application of electricity far beyond anything that had hitherto been effected, by means of the high tension which was for the first time made available; and hence the large number of lamps and vastly improved distribution of light by means of one small lead. "Efficiency of conversion" was at the time quite a secondary object; in fact, the term had not then been coined, and the idea it expresses was perhaps scarcely in existence in connection with electrical machines.

Facility of manufacture was secured by rigidly adhering to stereotyped forms, allowing nothing to interfere with routine production in the workshop, or with the interchangeability of parts in the plant. Thus for a long time a dynamo was produced which maintained its form unaltered, even in detail, for several years; and the first great improvement in the form of a new wrought-iron laminated armature came into existence, not so much perhaps as a new invention as a natural growth, after a period of six years from the first introduction of the complete Brush system.

A specimen of the Brush machine with the improved armature was working in the electric light shed during the whole of the Health Exhibition last year. This year two of the improved machines, and one of the old type are working in the shed; in addition to which the Brush Corporation exhibit at their stall in the East Arcade skeleton armatures of both the old cast-iron and the new laminated wrought-iron forms, partly wound, and in a state which affords the best means of comparison of the two types.

The old form of armature is well known. It consisted of a ring of cast iron, grooved on the sides and periphery, and with spaces, or "pockets," as they are called, having parallel sides for the reception of the coils. Fig. 4 shows a portion of one of these armature cores.

Fig. 2.

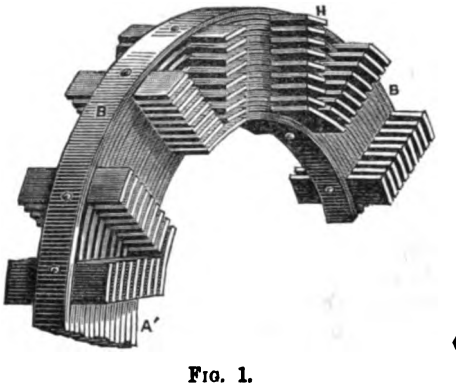

Fig. 1.

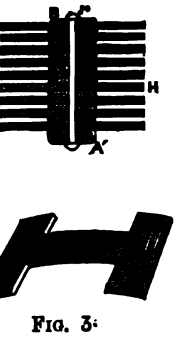

Fig. 3.

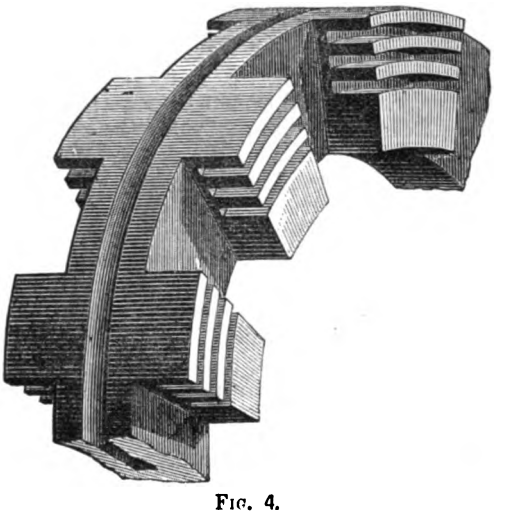

Fig. 4.

The new armature, the construction of which is shown in Figs. 1, 2, and 3, is the same in general outline as the old one, but it is formed by winding up a volute spiral of iron strip or ribbon (B, Figs. 1 and 2) on an inner iron foundation ring of suitable strength (A', Figs. 1 and 2). Between the successive turns or convolutions of the ribbon, and held by them as the process of construction is carried out, are H-shaped pieces of sheet iron (Fig. 3) of the same thickness as the ribbon, the ends of the parallel portions of these H-shaped pieces forming "Pacinotti projections" passing out from the core between the several

Digitized by Google

coils, and approaching closely to the pole pieces. These pieces are secured by radial rivets (*r*, Fig. 2) to prevent movement on their part, and to strengthen the armature as a whole. The figures are, for the sake of clearness, purposely rather diagrammatic, and on that account give an incorrect idea of the thickness of the plates, and of the degree of lamination. As a matter of fact, the iron is very thin, and the number of pieces employed is very much greater than shown by the figures, which, however, serve to give a correct idea of the mode of construction.

The improvement effected by the new armature is entirely due to the almost complete elimination of eddy currents. The sizes of the various armatures are the same as before, and the winding is unaltered. In the old armature, although the iron was almost severed by the deep grooves cut or cast in it, there were in some places solid masses of metal of considerable size, and nowhere did the grooving produce anything approaching the fine lamination which is necessary if the eddy currents are to be prevented.

The gain obtained by the use of the laminated armature over the old form amounts, as far as output is concerned, to as nearly as possible 50 per cent. at the normal working speed of the machines. It may, however, be better expressed by taking the case of one of the new as against one of the old armatures, and finding the various gains. Thus the new laminated armature does the normal work of the old one with a 34 per cent. decrease in speed, a decrease in power absorbed of over 20 per cent., and an increase in "commercial efficiency" of 15 per cent.

It will be seen that one result of the alteration is a large increase in the surface of the iron exposed to the air. There is an advantage in this, inasmuch as it allows of an extremely rapid dissipation of heat. So good is the ventilation that it would enable the armature to work and to keep moderately cool with a far greater loss in heat caused by eddy currents than is the case even with the old solid armatures; and it will, therefore, readily be imagined that this increased ventilation obtained by the new construction, where so little facility is offered for the generation of these currents, enables the armature core practically to keep "cold." The increased ventilation is incidental to, but is not a special object of, the improvement; and it could, in fact, very well be dispensed with. "Prevention is better than cure" is an adage that applies forcibly to the subject of heat loss in dynamos; and, at the best, getting rid of heat by good ventilation is an unsatisfactory way out of the difficulty. Ventilation may cause heat to be dissipated, but it cannot increase economy (except very slightly, by its effect on the resistance of the wire); therefore, we see that the gain in economy is not, and cannot be, the result of ventilation. This gain is caused by the "prevention" and not by the "cure" of what was the occasion of the loss.

As the writer has facilities for experiment with these dynamos, he is able to give some of the results of tests which he has made.

In Fig. 5 three curves are given, which show at a glance the output of the machines. The curves were constructed by working the machines at various speeds; the external circuit in each case consisting of open resistance coils of iron wire of such a size that the temperature was not much raised by the current which traversed them.

The temperature of the coils is, of course, not a point of any importance as far as the output of the dynamo is concerned, as smaller wire obtaining a much higher temperature would serve the purpose; but in small wire the variations of resistance due to changes of temperature are so large that more adjustment is required to obtain any required quantity, and experiments cannot therefore so readily be carried out. Measurements of this kind are made with the greatest facility when the value of resistance is least altered by the passage of the current. In these experiments the resistance was arranged at each speed so that the current was 10 amperes, this being the normal working current of the dynamos. The difference of potential at the terminals was then taken by an Ayrton and Perry voltmeter, into the circuit of which resistance could be introduced to render it suitable for measuring the high potential maintained. In the case of the larger machines nearly 3,000 volts were measured in this way with considerable accuracy, as checked by taking the product of current and resistance. In Fig. 5 ordinates are difference of potential at terminals, abscissæ being revolutions. As the current was 10 amperes throughout, ordinates may also be taken to represent watts (E × 10). The lower curve, A, is that of an old type armature; B is the curve of the improved armature of American construction; and C shows the results obtained in the latest form of armature constructed in the works of the Brush Corporation in London, the output in this latter being higher than that given by the American machines, as a result of some modifications introduced on "this side." These curves were all taken with the same field magnets, the armatures only being different. The dynamo was size No. 7, the old "16-lighter," the diameter of the armature being 20 inches.

If taken comparatively instead of actually the curves almost equally well express the results obtained with the other sized machines, the relative heights of the ordinates giving the comparative output in volts or watts for any speed.

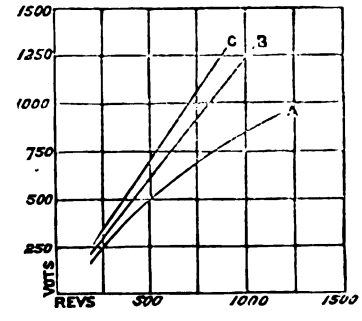

FIG 5.

There is a striking dissimilarity in these curves which demands some explanation. It will be noticed that B and C are straight lines—they are not "curves" at all—while A, the curve of the solid armature, has a decided bend in it, the relative output falling away rather rapidly as speed is increased. There is no such falling off in the lines B and C, and it may be interesting to mention that the writer has run one of these armatures up to a most unsually high speed to ascertain whether any turning down of the curve takes place under such circumstances, with the result that even at speeds altogether above the limits of practice no indication was found of any such tendency. It is not difficult to trace the cause of the fall of the curve C. It is not due to saturation of the field-magnets, because the current being constant at one value the excitation is the same throughout. It is certainly not a result of any extension of the "lead" produced by increase of speed. There is no such thing as an alteration of lead from this cause, and it is noteworthy that the position of the brushes is the same throughout the whole range of speed as long as the current is maintained constant. This matter of the supposed relation of speed to displacement of the brushes was experimentally examined by the present writer some time ago with reference to the Brush dynamo, as well as to machines of another type,* and it may be well to mention that the experiments with the new machine fully bear out the conclusions arrived at as a result of that inquiry. Neither is the fall in the curve the result of any increase in the current collected from the armature, which, of course, is constant. Such an increase, if it took place, would produce this effect; but another explanation must be sought, and we are left with the only remaining one, viz., that it is caused by the demagnetising action of our old foes the eddy currents, which, being generated in masses of iron of low resistance, attain a large value when the E.M.F. to which they are due rises with the speed. It might be thought that in the laminated armature the same thing would occur if only to a small extent, but as experiment does not bear out this expectation it must be assumed that in it, even at the highest speeds, the effect is not sufficiently prejudicial to be perceptible.

* See Prof. Thompson's "Dynamo-Electric Machinery," pp. 396-398.

Digitized by Google

It will be evident from what has been stated above that the gain in output costs very little. And this point is one of very considerable importance, not only in this improvement of Brush's, but in all armatures of any allied type. It shows how strong is the reaction between eddy currents and the currents in the conductor proper. In eliminating eddy currents in the iron, not only is the waste of energy due to those currents avoided, and the machine made more economical in consequence; but the E.M.F. in the conductor is increased, and the machine is made capable of doing more work, or of doing the same work at a lower speed than before. These results show that there has been, as it were, a transfer of work from the armature to the external circuit, that the energy which previously was being wastefully expended in producing currents which heated and tended to demagnetise the iron of the armature is now, without any increase of speed, producing results which appear as heat and light in additional lamps on the external wire.

Two of the three Brush dynamos used at the Exhibition are constructed to yield a current of 20 amperes, for the purpose of feeding arc lamps of greater power than those usually employed in the Brush system, which, as is well known, are worked with a current of 10 amperes. This doubling of the current is readily effected by merely altering the connections of the machine, and without any modification in the winding. As ordinarily connected, the coils, which are diametrically opposite one another, are joined in series, each of the two ends of the double coil being connected to a commutator plate. By joining each pair of coils parallel, instead of in series, the E.M.F. is halved and the current is doubled. Similarly, instead of connecting the four field-magnet coils in series, as is done with the 10-ampere dynamos, they are joined in the 20-ampere machines in question in multiple series, two and two, thus retaining their normal excitation. Figs. 6 and 7 show the

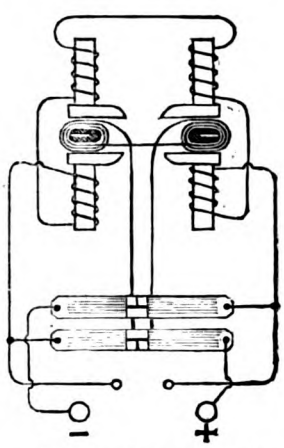

FIG. 6.—Connections for 10 amperes.

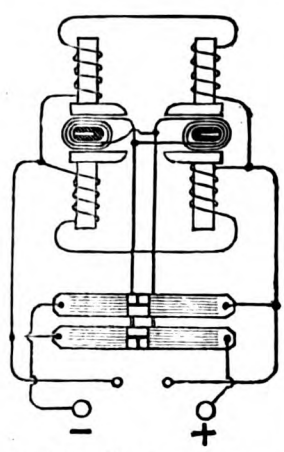

FIG. 7.—Connections for 20 amperes.

connections of the machine in the two cases. The effect on the resistance of the alteration from 10 to 20 amperes is to reduce it to a quarter of what it was, the internal loss, of course, remaining exactly the same as before; in fact, the power consumed and the work done in every part of the dynamo remains unchanged, the difference being one not of output, but only of the form in which the electrical power is delivered to the external circuit.

It is worth while to glance at the effect of this change in the form of the power, because it illustrates so well the cardinal fact of the practical economy of the method of working with small currents, a point which is now, happily, generally recognised. If it be required to light a given street with arc lamps, and to expend as loss in the leads not more than a certain percentage of the energy obtainable from the dynamo; and the choice rests between a certain number of 10-ampere arcs, or half that number of 20-ampere arcs, the section of the copper conductors in the latter case, and therefore their weight, must be four times as great for the latter case as for the former. This means in practice at least a fourfold increase in the cost of conductors in deciding in favour of 20 rather than 10 amperes.

The important question of the automatic regulation of dynamos is one which has recently attracted a great deal of attention, and deservedly so, since it is one of considerable importance. In the future the working conditions of circuits will be, to a much greater extent than in the past, varying conditions. Instances where the supply is required to be constant during the whole period of working, and where these requirements may be met by engines ordinarily governed, are becoming relatively rarer every day. Sensitive electrical automatic regulation of engine or dynamo, or of both, to supply the wants of varying circuits, are necessities of the great majority of the installations with which electrical engineers are now concerned. In a previous article* the writer dealt briefly with some of the conditions of this question, and gave a short account of the directions in which inventors had principally worked in their efforts to obtain automatic regulation. Leaving out of account regulation by alteration of speed, which is only practicable where a separate engine can be used for each circuit, and methods of winding or "compounding," which necessitate a steadiness of speed unfortunately by no means common, the conclusion arrived at bearing on the subject before us was that regulation "in series dynamos is best accomplished by

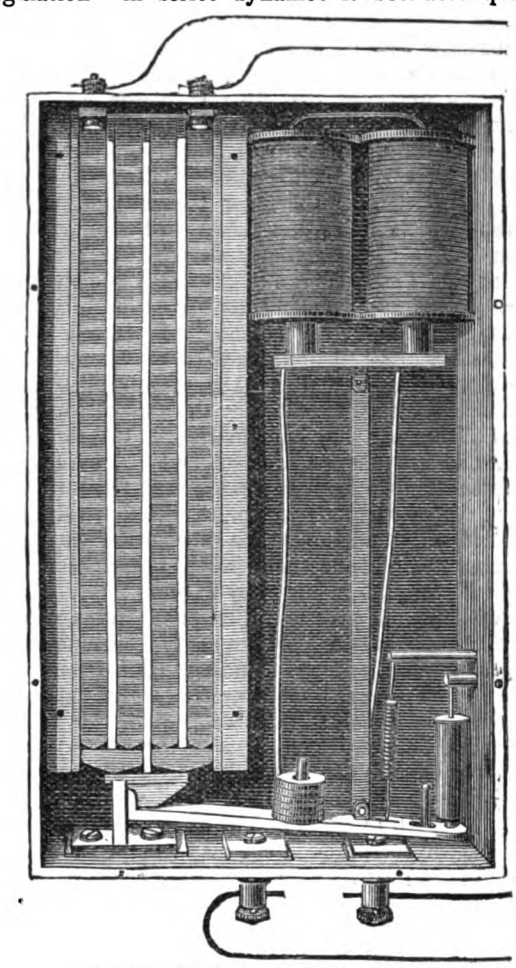

FIG. 8.—Brush Automatic Regulator.

employing a variable shunt placed across the terminals of the field magnet coil. . . . . The resistance should be capable of perfectly gradual variation, such as may be obtained by the compression of carbon, or by the use of a liquid resistance with movable electrodes." This principle has the advantage that it enables a saving to be effected in the work done in the field-magnet coils, as well as a reduction of any loss in the iron of the armature as the load is reduced.

The Brush Automatic Regulator, which is exhibited at the Corporation's stall in the East Arcade, is based on the above-mentioned principle. Fig. 8 illustrates the instrument used to regulate the No. 8 Brush dynamo, the new form of which supplies from 55 to 60 arc lamps in series. This instrument

* Supplement to *The Electrician*, July 31, pp. 22, 23.

Digitized by Google

is very simple in construction. Two solenoids, which will be seen in Fig. 8 on the right, are placed in the circuit by means of the two terminals at the bottom of the case. Projecting into these solenoids are the two limbs of a U-shaped core of soft iron, which is attracted and drawn more or less into the solenoids when the current is passing. This iron core is connected by a long connecting-rod of brass to a lever of the second order, the fulcrum of which is a short standard provided at the top with a knife edge, on which one end of the lever rests. Near the fulcrum an adjustable screw (not shown), tapered to a point at the upper end, passes vertically through the lever, supporting a block which receives the weight of four parallel columns, each column consisting of a great number of thin plates of carbon about 1in. square. These columns are separated from each other by strips of slate, but at the top and bottom are connected by small slabs of carbon which join the four columns in series. At the top of the case are two screw terminals, to which are attached wires leading to the ends of the field-magnet circuit. These two terminals make contact respectively with two fixed blocks of carbon, against which, when the lever is raised by the action of the solenoids, the tops of the right and left carbon piles or columns press. A dashpot is provided for the purpose of checking sudden movements of the lever; and a spiral spring capable of being varied, together with some small weights placed on the lever, are used to facilitate adjustment of the instrument.

It will be observed that this regulator contains only a small number of parts, and is everywhere accessible for examination. Its action will be readily understood. When no current is circulating in the solenoids the lever is not raised, and in this position of the lever the piles of carbon do not touch the two fixed carbon blocks attached to the screw terminals. When the dynamo is working with a normal current, as when it is operating its full complement of lamps at full speed, or any smaller number at a suitably reduced speed, the strength of the solenoids is insufficient to raise the core and its attached lever, or only sufficient to very slightly raise them; and as the carbon piles under these circumstances are open-circuited by the gaps between them and the fixed pieces, the full current circulates through the field-magnets. But when lamps are switched out of circuit, or the speed of the dynamo from any cause is allowed to increase, a slight increase of current takes place, the core is drawn further into the solenoids, and the carbon piles are raised by the lever, being brought into connection with the upper terminals, which, as already explained, are joined by wires to the ends of the field-magnet winding. Thus the carbon piles are made to form a shunt on the fields. A portion of the current now passes through the carbon, and the field strength is thereby reduced until the normal current is again arrived at. The variation in the resistance of the carbon shunt necessary for the regulation of the current throughout the whole working range of the dynamo is obtained by means of the pressure exerted on the columns by the solenoid and its connected lever; this compression being automatically maintained at that which is necessary to give the proper excitation of the magnets for the requirements of the circuit. When from any cause the current tends to decrease, the core is slightly lowered, the pressure on the carbons is reduced, the resistance in consequence increases, as does also the field strength, until the proper current is obtained in the external circuit. Similarly, any tendency toward an increase of current, by a series of reverse actions to the above, is checked and corrected.

The use of a regulator of this sort is often a great convenience. In the case of the alteration of the number of lamps in circuit it is especially so, since it enables the dynamo to be run by an engine which is doing other work, and which on that account cannot have its speed altered. It is also very useful in maintaining a constant current with an irregular driving speed, in many cases enabling the electric light to be supplied in factories and other places where the employment of a separate engine for this purprse is objected to on account of its first cost, and the expense of attendance and maintenance. An exceptional case may be mentioned. A dynamo was supplied to be driven by an engine whose speed as a result of its special work varied in a regular pulsation to the extent of 40 per cent. The dynamo was to feed a certain number of lamps which were required to be steady. By so arranging the driving that, at the lowest speed of the engine, the machine was able to supply the proper current to the lamps, and by connecting an automatic regulator in the circuit, the difficulty was overcome, and the installation was successfully carried out.

Another point in connection with the Brush apparatus, and one which is attracting some attention at the present time, is the peculiar construction of dynamos for the electro-deposition of metals patented seven years ago by Mr. Brush. We are not concerned in this article in any question of patent rights or priority of invention; but it may be interesting to examine into the character of the effects produced in these machines, especially as, so far as the writer is aware, no results of electrical tests have hitherto been published.

It is doubtless well known that the Brush electro-plating dynamos have for some years been constructed on the principle described in the patent alluded to above, which is now known as "compound-winding." That is to say the field-magnets have been wound with two wires, one a conductor of large section, connected, as is customary in series dynamos, in the main circuit in series with the armature and external circuit; the other a comparatively long and fine wire known, according to the American technical phraseology, as a "teaser"—connected directly to the brushes as is usual in shunt machines, or, as a modification, to the terminals of the machine.

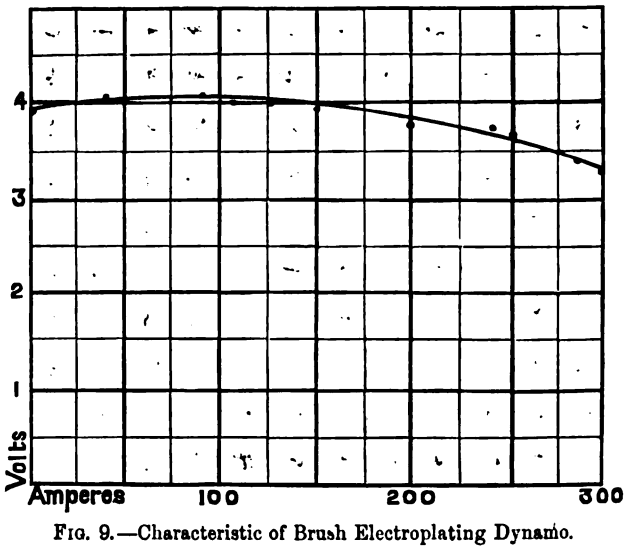

FIG. 9.—Characteristic of Brush Electroplating Dynamo.

One of the objects of this mode of construction, as stated in the patent specification, was to enable the dynamo to do either a large or small amount of work. Now in an electro-plating bath, where all the articles to be plated are connected parallel, the requirements of the case demand that the difference of potential between the electrodes should be as nearly as possible constant, in order that the character of the deposit may be uniform, however the number of articles in the bath may vary; or, in other words, whatever the amount of current flowing. This constancy of potential was not then even approached with shunt machines nor with series machines, which latter are also objectionable on other grounds for this kind of work. The two systems of winding will, however, in combination produce the required results, as is now perfectly well known.

Fig. 9 is the "characteristic" of a small Brush plating dynamo, intended for the deposition of copper, manufactured several years ago. This curve shows that, although the machine might not compare favourably with the latest results obtained in compound winding, its maker had succeeded to a remarkable extent—considering the period—in preventing the great variation of potential which would have been caused by alterations of the load in the machines as ordinarily constructed. Indeed, there are many "compound" dynamos in use, constructed even within the last two years in this country, which are characterised by curves no better than that of this old American plater.

NOTES.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 2nd inst. amounted to £3,148.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending 30th September amounted to £3,680.

PERSONAL.—Advices from Cairo state that Mr. Floyer, Inspector-General of the Egyptian Telegraphs, returned on the 6th inst. from the recent Telegraph Conference at Berlin.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of September were £1,770, against £1,663 in the corresponding period of last year.

THE NORTH WALES UNIVERSITY COLLEGE.—Particulars will be found in our advertisement columns of the departments of Physics, Chemistry, and Biology at this College for the Session 1885-86.

THE OATH OF SECRECY.—A few days before the inauguration of the "Tannergram" fifty lads were marched into the Thames Police-court, London, for the purpose of being sworn in as telegraph boys.

SUBMARINE CABLES TRUST.—This trust give notice that the coupons due on the 15th inst. will be paid on and after that date by Messrs. Glyn and Co., between 10 and 2. The coupons must be left three days for examination.

THE EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of September amounted to £41,845, against £41,590 in the corresponding period of 1884; increase, £255.

GREAT NORTHERN TELEGRAPH COMPANY.—The receipts of this company for September amounted to £25,200; from 1st January to 30th September, £217,240, against in the corresponding months of 1884 £208,680, and 1883, £191,880.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 2nd October, were £2,451, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

SCHOOL OF ART AND SCIENCE, READING.—The annual distribution of prizes will take place this (Friday) evening, in the New Town Hall. Mr. J. Walter, M.P., the president, will occupy the chair, and Mr. W. H. Preece, the chief electrician at the Post Office, will deliver an address.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 30th September are £1,849, as compared with £2,009 in the corresponding period of 1884. The June receipts, estimated at £5,860, realised £5,945.

ELECTRIC LIGHTING IN NEW ZEALAND.—Messrs. Fletcher and Co., electrical engineers, Dunedin, are fitting up the Mosgiel Factory, Wellington, with a Victoria dynamo for 300 lamps, which will be the largest incandescent installation in the colony. Messrs. Fletcher and Co. are also fitting up the Roslyn Mill with the electric light.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of September was 2,582, estimated to produce £2,100, against 2,645 messages, producing £2,163 in the corresponding month of last year. The traffic receipts for the month of June, estimated at £3,000, realised £3,032.

THE DIRECT UNITED STATES CABLE COMPANY.—The Board of Directors of this company resolved, on the 2nd instant, upon the payment of an interim dividend of three shillings per share, being at the rate of three per cent. per annum for the quarter ending 30th September, 1885, such dividend to be payable on and after 24th inst.

THE ELECTRIC LIGHT BROUGHT HOME TO US.—Under the above title a penny *brochure*, evidently issued by the Anglo-American Brush Electric Light Corporation, gives much practical information on the somewhat difficult subject of domestic lighting. The little work is written in a very popular manner, and should find favour with the public.

THE SOUDAN TELEGRAPHISTS.—It is officially notified that the under-mentioned non-commissioned officers and men attached to the 24th Middlesex (Post Office) Rifles have been "specially commended" for the good service rendered by them as telegraphists during the late campaign in Egypt and the Soudan:—Sergeant J. Parrish, Lance Corporal J. Hopgood, and Sappers A. Isles and W. C. Tee.

THE TELEPHONE AT SHANGHAI.—Not long ago the Telephone Exchange at Shanghai was connected with the band stand in the gardens, a swinging transmitter, placed near the ceiling of the stand so as to be out of reach, being used. The music was heard, we are informed, with great distinctness in the office of the China and Japan Telephone Company, which is situated at some distance from the gardens.

GENERAL GORDON'S TELEGRAPH.—According to Major Kitchener's "Notes on the Fall of Khartoum," General Gordon had a complete system of telegraphic communication with all the posts along the line of fortifications, and there must, says Major Kitchener, have been great irregularity in the telegraph stations to account for his being left entirely unwarned of the attack and entry of the rebels. Doubtless Farag Pasha was responsible, to some extent, for this.

ANGLO-AMERICAN TELEGRAPH COMPANY.—At a meeting of the Board of Directors of this company, held on the 2nd inst., it was resolved, after placing the sum of £25,000 to the renewal fund, to declare an interim dividend for the quarter ending 30th September, 1855, of 5s. per cent. on the ordinary stock, and 10s. per cent. on the preferred stock, less income-tax, payable on the 31st October to the stockholders registered on the books of the company on the 30th of September, 1885.

"TANNERGRAMS" AT HULL.—The Post Office officials having declined to continue the delivery of telegrams at the Exchange, instead of at the regular place of business of the addressee, unless porterage to the amount of sixpence be paid, an indignation meeting has been held and resolutions passed condemning the action of the authorities. The meeting was of opinion that the authorities should consider it a privilege to be permitted to deliver messages at the Exchange. Suppose the authorities are content to waive the privilege?

A "TANNERGRAMMER" IN TROUBLE.—A correspondent of *The Times*, who resides in the verdant locality of Lincoln's-Inn-Fields, bewails the fact that accident of location mulcts him comparatively of the sum of one penny every time he sends a "tannergram." He takes exception to the fact that by living at a polysyllabic district within a township he has to devote one-third of his telegraphic income to the State. Redress is, however, procurable. Let him take comfort and a house in Oldham-cum-Newton-le-Willows, and the tables will be turned.

INTERESTING ARTICLES.—In the current number of the *Philosophical Magazine* Prof. Oliver Lodge continues his very valuable remarks on the "Seat of the Electromotive Forces in a Voltaic Cell," and discusses the theories of Wiedemann and Helmholz. Some notes upon the same subject by Dr. J. Hopkinson also appear in the same number. Owing to the pressure upon our columns we are compelled to withhold these articles for the present, but as they are supplementary to Prof. Lodge's former paper, which our readers will remember we published *in extenso*, we shall deal with them at an early date.

THE "EXMOUTH" TRAINING SHIP.—The installation of about 150 lights, which is being put down by Messrs. R. E. Crompton and Co. on board this ship, is rapidly approaching completion. The "Exmouth" is moored in the Thames, off Grays, and on Tuesday last the cable to connect the ship with the engine and dynamo rooms on shore was successfully laid. During the laying operation, which was witnessed by Mr. Albright, of the firm of Crompton and Co., and Mr. Phillips, of Phillips Brothers, who have supplied the cables, valuable assistance was lent by the chief officer of the "Exmouth," and a number of the lads under his command.

THE EASTERN TELEGRAPH COMPANY.—This company announce the payment on the 15th instant of a dividend of 3s. per share on the preference shares of the company, less income tax, for the quarter ended 30th September, 1885, and that an interim dividend of 2s. 6d. per share in respect of profits for the quarter ended 30th June, 1885, on the ordinary shares of the company, free of income tax, will be paid on the same day. The register of transfers will be closed from the 8th to the 15th October instant, both days inclusive.—The traffic receipts of this company for the month of September amounted to £47,849, against £50,913 in the corresponding period of 1884.

SOIREE AT GUY'S HOSPITAL.—A soirée took place at the above hospital on Thursday last, the rooms being very beautifully lighted with Woodhouse and Rawson's incandescent lamps, worked off Faure-Sellon-Volckmar accumulators, delivered on the morning of the soirée. The installation was a very scattered one, 900 yards of main lead alone being used. The rooms lit were as follow:—The Museum of Comparative Anatomy was lighted by twelve 20 candle-power lamps, and the new Museum was given nine 20 candle-power lamps, while the entrance hall and staircase were very prettily lighted with suspended lamps, floral wreaths being used to form festoons from which the lamps hung.

ELECTRICITY AND CALCULATING MACHINES.—Electricity has recently been applied to the working of calculating machines by an enterprising American inventor. The record is shown on dials somewhat in the same manner as on the street car conductors' register, except instead of making nine motions to register 9 units, one movement only is required, and the movement of the dials is effected by electricity instead of by cogs. The perfection of the device is such that on the machine in the Massachusetts Census Office, in Boston, which has nine dials, the addition of one unit to the registered number 999,999,999 sets all the dials at zero, so that if there was another dial the record would be 1,000,000,000.

ELECTRICAL GAS-PRESSURE ALARM.—At a recent meeting of the Midland Association of Gas Managers, Mr. Tindall showed in action one of Bishop's electrical gas-pressure alarms, made by the Walsall Electrical Company. This apparatus is suitable for use in the exhauster-house, where any undue vacuum or back pressure is at once signalled in an unmistakable manner, and on the matter being righted the appliance is at once ready for action again. If fixed in the purifier-house, the rise of back pressure beyond a determined point is similarly rung out. Floats are placed in the tubes of the gauge, and while serving to distinctly show the water-levels, make the electrical contact at any desired point, and thus ring a bell, which, of course, can be placed in any position, and, if desired, drop an indicator, showing that the bell has been in action during the manager's absence.

CITY AND GUILDS OF LONDON TECHNICAL COLLEGE, FINSBURY.—The inaugural dinner of the Old Students' Association took place at the Manchester Hotel, on Thursday, the 1st inst., when over forty sat down to dinner. The company included Prof. S. P. Thompson, D.Sc., principal of the college; Prof. Perry, F.R.S., Prof. R. Meldola, Prof. Armstrong, F.R.S., and Messrs. Walmesley, Blaine, Adams, and others. A very pleasant evening was spent, and excellent speeches were made by Prof. Thompson, Prof. Perry, Prof. Meldola, Prof. Armstrong, Messrs. H. L. Lawrence, A. Chatterton, and others. Mr. H. L. Lawrence was elected president for the year, and Mr. A. C. F. Webb, hon. sec. Besides the forty-one present at the dinner, as many more have promised to join the association. We understand the first business meeting will take place at the College, Leonard-street, on Friday, November 6th, at 7:30 p.m.

UNIVERSITY COLLEGE, LIVERPOOL.—We have received the prospectus of day classes on art and science, and evening lectures, for the Session 1885-6, in connection with the above college. The academical year consists of three terms, Autumn, Lent, and Summer. In the year 1885-6, the Autumn Term commences October 5th, and ends December 19th; the Lent Term commences January 11th, and ends March 27th; and the Summer Term commences April 28th, and ends July 8th. During vacations, and also on Whit Monday, the college will be closed. At the commencement of the Autumn Session there will be a public meeting in St. George's Hall, at which the award of medical scholarships will be published and the medical school prizes be distributed to the successful students. The college provides day and evening classes, both of which are open to male and female students alike. The classes of the medical faculties are open to male students only. No person under fifteen years of age will be admitted as a day student, and all under sixteen will be required to pass a preliminary examination previous to admission. The Chair of Engineering is occupied by Prof. H. S. Hele Shaw.

L'ECOLE DE TELEGRAPHIE, PARIS.—The list of preparatory courses at L'Ecole Supérieure de Télégraphie, Paris, for the scholastic year 1885-86 has been issued. The candidates are to be between the ages of 20 and 30 years, and to be *employés* of the Posts and Telegraphs, with not less than two years' service in their special grade; or ex-pupils of one of the following schools:—Ecole Polytechnique, Ecole Normale, Ecole des Mines, Ecole des Ponts et Chaussées, Ecole Forestiére, or Ecole Centrale des Arts et Manufactures, having duly graduated. The subscription is to be 1,800 francs per annum. The courses are very comprehensive. The students will be given facility to study electrical work of all kinds, including submarine telegraphy, not only at the school itself, but in such workshops and cable stations as may be selected by reason of their great practical efficiency. After having passed through the courses and satisfied the examiners, the students will be admitted into the Government telegraph service in the capacity of junior electrical engineers. We consider this a most excellent project, and must congratulate M. Cochery upon the valuable scheme he has formulated. Such a school should add to the prosperity of France.

HUMAN ELECTROTYPES.—*The Scientific American* ventilates a somewhat ghastly idea evolved by M. Kergovatz, a chemist of Brest, who has proposed a new method of disposing of the human body after death. His system is an antiseptic one, much simpler and less expensive than the old process of embalming, and is nothing more than a new galvanoplastic application. The body is coated with a conducting substance. such as plumbago, or is bathed with a solution of nitrate of silver, the after decomposition of which, under the influence of sunlight, leaves a finely divided deposit of metallic silver. It is then placed in a bath of copper sulphate, and connected for electrolysis with several cells of a gravity or other battery of constant current. The result is that the body is encased in a skin of copper, which prevents further change or chemical action. If desired, this may be again plated with gold or silver, according to the taste or wealth of the friends of the dead. M. Kergovatz has employed the process eleven times on human subjects, and on many animals, and states that in all cases it was perfectly satisfactory. In spite, however, of his warm recommendation, the idea is repulsive. It seems a mockery to give permanence to the temple, when all that once made it valuable is gone.

COMPOUND WINDING.—Some surprise has been manifested that we have not hastened to comment upon the present position of the patents relating to compound winding. Although not arrogating to ourselves the position of elevated beings, we certainly think that those who can so easily (to their own satisfaction) determine the present position of parties partake somewhat of the character of the other beings referred to in the old adage. We shall not be surprised to find that those most interested in the matter will agree that it is not wise to test the validity of any patent. The mere fact that a disclaimer has been allowed does not make a patent valid. The proving of a patent invalid may throw open a process to the whole world. The validity of a patent is a complicated question, and one that cannot be decided by the off-hand remark that "this has been patented before." We should advise those who are at all interested in patents to keep beside them the "Abridgments of Specifications," issued at the Patent Office. The price of Part II., A.D. 1867–76, is one shilling, and this contains on its last page the abstract of Varley's specification, which has been said to cover "compound winding;" but we also think a closer examination of these and other volumes of abstracts will open the eyes of many who imagine recent patents contain new ideas, new discoveries, and new combinations.

THE TELEPHONE IN SHEFFIELD.—On Sunday two interesting experiments were made in Sheffield with the telephone. That day harvest festival services were held in St. Paul's Church, Manningham, near Bradford, and with the object of exhibiting the powers of their telephone, the National Telephone Company extended their wires between Sheffield and Bradford to the church. During each service there was a number of persons at the local office of the company listening to the proceedings, the choral part of which they heard almost as distinctly as if they had been in the church itself. Three "Blake" transmitters have been introduced in the church, one being placed in the pulpit, another on the reading desk, and the third on the lectern. There are permanent fixtures to enable invalids and others to listen to the services from their residences on any Sunday, a kind of advantage which, although promised when the invention was brought before the public, was scarcely expected to be realised by many people. Notwithstanding the number of telephones attached to the two wires employed, the power of sound reproduction was strong in Sheffield, and not only were anthems and hymns clearly heard, but the voice of the clergyman came out well at times. Conversation with the telephone managers was easily carried on, and even a a laugh at the Sheffield office was audible to the Bradford agent.

NEW ZEALAND INDUSTRIAL EXHIBITION.—An Industrial Exhibition was recently opened in Wellington, New Zealand. Amongst the electrical exhibits Messrs. R. E. Fletcher and Co., electrical engineers, of Dunedin, had a varied collection of interesting apparatus for electric lighting. In addition to three arc lamps, which were suspended from a mast 100ft. in height, several suites of rooms in the drill shed were also lighted up by the same firm. Some of the fittings used for the Swan incandescent lamps were of a very ornamental character. One of the most interesting exhibits in the building was a working model of Prof. Fleeming Jenkin's telpherage system. The model at the Exhibition is actuated by a miniature dynamo, and this dynamo was driven by a small water motor. Another interesting exhibit was a model tramcar, which ran upon an elliptical track in the court yard. The combination of water-power with electricity must have an important bearing on the future of New Zealand. Already Messrs. Fletcher and Co. are using two Felton wheels in the Lake County, Otago, the electricity being transmitted two miles and used for working quartz crushing machinery. Dr. Hector, in conjunction with Mr. Prince (late electrician to the Union Company, but now a member of the firm of Fletcher and Co.), delivered a lecture on the telpher system of communication during the Exhibition.

THE "VRIL" STICK.—Those who have read the "Coming Race" will at once grasp the wonderful possibilities offered by the following novel invention. It is scarcely necessary to say that a non-technical contemporary is responsible for the account of it:—"One of the latest applications of electricity is an invention made in the interests of lion tamers, which consists of an apparatus of great power, shaped like a stick, about 3ft. 6in. in length. M. Rauspach, the inventor, is a lion tamer himself, who has been a 'good deal worried' during a long and successful career. He has already experimented with it upon the denizens of the cages in his menagerie, and relates the different effects upon the brutes. Three of his lions receiving the shock immediately showed signs of the greatest terror. They were seized with trembling, and growled fitfully. The tiger was more quickly subdued, became stupefied, and crouched in a corner of the cage. Bruin was more refractory to electricity, which seemed scarcely to affect him. He would growl and show his teeth, but was subdued after repeated discharges. The most astonishing effects, however, were perceptible in the boa constrictor. On receiving the discharge the specimen from Cayenne, nearly 20ft. in length, became at once paralysed, and remained motionless for six hours afterwards. When he recovered he showed signs of helplessness for three whole days. Finally, the elephant, on being electrified by a touch of the stick upon the tip of his trunk, set up a series of wild cries, and became so strange that the tamer feared the brute would break his heavy iron chain."

BLUNDERS IN TELEGRAMS.—A correspondent of the *Standard* says:—"If I may trespass a little on your valuable space I should like to bring before the public a matter which is not, I believe, at present widely known. A short time since I sent a cable message to my sister, in Massachusetts, to this effect:—'Can receive you in Wales.' The message was transmitted, 'Can't receive you in Wales.' It would be impossible to describe the confusion and annoyance caused by this careless

Digitized by Google

error. Yet I am informed by the Postal Authorities that I can get no redress because the conditions applying to foreign messages were not adhered to. These conditions necessitate an extra payment (of about half the original sum paid for the message) to insure accuracy. This arrangement is, I believe, unknown to the majority of the public, although it is printed in the "Postal Guide." Still, as very few people have time to refer to this interesting publication before despatching a telegram, it seems as if the least that can be done is that the Post Office official should refer the sender of the message to these conditions. If a tradesman sells you an inferior article, or you suffer annoyance from any of his *employés*, he is willing at once to make you all the reparation in his power; yet in a matter of far greater importance the Post Office authorities decline all responsibility with regard to the accuracy of a message in its transit. Surely this calls loudly for investigation and amendment. Either the charge for foreign messages should be raised to an amount that will ensure accuracy, or the public should be informed that they must not expect their messages to be correctly transmitted."

CONTINENTAL ITEMS.—The students of the new lycée Louis-le-Grand in Paris have expressed their warm appreciation of the installation of 400 10 candle-power incandescents recently put down in the building by the Edison Company.—Under the heading of "Saint-Etienne at the Head of Industrial Progress in France," the *Echo des Mines* protests against the impression which has been gaining ground that the provincial towns of France are hostile to anything approaching innovation. They would all like the electric light, but don't want to bestir themselves. Human nature is human nature all the world over.—The French Academy of Medicine has received from Dr. Brondel a communication upon the economic preparation of medicines by dielectrolysis.—The Belgian Electrical Society are about to conduct a series of experiments with a new electric launch in the basin attached to the Antwerp Exhibition. It is expected that the launch will attain to a speed of over nine knots an hour.—Mr. Guilleaume, of the firm of Felten and Guilleaume, has left Cologne for Paris with a view to procuring the adoption of his anti-induction cables for the State telephone lines.—The French Minister of Posts and Telegraphs expects to open shortly the telephone lines between Paris and Reims.—The Gallerie De-Cristoforis in Milan is to receive an installation of the electric light, to be put down by the Edison Company.—The St. Petersburg journals state that a Russian named Stepanow has invented a new primary battery that will give us the electric light at a cost of 10 per cent. less than that of gas. The fun of it is, however, that the Stepanow battery is a *modification of the Daniell.*

ANOTHER FACSIMILE TELEGRAPH.—A contemporary says that a correspondent, writing from Toronto, has forwarded information of a further extraordinary invention in the domain of electricity. This consists of nothing less than the transmission of handwriting. The inventor is a young man of only some 24 years of age, and it is his intention to offer his discovery in the first place to the British Government, whose acceptance it would, it is assumed, be an absolute test of its value in practice. The method of transmission is something like the following:—"On a strip of foil the writing is traced with any common ink to which an acid has been added. The acid bites into the foil, which is then, after being dried, put on a drum and an electric needle made to work rapidly across every part of the foil. At the other end of the wire a similar needle and drum are placed in circuit, and the result is the *vera effigies* of the writing. The process has been worked well up to a distance of 130 miles in America, and it is believed that a like success would be obtained over any distance. Its uses are not, it can be understood, restricted to caligraphy. The electric needles will reproduce all lines engraven on the foil, so that designs and drawings will be telegraphed. The inventor claims for this method of telegraphy an important economic value, as the direct transmission of the handwriting of the senders of messages will be effected with no intervention of the human intelligence to interpret the written language by means of arbitrary telegraph signals." There is nothing extraordinary in this invention as far as we can see, and it certainly is not new. The process is undoubtedly a very slow one, and is probably expensive. We shall be surprised if we hear of its practical application for other than experimental purposes.

THE NEW PERSIAN GULF CABLE.—The ss. "Dacia" sailed from Greenhithe on Tuesday afternoon with a portion of the new cable for the Persian Gulf section of the Government Indo-European Telegraph. The rest will follow in the ss. "International" to-day (Friday). The expedition is under the personal direction of Colonel Bateman-Champain, R.E., Director-in-Chief of the Indo-European Telegraph Department, assisted by Sir Henry Mance, electrician of the Persian Gulf section, and a competent technical staff. The new cable is intended to strengthen the weakest portion of the Indo-European system, viz., the section from Jask, near the mouth of the Persian Gulf, to Bushire. From Kurrachee to Jask there is a land line as well as a submarine one, and from Bushire to England there are two distinct lines, one (the Indo-European) through Persia, Russia, and Germany, and the other *vid* Bussorah, Bagdad, and Constantinople. While there are thus alternative lines at all other parts of the Indo-European system, the Jask-Bushire portion depends entirely on submarine cables, of which there are at present two—one laid in 1864 and the other in 1868. From age both have long been in a dangerous condition, and in need of constant repair. The question, therefore, arose whether this weak section should be strengthened by a new cable or by a land line from Jask to one of the stations in Persia—Shiraz, for instance. The former course was decided upon last May, and the present expedition is the result. The new cable is 530 miles in length. Including the expense of laying, it will cost £80,000. Among those who assembled at Greenhithe to wish the expedition God speed were Mr. Juland Danvers and Major Jopp, R.E., of the India Office, and Colonel Murdoch Smith, R.E., Director of Persian Telegraphs.

ELECTRICAL TRANSMISSION FROM NIAGARA.—There appears in the current issue of *The Electrical Engineer* an interesting article which treats, under above title, of the Falls of Niagara as a source of power. The power of Niagara can be estimated very approximately. The average flow of the river, according to the many careful measurements of the U. S. Lake Survey, is 275,000 cubic feet per second. The fall in the river through the rapids immediately above the Falls is 65ft., height of the Falls 165ft; total, 230. Then we have the whole power: $\frac{275{,}000 \times 230 \times 62}{550} = 7{,}000{,}000$ horse-power. To utilise this amount of power by water wheels, generate electrical currents, and transmit to various cities within 500 miles, would necessitate a plant representing at least five thousand million dollars. Such figures as these give some idea of the enormous amount of power here in reserve. In order to transmit currents of electricity profitably to a distance several conditions must be observed:—1st. The cost of transmission must be less than the difference between the

Digitized by Google

cost of steam and water power. 2nd. The distant point must be one where the currents of electricity can be used; and 3rd. Where water-power cannot be obtained. The author selects the city of Buffalo as the point most likely to fulfil these conditions, and in an estimate based upon the Brush system, with which he is most familiar, goes on to show that the total cost per horse-power of power delivered in Buffalo would be 20 dollars (£5) per annum. In comparison with steam as the source of power the saving would, he thinks, on a plant of 1,000 arc lights, be about 40,000 dollars yearly.

MR. CAMERON ON CHEAP TELEGRAMS.—To the *Fortnightly Review* for the current month Dr. Charles Cameron, M.P., contributes a paper reviewing the history and prospects of the Sixpenny Telegram scheme which came into operation on the 1st inst. He entertains no doubt as to the financial success of the new tariff, and regards it only as a preliminary to a still more popular one. With vigorous and careful management the telegraph system of the country is capable, he believes, of a great developement, "in which the introduction of the sixpenny tariff can only be regarded as a first step." He proceeds then to indicate the sort of measures and management likely to contribute to this development. Contrasting our system with that of France and Australia, he points out that in the latter countries a form is in use which enables the receiving clerk to write the name and address of the addressee on a flap which can be folded over and sealed for delivery without further trouble, the operator in fact handing it fastened up to the sending-out clerk ready for delivery. The message as well as the address in these countries is, it appears, written with ink. Mr. Cameron's second suggestion is that the fee for registration be reduced from 20s. to 2s. 6d. or 5s., and he points out that in America the companies register the addresses of their "more important clients" free of charge. In order, however, to recoup the revenue for any immediate loss caused by the reduction of the general tariff, Mr. Cameron insists that the telegraph system "must be worked to its fullest capacity;" and to accomplish this he recommends the adoption of the Belgian plan of express messages, or that which prevails in India, where three classes of messages, ordinary, deferred and express are permitted. To increase the traffic of the "ordinary" kind he would reduce the tariff still further by one-half; or, if that could not be done, he would double the maximum number of words allowed for this class of telegram, thus insuring, as he predicts, the full occupation of all the wires to all places. Further, he would utilise the "idle" wires for the convenience of commercial men, who might be allowed to hold conversation with each other on any idle telegraph circuit at a charge of £1 per hour. Lastly, he urges greater publicity to the permission to drop telegrams into letter boxes, a system which has utterly failed, simply because, as he thinks, the public are not aware of the privilege. We shall take an early opportunity of discussing these, Mr. Cameron's, ideas of telegraphic development.

ELECTRICITY AND MINING.—The first lecture for the session 1885-6, in connection with the Durham College of Science Newcastle, was delivered on Saturday afternoon, in the theatre of the Literary and Philosophical Society, by Prof. Merivale, who, in the course of his address, said that electricity was not a substitute for coal. Coal was a *source* and electricity a *form* of energy—very different things. He would first of all show that by means of a magnet they could produce a current of electricity, and also the converse—that by means of a current of electricity they could produce a magnet. All the practical applications of electricity depended upon these two facts. The dynamo was merely a magnet moving in the neighbourhood of a coil of wire, or a coil of wire moving in the neighbourhood of a magnet. He then referred to appliances which would assist the mining engineer. A serious danger to the miner arose from the presence of fire damp. Ten years ago people were under the impression that unless there was 6 per cent. of gas present there would be no explosion. The Davy lamp detected 3 per cent.; but it had been discovered that 1½ per cent. of coal damp could cause an explosion, and, therefore, no dependence could be placed upon the Davy lamp to find the presence of coal damp sufficient to cause an explosion. The electric current in Ansell's fire damp detector was affected by gas in sufficient quantities to cause the risk of an explosion. Liveing's detector glowed in the presence of gas according to its density, and, to prevent it from causing an explosion, the flame was enclosed in gauze. The lecturer said electric light seemed to afford every possible safety, because the light, burning in a vacuum, could not possibly cause an explosion. MM. Benoit and Dumas had patented one lamp, the difficulty with which, however, was in supplying sufficient electricity for the various purposes of the mine. Mr. Swan had lately brought out a portable miners' light which he (Prof. Merivale) hoped would succeed. The difficulty was in getting a portable battery. He was glad to show them a patent magnetic lock, providing against the danger of miners unlocking their lamps. They could not unlock this one without a very powerful magnet, and the lamp was relighted without opening it. The electric light was exceedingly convenient when placed upon coal screens, and also for lighting the workings in the neighbourhood of the shaft. It gave a far better light than either gas or oil, and was both safer and cheaper. The light which he exhibited was obtained by the "shunt" dynamo heating the platinum wire. A couple of wires, having two lights suspended from them, were stretched along. There were sundry subsidiary wires, and all that was required, was an engine to turn the dynamo. They now came to consider how they could get the coal more readily and more cheaply by means of electricity and magnetism. The earliest adaptation was the compass. After the compass came, undoubtedly, the different methods of signalling by electricity. When they considered the great inconvenience of signalling in the old way—and he was sorry to say the way which they still found in a great many collieries—the wonder was that a simpler method, such as by electricity, did not come in sooner. The lecturer then explained the single wire system, and the double wire system, showing a model of a pit and the working of the bells in signalling the point of contact with the wires. Another subject of interest was the distribution of carrying power in mines, making large quantities on the surface and transmitting it below into the different districts. He hoped that some day electricity would be used for this purpose, but, at present, the only appliance that they knew was air compressed at bank. They had, however, to consider that they got not above 30 per cent. of the power they were expending at bank, while in the case of electricity they could get something like 70 per cent. of the power put in at the surface. If distribution of electric power were needed, they would have to transmit it to each district by means of resistance wires and regulators. Prof. Merivale then exhibited a few working models to illustrate how electricity could be used in mines. The experiments concluded with an electric locomotive being driven quickly round a circular railway, and the lecturer stated that such traffic in pits was perfectly possible, and he had no doubt would be more economical than the present system of hauling, in which they had to use long and heavy ropes, and, of course, supply the motive power.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.

BY OLIVER HEAVISIDE.

(Continued from page 307.)

Magnetic and Electric Comparisons.

(*a*). Let two large masses of iron be united by a thin iron wire. For simplicity of exposition let the two masses and the wire be homogeneous throughout, and only "elastically" magnetisable. Call the masses P and Q, and the wire *w*. Let air surround them to a great distance, to get rid of foreign influences. The masses may be conveniently imagined brought near one another, and the wire not to join them straight, but to be led round through the air, although these assumptions are immaterial.

Now let a portion of the wire, which we shall call *x*, be intrinsically magnetised to intensity I parallel to its length. Here, again, we may conveniently imagine *x* to be very short, to be a mere disc, in fact, perpendicular to the axis of the wire. The magnetisation I is the same as an impressed magnetic force *h*, similarly distributed, if $I = \mu h/4\pi$, and μ is the permeability of the iron. Instead of this impressed force in *x*, we may equivalently have an electric current round *x*, say in a coil of very small depth. Or, instead of this real current, we may refer to a false electric current round *x*.

The magnetic induction passing through *x* due to *h* (or its equivalents) is both altered in amount and in distribution from what it would be were *x* alone in the air. Its amount is increased by the permeance of the magnetic circuit being increased. And its distribution is altered, on account of the permeability being changed unequally in different places. It is, to a certain extent, led along the wire to the mass P (of course with a large amount of leakage on the way), through the air to Q, and through the wire back to *x*, completing the circuit. But if we increase the permeability of the iron we increase the induction, and at the same time cause relatively more of it to pass through P and Q, with relatively less loss from the wire (out on one side of *x* and in on the other). Indefinitely increase the permeability. The total induction in the circuit reaches its greatest value. The leakage becomes relatively insignificant, and by making the wire thinner may be reduced indefinitely. Thus nearly all the induction is led through the wire to P, through the air to Q, and back to *x* through the wire. The total induction depends on the form and relative position of P and Q (with which, to be exact, we must count the two portions of *w* on opposite sides of *x*). In this final state the magnetic force in the air is everywhere perpendicular to the surface of P, Q, and *w*, except at *x*, where it is partly tangential.

(*b*). Replace the iron by a solid dielectric non-conductor of high electric capacity or low electric elasticity. Replace the impressed magnetic force *h* by impressed electric force *e*; or by intrinsic electrisation of intensity $J = ce/4\pi$, if *c* is the electric capacity; or, finally, by a magnetic current round *x*, similar to the before-used electric current, except that it must circulate the reverse way. The flux is now elastic electric displacement. Its distribution is similar to that of magnetic induction in (*a*). On indefinitely increasing *c*, or doing away with the electric elasticity in the solid dielectric, the greatest displacement is obtained. It then passes through the air mainly from P to Q. The electric force in the air is normal to the surface of the solid dielectric, except at *x* again.

(*c*). If in the case (*b*), before making the capacity infinite, and when, consequently, the final state (*b*) is not assumed, we communicate to the solid dielectric throughout its whole substance any finite degree of electric conductivity, we shall cause the displacement in the air to immediately (practically) assume the final state (*b*). The conductivity may vary anyhow, and likewise the electric capacity, which last may in fact be zero now. This is the common case of charging a condenser, except that it is usual to consider the conductor as having no electric capacity.

(*d*). If, in the case (*a*), of magnetic induction, we could communicate to the iron any finite degree of what, by analogy, we may call magnetic conductivity, rendering it impossible for the iron to support magnetic force without a magnetic conduction current, with dissipation of energy, it would be unnecessary to make the permeability infinite to obtain the final distribution in the air there mentioned. The permeability might be finite or zero, and the magnetic conductivity have any distribution in the iron. The final state would be as in (*c*), with magnetic induction instead of electric displacement. The examples (*a*), (*b*), and (*c*) are real, except as regards the assumption of infinite values of μ and *c* in (*a*) and (*b*) respectively, which may be conveniently imagined to become very great, though not really infinite, thus letting us approximate to the required results without using impossible conceptions. The example (*d*) is unreal. It is introduced to show the analogy.

In examples (*b*) and (*c*) the displacements out from P to the air, and in from the air to Q are identical. (The final state (*b*) is referred to.) But there is no electrification in case (*b*), whilst there is in case (*c*). If in case (*b*) we remove the wire from P and Q to a distance, we shall at the same time do away with the former apparent charges of P and Q. There will be left merely the small displacement from the wire on one side to that on the other side of *x* where the impressed *e* is, some small part of which will of course go through P and Q *viâ* the air. But if, in case (*c*), we remove the wire, P and Q will be left charged as before; besides that we have an insignificant wire charge. Herein lies the difference between elastic and conductive displacement.

Similarly, if in the example (*a*) we remove the wire from P and Q, we at the same time do away with their apparent magnetic charges. Whilst, if we could realise the case (*d*), on removal of the wire the bodies P and Q would be left really charged magnetically. They would apparently be unipolar magnets, though without any interior polarisation, it being a matter of the terminal induction of the medium between them. In the final states of (*a*) and (*b*) there is finite interior induction or displacement, being the exact complements of those outside in the air, although there is no interior magnetic or electric force, and consequently no interior magnetic or electric energy. But in examples (*d*) and (*c*) having the same external induction or displacement as in (*a*) and (*b*), we have no interior induction or displacement as well as no magnetic or electric force and no interior energy.

(*cc*). Going back to (*c*), with an impressed electric force in the wire, let us join P to Q by a second conducting wire, attaching it to them anywhere, but for distinctness, away from the first wire. We shall now have a steady conduction current in the closed circuit made, as well as elastic displacement in the air, having a different distribution to the previous; the amount of change depending materially upon the resistance of the second wire compared with that of the rest of the circuit, being small when it is great, and conversely. The electric force is no longer normal to the conductors at any part of their boundary. There may now be any amount of internal electric energy, existing independently of the external, depending upon the internal capacity of the conductor, in which there is electric force, and consequently elastic displacement if there be capacity for it.

(*bb*). If, in the final state (*b*), we unite P to Q by a second dielectric wire also of infinite capacity, we make a closed dielectric circuit which has no elastance (or elastic resistance to displacement), and in which infinite displacement corresponds to finite impressed force, and likewise infinite electric energy. Clearly this is an impossible example, and we should never reach the final state. Let us therefore modify the conditions somewhat. Do away with the impressed force *e* at *x*, and substitute a bodily distribution of impressed force similar to that of the polar electric force (reversed) in the conductor in example (*aa*). Or, substitute equivalent intrinsic electrisation. Or, finally, a distribution of magnetic current on the boundary given by $g = VFN/4\pi$, if F is the external electric force in example (*aa*), and N a unit vector normal from the solid to the air. This magnetic current goes round the wire at *x* in the same direction as in (*b*), and oppositely round all the rest of the circuit. It is strong at *x* and weak

Digitized by Google

elsewhere, of such strength that total at x equals that elsewhere.

With this changed distribution of impressed force or equivalents, the external electric field will be identically that in (*cc*). The impossible infinite internal displacement is abolished, the total impressed force round the circuit (of the solid dielectric) is zero; there is a finite internal displacement which exactly closes the external; and there is no internal energy, because there is no electric force. (That is to say, as c is increased the internal energy becomes less and less without limit, the electric force going down to zero, the displacement assuming a finite value.)

(*aa*). If in the final state (*a*) we unite P to Q by a second iron wire, also of infinite permeability, we make a circuit of infinite permeance in which is a finite impressed force, so that we have infinite internal induction and magnetic energy to correspond. Modify as in (*bb*). Do away with the impressed magnetic force h at x, and substitute a bodily distribution of impressed magnetic force (or intrinsic magnetisation) similar to that of impressed electric force in (*bb*) or of the polar auxiliary force (reversed) in (*cc*). Or, substitute a distribution of electric current on the boundary given by $\gamma = VNH/4\pi$, if H is the external magnetic force, when similarly distributed to the external electric force in (*aa*) and (*bb*). This boundary false electric current is similarly arranged to that of magnetic current in (*bb*), except in reversal of direction of circulation everywhere.

Under the changed circumstances, there will be no internal magnetic force, and no magnetic energy, but finite magnetic induction, which will exactly close the external induction, which, again, has the same distribution as the displacement in the air in cases (*cc*) and (*bb*).

(*dd*). We should cause the same external induction, as just arrived at, without modifying the distribution of impressed force, if we could impart magnetic conductivity to the iron circuit. That is to say, in example (*d*) unite P to Q by a second magnetically conductive iron wire. If the distribution of magnetic conductivity be the same as that of electric conductivity in (*cc*), we shall have the external magnetic induction distributed like the electric induction in (*cc*) and (*bb*), and like the magnetic induction in (*aa*). There would be a steady conduction magnetic current in the iron circuit, similar to that of electric current in (*cc*), and the internal magnetic energy (like the internal electric energy in (*cc*)) would be arbitrary, depending upon the permeability of the iron. (In this replacement of electric conduction current by magnetic conduction current, the electric conductivity of the iron circuit is ignored. Similarly in (*ddd*), later).

Any magnetic field is accompanied either by true electric current Γ or by impressed magnetic force h. For the latter we may substitute a distribution of false electric current γ, such that if it were real the induction would be the same. Similarly, in a non-conducting dielectric in which there is no electrification, the elastic displacement is accompanied either by a true magnetic current $G = \dot{B}/4\pi$, if B is the induction, or by impressed electric force e (or equivalent electrisation). For the latter we may substitute a false magnetic current g. Also, U being the whole electric and T the whole magnetic energy, we have

$$4\pi\gamma = \text{curl}.h;\ 4\pi g = -\text{curl}.e;\ T = \tfrac{1}{2}\Sigma A(\Gamma+\gamma);\ U = \tfrac{1}{2}\Sigma Z(G+g).$$

Here A and Z are the electric and the magnetic impulses that would arise on the sudden removal of h and of e respectively (also partly due to Γ or to G), when the induction or the displacement would wholly subside and spread.

Now, if we confine ourselves to a limited region, we shall still have the electric energy within it expressed in the same manner, provided we include in the false magnetic current g a boundary magnetic current given by $g = VFN/4\pi$, if F be the electric force (not counting impressed e) and N a unit normal from the boundary to the region; and further, provided it be possible to close the displacement outside the region, thus not interfering with that within it. This is not always possible. And the magnetic energy is expressible in the same manner, if we include in γ a boundary false electric current given by $\gamma = VNH/4\pi$, if H is the magnetic force, not counting impressed h; with no reservation as to the possibility of closing the induction outside the region, because it is always possible.

But in neither case is it generally true that these distributions of current (including those on the boundary), would, if they existed alone, set up the identical displacement in the one case and induction in the other, independent of what may be beyond the region. (To illustrate this we need merely take a piece of a round tube of induction, with plane ends cutting the tube perpendicularly. If the induction is uniform and steady, the only electric current is the false current round the round part of the tube, and this solenoid will clearly not produce uniform induction, but induction that spreads out in passing from the middle to either end of the tube.) But we may very easily produce independence of the external state, by short-circuiting the unclosed displacement or induction, as the case may be, by making either the electric capacity or the permeability infinitely great beyond the region. Or, merely by making c or μ infinite in a mere boundary skin, or over enough of it to completely close the displacement or the induction. When this is done, the currents, magnetic or electric as the case may be, produce the exact given displacement or induction within the region, without external aid.

In examples (*b*) and (*c*) we have identical displacement outside the solid dielectric or the conductor. Since the states are steady, $G = 0$. And, as there is no impressed force in the air, which is our region of electric energy, g is reduced to the surface current $g = VFN/4\pi$. This is zero except round x (because F is normal elsewhere), and there it is $g = VNe/4\pi$, which is the value of g in the expression $U = \frac{1}{2}\Sigma Zg$ for the electric energy in the air.

In examples (*a*) and (*d*) the total magnetic energy in the air in the identical distributions of induction is $T = \frac{1}{2}\Sigma A\gamma$, since there is no true electric current. And the false electric current (or it might be a true current in a thin coil) is confined to round x, being given by $\gamma = Vh N/4\pi$.

But in example (*cc*), with electric current in the wire, and in (*bb*) as modified, the magnetic current is no longer confined to be round x, but extends over the whole conductor in (*cc*), and solid dielectric in (*bb*); being $g = VFN/4\pi$, wherein F is no longer normal to most of the surface. This g, used in $U = \frac{1}{2}\Sigma Zg$, gives us the electric energy in the air in both cases. But there is a perfectly arbitrary amount in the conductor in example (*cc*), and none in example (*bb*). In order, therefore, that in (*cc*) the magnetic current should exactly correspond to the external displacement, we must, as before explained, short circuit the latter beyond the air; *i.e.*, make $c = \infty$ outside the air region. We then get the case (*bb*) as modified, and see the reason of the modification.

Similarly, in examples (*aa*) and (*dd*) the energy of the identical external magnetic inductions is $T = \frac{1}{2}\Sigma A\gamma$, wherein γ is the boundary electric current given by $\gamma = VNH/4\pi$. But in (*dd*) there is also an arbitrary amount of internal magnetic energy, so that the boundary current γ would not generally, existing alone, produce the actual external magnetic induction It can be made to do so by abolishing the impressed force h at x in (*dd*) and making $\mu = \infty$ throughout the iron. Then we obtain (*aa*) as modified.

(*ccc*). In example (*cc*), with dissipation of energy by conduction, there is also magnetic energy, not before mentioned, as it would have introduced some confusion. For all space its amount is $T = \frac{1}{2}\Sigma AC$, if A is the electric impulse and C the conduction current in the wire. That part of it in the air is $\frac{1}{2}\Sigma A\gamma$ where $\gamma = VNH/4\pi$. This is a boundary current, not round the wire, but along it, of the same total amount as the real current in it, as if it were all pressed to the surface. It would not alone set up the external field, but would do so if we short circuit as much of the induction of the field that is unclosed (at the boundary).

(*ddd*). Similarly, in the unreal example (*dd*) with dissipation by the magnetic conduction current in the iron circuit, there is, besides the magnetic energy, also electric energy. In all space, the amount is $U = \frac{1}{2}\Sigma ZG$, if G be the magnetic current in the wire. That in the air alone amounts to $\frac{1}{2}\Sigma Zg$, where g is a surface magnetic current given by $g = VFN/4\pi$. It is

Digitized by Google

along the wire like G inside, of the same total amount, as if G were pressed to the boundary. It would exactly correspond to the external displacement, if the latter were short-circuited at the boundary.

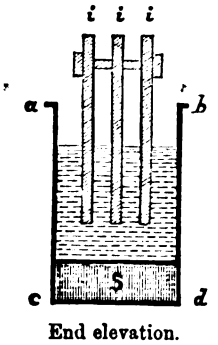
The unreal (*d*), (*dd*), and (*ddd*) are merely brought in because they, to a certain extent, assist the other comparisons.

To be continued.

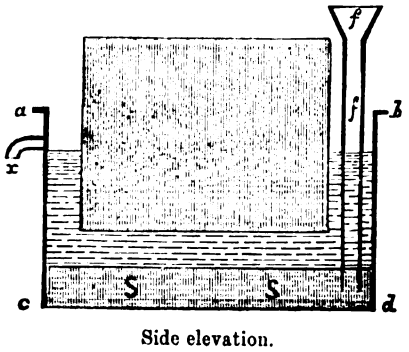
A MODIFICATION OF DANIELL'S BATTERY, USING IRON AS THE ELECTRO-POSITIVE ELEMENT.

By J. J. Coleman, F.I.C., F.C.S., President of the Chemical Section Glasgow Philosophical Society.

"It seems very singular to me that more attention has not been bestowed upon the utilisation of iron as the substance to be burned in the battery, seeing that the oxidation of iron, according to the researches of Andrews and Favre and Silberman, develops two-thirds or three-fourths as much heat, weight for weight, as zinc. The exact figures are these—677 as against 847, supposing the iron is used to precipitate copper sulphate solution instead of zinc. Iron has been frequently used as the electro-negative element of a battery, especially when in the passive state by contact with concentrated nitric acid. Probably the objection to its use as an electro-positive element has arisen from the earlier experiments finding local action uncontrollable, which in the case of zinc could be obviated by the expedient of amalgamation. I have recently made some experiments in this direction. In point of fact, I have constructed a sulphate of copper cell in which the copper is used in contsct with sulphate copper, as is customary in Daniell's cell, but the zinc is replaced with iron used in contact with ferrous sulphate. I find that three of such cells connected in series decompose water, so that the electromotive force is probably what theory indicates, about two-thirds of a Daniell cell. Moreover, such a form of battery gives what the practical chemist dearly loves, viz., a chemical cycle easily worked, and restoring the materials to their original state. The solution of sulphate of iron produced by the working of the battery on evaporation and distillation yields sulphuric acid and peroxide of iron, the former ready to be combined again with the deposited copper, and the latter ready for the blast furnace to be reconverted into metallic iron. For the prevention of local actions, I find that a form of battery similar to the Medinger or Sir William Thomson battery answers, with some important practical alterations of detail, and this battery, requiring no porous cells, can be made of any size desirable.



End elevation.



Side elevation.

These words formed a portion of a recent address to the Philosophical Society of Glasgow, but since then I have had occasion to construct a constant battery for working a Ruhmkorff induction coil, employed for a lengthened series of experiments upon ozone during the months of June, July, and August of this year. The battery was constructed of twelve cells, having the following form, and worked remarkably steady for the whole period of three months, as evidenced by the length of the spark of the induction coil, which was sometimes worked for thirty hours consecutively:—*a b c d* is a copper cell, *i i i* are iron plates dipping into solution of ferrous sulphate dissolved in four parts of water. *s s s* is a layer of saturated solution of copper sulphate introduced by the funnel *f f f*, having a wide stem so as to prevent hydrostatic pressure causing current in the ferrous solution.

When the cell was thus prepared it was found that the layer of sulphate of copper solution remained without any appreciable diffusion into the sulphate of iron solution for two months.

After the iron plates *i i i* were placed in position, and the 12 cells were connected in series, the surface of the iron solution was protected from the oxidising influence of the atmosphere by a layer of oil, and the whole was allowed to remain at rest, with the exception that as the sulphate of copper became exhausted a little fresh saturated solution of sulphate copper* was poured down the funnel *f*, and a corresponding quantity of sulphate of iron solution was drawn off at the point *x*. It was found that cast-iron plates were very unevenly acted upon; they became friable and spongy, and resembled in appearance cast iron which has been immersed for a number of years in sea water. Mallable iron plates were more satisfactory, and were easily cleaned, after being in use for a period of three months.

Mr. Bottomley has been kind enough to test one of the cells in Sir W. Thomson's laboratory, and has found the E.M.F. to be ·53 of a Daniell cell. Possibly better results may be obtained, and for this reason a few more tests will be made with a few cells connected in series. Meantime it has been noted that with about 100 square inches of surface of the copper plate, the *electrolytic* deposition of copper in each cell amounts to about 1oz. avoidupois in 24 hours, the electrodes being connected with thick wire.

Although the E.M.F. of this battery is small, the cheapness of the materials and the facility with which they may be obtained and restored to their pristine state in unlimited quantity makes it worthy of some notice. There is no doubt that any method of constructing a primary battery which involves selling of a product likely to glut the markets is of little national importance, but any effort to utilise a material like iron, even although the action may be slow, or the apparatus cumbersome, is worthy of attention. Moreover, the recovery of the sulphuric acid by the simple process of distillation from sulphide of iron has been practised a long time in Germany, the product being called nordhausen sulphuric acid, and the manipulation of copper solutions with iron is already carried out on an enormous scale in this country at the works of Tharsis and other copper works.

THE ELECTRO-OPTIC ACTION OF A CHARGED FRANKLIN'S PLATE.†

BY J. KERR, LL.D.

The experiments described in this paper were carried out by the author in 1882, and he has now made them known in view of certain statements made by M. Wiedemann in his *Die lehre von der Electricität*, Vol. II., particularly where he says that there appears to be no electro-optic double refraction in the case of a uniformly charged Franklin's plate. The results obtained were shown by the author to prove that electrostatically strained glass acts in the polariscope as if compressed along the lines of electric force, *and this always whether the electric field is uniform or not.*

MULTIPLYING POTENTIAL.‡

BY SIR WILLIAM THOMSON, F.R.S.

The method described by the author was to arrange in series a number, *n*, of condensers, where *n* is the number

* Care must be taken that the sulphate copper solution is absolutely saturated with the salt.

† Abstract of a Paper read at the British Association meeting at Aberdeen.

‡ Abstract of a paper, entitled "On a method of Multiplying Potential from a Hundred to Several Thousand Volts," read at the British Association meeting at Aberdeen.

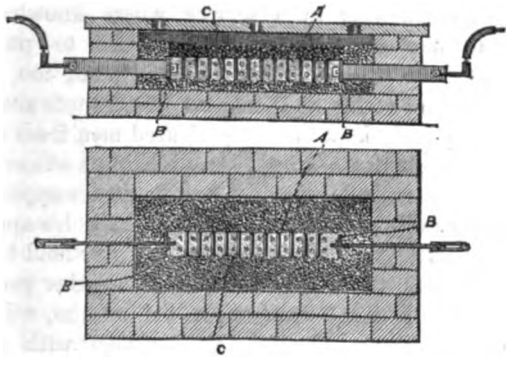
Digitized by Google

indicating the required multiplication. A terminal is connected to the junction between each pair of adjacent condensers. This series of n and the terminals is conveniently placed, so that by a suitable mechanism a pair of movable electrodes, between which a known difference of potentials exists, may be brought successively into contact with each pair of adjacent terminals in the series, moving always in the same direction along them. In this way the difference of potential established between the two end terminals of the series of condensers is n times the known difference of potentials between the movable electrodes.

AN ELECTRICAL FURNACE FOR REDUCING REFRACTORY ORES.*

BY DR. T. STERRY HUNT.

The application of electricity in the extraction of metals has hitherto been chiefly confined to the electrolysis of dissolved or fused compounds of these by various methods. The power of electric currents to generate intense heat in their passage through a resisting medium has, however, long been known, and the late W. Siemens thereby succeded in fusing considerable quantities of steel. It was, however, reserved to Messrs. Eugene H. and Alfred H. Cowles, of Cleveland, Ohio, to take a new step in the metallurgic art by making the heat thus produced a means of reducing in the presence of carbon the oxides not only of the alkaline metals, but of calcium, magnesium, manganese, aluminium, silicon, and boron, with an ease that permits the production of these elements and their alloys with copper and other metals on a commercial scale.



Electrical Furnace for Reducing Refractory Ores.

In the apparatus devised and now employed by the Messrs. Cowles a column of fragments of well-calcined charcoal, so prepared and arranged as to present the requisite electrical resistance, is embedded horizontally in finely-pulverised charcoal, and covered by a layer of the same material coarsely broken, the whole being arranged in a box of fire-brick, covered with perforated tiles and opened at the ends to admit two carbon electrodes an inch and a half in diameter. Through these the current from a dynamo-electric machine of 30 horse-power is now made to traverse the central core of carbon, whereby such a temperature is at once produced therein that platin-iridium may be instantly melted, and the most refractory oxides already named may be not only fused and volatilised, but reduced to their elemental state with formation of carbonic oxide gas.

If alumina in the form of granulated corundum is mingled with the carbon in the electric path, aluminium is rapidly liberated, being in part carried off with the escaping gas, and in part condensed in the upper layer of charcoal. In this way are obtained considerable masses of nearly pure fused aluminium and others of a crystalline compound of the metal with carbon. When, however, a portion of granulated copper is placed with the corundum, an alloy of the two metals is obtained, which is probably formed in the overlying stratum, but at the close of the operation is found in fused masses below. In this way there is got, after the current has passed for an hour and a half through the furnace, from four to five pounds of an alloy containing from 15 to 20 per cent. of aluminium, and free from iron. On substituting this alloy for copper in a second operation, a compound with over 30 per cent. is obtained. Already the small experimental plant with a 30 horse-power dynamo is producing daily over five pounds of aluminium in the form of a rich and brittle alloy, which by suitable additions of copper is converted into different grades of aluminium bronze. The valuable qualities of these are so well known that it is only their great cost hitherto that has prevented their more general use in the arts. They are now offered for sale at Cleveland on a basis of five dollars a pound for the contained aluminium. The reduction of silicon is even more easy than that of aluminium. When siliceous sand, mixed with carbon, is placed in the path of the electric current, a part of it is fused into a clear glass, and a part reduced, with the production of considerable masses of crystallised silicon, a portion of this being volatilised and reconverted into silica. By the addition of granulated copper there is readily formed a hard, brittle alloy, holding six or seven per cent of silicon, from which silicon bronzes can be cheaply made. The direct reduction of clay gives an alloy of silicon and aluminium, and with copper a silico-aluminium bronze that appears to possess properties not less valuable than the compound already mentioned. Even boric oxide is rapidly reduced with evolutions of copious brown fumes, and the formation in presence of copper of a boron bronze that promises to be of value, while under certain conditions crystals of what appears to be the so-called adamantoid boron are formed. In some cases, also, crystalline graphite has been produced, apparently through the solvent action of aluminium upon carbon.

Remarkable results are got by alloying small quantities of aluminium with an admixture of copper and nickel. One of these compounds broke with a strain of 111,000 pounds to the square inch, with an elongation of 35 hundredths, while a 10 per cent. aluminium bronze broke with 109,000 pounds. An addition of from 2 to 3 per cent. of aluminium to brass greatly increases its tensile strength, and renders it less susceptible to oxidation. While 15 or 20 per cent. of aluminium with copper yields a brittle compound, an addition of 10 per cent. gives to pure aluminium a great increase of hardness and tenacity, forming an alloy that may have a wide application. It may be added that the difficulties in the way of getting together the reduced aluminium without the aid of copper promise to be overcome at an early day, so that we may expect the cheap production of such alloys and of pure aluminium.

The Messrs. Cowles, in their later work, have been aided by the chemical skill of Prof. C. F. Mabery, now of Cleveland, who is associated with them in some of their patents. These now cover not only the reduction of aluminium, silicon, and boron, as described, but the extraction of manganese, magnesium, and the alkaline metals by the electric furnace. I had the pleasure of hearing Prof. Mabery give the first scientific notice of this discovery before the American Association for the advancement of Science, at Ann Arbor, August 28th, and then spoke of the early results of Deville, and those of Debray, on aluminium and its alloys, having myself witnessed many of the experiments of both of these chemists thereon. I also insisted that the importance of this new instrument that the Messrs. Cowles have placed in the hands of chemists for producing and controlling degrees of temperature never before obtained can scarcely yet be estimated, either in its economic or its scientific aspect. This heat of the furnace realises the dream of the alkahest or universal solvent of the alchemists, and he who can rightly use it will be worthy of the ancient title of "magister magnis in ignis."

I then suggested trials for the reduction of titanium, both from rutile and from titanic iron ore, which will probably soon be made.

I may add that, through the courtesy of these gentlemen, I have since been enabled to spend two entire days in their experimental works at Cleveland, with the brothers Cowles and Professor Mabery, when they explained to me several points not yet made public, and allowed me to direct experiments with one of their furnaces. The fusion of quartz and the reduction of silicon without the presence of copper was repeated, the reduction of boron and the formation of boron bronze, with many other interesting experiments.

The present plant at Cleveland is but a first experimental one, and has only been in operation a few months. The Cowles Electric Smelting Company has secured a large water-power at Lockport, New York, and a dynamo electric machine of 125 horse-power is now building for them at the Brush Works in Cleveland, which will soon be in operation at Lockport, and will permit of the establishment of the electric furnace on a larger scale.

A series of experiments of the products got by this remarkable discovery is, by the courtesy of these gentlemen, placed before the members of the Institute.

THE INDIAN TELEGRAPH SERVICE.

Although the officers of the Indian Government Telegraphs are greatly to be commiserated in respect to the block of promotion which has existed in that service for many years past, they may count themselves extremely fortunate in the interest they have aroused by laying their grievances before the English public. The letters and articles on the subject which have recently appeared in the home press show that the welfare of our countrymen and fellow workers in India is not a matter of indifference to us; but they also show that the parties most nearly concerned have a shrewd practical knowledge of the ways of English journalism. However warm may be our sympathy, we cannot write sympathetically without some knowledge of the facts; and these the wideawake Telegraph Engineers of India have taken care to supply with a free hand. The documentary evidence, bearing date Simla, 15th August, 1885, and printed apparently by the aggrieved officials, supplies all the details that were wanting in the preliminary letters and articles which appeared some little time back, one of which we reprinted in *The Electrician* of 28th August. Judging by precedent and experience, we should confidently say that the memorialists will succeed in their efforts. They certainly deserve to succeed, for they have not only a good case, but one which they have had the courage and sense to put forward in a way that renders failure almost impossible. Heads of Departments often incur the reproach of yielding to clamour; but clamour is none the less necessary at times to give a plausible excuse for yielding to claims which, though undeniably just, are not self-evident. The case of the Indian Telegraph Service can no longer be hushed up by the Government of India; and a thorough investigation, the materials for which are now in the hands of the English public, must certainly result in some substantial redress.

Into all the particulars of this strange business we need not enter at length. The latest memorandum of the Director-General of Indian Telegraphs dealing with the subject is sufficient of itself both to establish the case of the complainants and to condemn the proposed remedy. This memorandum, dated 16th July of the present year, admits the fact that most of the surviving officers of the seventy-two who were added to the Superior Establishment as long ago as 1868-72 are debarred by the organisation of that establishment from receiving promotion; but the only relief it suggests to improve their prospects and those of their juniors on the list, who are of course similarly blocked, is the offer of a transfer to another branch of the Indian Civil Service—the Accounts Branch of the Public Works Department. From an administrative point of view such a proposition seems almost incredible. What are we to think of a department which coolly proposes to deprive itself of a number of experienced technical and scientific officers, of fifteen years' standing in a service where knowledge and experience count for everything, in order to push their juniors into the vacant places? And what, too, of that other department of Public Works whose accounts are capable of being adequately kept by inexperienced men fresh from the field of Telegraph Engineering? Any telegraph officer desirous of being so transferred is invited to submit his application at once; the meaning of which is plainly, that if his application is not made forthwith the officer must for ever hold his peace. We suspect that the Director-General, or rather perhaps we should say the Indian Government behind him, will be mistaken in both these calculations. No man with any self-respect would voluntarily quit a department in which he has spent the best of his days to become an interloper in another of which he knows nothing, unless his transfer is accompanied by substantial advantage such as would convert an otherwise ignominious shunt into an honourable distinction. The proposition in question effectually bars any move of the kind, by declaring that, as to the terms of transfer, "all that can be said at present is that no officer will receive in his new position less pay than he draws at present." As there is no trace of conscious humour about the wording of this grotesque deliverance we can only suppose that it was deliberately framed as an affront and a snub.

Of course the official mind, which is always ready to seize the weak points in a memorial, will find some in this. It will notice that the memorialists have occasionally overdrawn their case, more in the spirit of the special pleader than of "gentlemen by education and feeling." Also that, in spite of disclaimers to the contrary, there is some unseemly asperity displayed towards the old establishment officers, who, though not less deserving than themselves, have been more fortunate, and who on this account are flippantly spoken of as "the men who create the block." Lastly, the remedy proposed by the memorialists themselves is open to the remark that it amounts precisely to the same thing as that suggested by the Government, only the "men" are different. If it be right to pension off a number of old servants to make room for younger ones, it cannot be wrong to transfer these younger

Digitized by Google

ones to make places for others that are younger still. This is an obvious departmental retort, and the officers now suffering from ten years' stagnation in promotion would have been better advised to have shown more consideration not only for the interests of the service, but the feelings of the men of the older establishment. If these latter are willing to quit the service, and if they can be dispensed with without detriment to it, then the case is different; but it ought to have been set forth in the memorial. For our own part we do not like the idea of enforced pensioning, except where there is proved incompetency; and as a mode of clearing the way for fresh promotions it involves an obvious waste of money. A lesser extravagance, it seems to us, would be to repeat, so far as may be needful, the step taken in 1867, namely, enlarging the establishment, but without repeating the blunder of that year—the importation of a redundant force from England. By all accounts the duties of the superior officers are very heavy and responsible. To lighten them and increase the emoluments would be a more rational course than to disburse large sums for pensions of an absolutely unremunerative character. As appointments fell in, either by casualty or superannuation, the duties could be apportioned among the existing staff, and the redundancy would be gradually got rid of.

We speak with diffidence, however, of a service with which we are necessarily in comparative ignorance; and practical remedies probably can be framed only on the spot. But we are clear as to the justice of the case put forward by the memorialists; and our sole misgiving is lest there should be any lack of justice on their parts towards their employers or their fellow officers. As regards the Indian Government, its duty in this matter is plain; the misrepresentations of 1866 must be atoned for, and the error in calculation which introduced to the service a great number of highly qualified persons, with great expectations impossible of realisation, must not be laid on them. We do not blame the Government for having filled the newly authorised appointments with men of the old establishment; it would have been absurd to put the new men over their heads. But the consequent deadlock is entirely the fault of the Indian authorities; and as it has resulted in a grievous wrong to the parties who were unwittingly deceived by them, this wrong should be promptly and cheerfully rectified, cost what it may.

CORRESPONDENCE.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The effect noticed by Mr. Williams, p. 395, is one familiar, no doubt, to all who have worked with several induction coils. I have frequently seen the vibration of the spring entirely stopped on the closing of the secondary circuit. This happens with medical coils, with a separate horse-shoe magnet for the break, when the spring is weak. If the two handles are brought into contact, the magnetism overpowers the spring, and sets up a residual effect, which holds the armature down, and breaks circuit altogether.

The stored energy of the magnetised core escapes at the moment of break, either as heat in the core or as electric current in the primary and secondary wires, dividing between these two in ratios governed by the construction and conditions. The variation of these ratios amounting to the resistance of the secondary circuit is manifested both by the rate of vibration of the spring and by the brightness of the spark at the break. These currents, being in the same direction as the primary current, reduce the speed of demagnetisation—that is to say, they represent the magnetising effect which equal currents would have if sent into the two circuits from an external source. This effect, of course, varies with the conditions existing in the two circuits, *i.e.*, the ampere-turn values modified by their distance from the core. Their effect is to retard the recoil of the armature and lengthen the period of the breach of circuit of the primary source. Therefore any variation in these currents results in a variation of the rate of vibration of the spring.—Yours, &c.,

JOHN T. SPRAGUE.

THE TELEPHONE IN CINTRA (PORTUGAL).

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the issue of *The Electrician* for June 26 last, Mr. Danvers has made rather a mistake in trying to claim the novel use of rockets in passing telephone wire as his own idea. Perhaps Mr. Danvers will remember my using the bow and arrow, slug sling, &c., in passing wires over the many forbidden houses, convents, vineyards, olive tree plantations, &c., in and out of Lisbon, as rockets were then too expensive an item.

By inserting the above you will greatly oblige, yours, &c.,

ALFRED J. THOMPSON, Electrician, China and Japan Telephone Company, Shanghai, China.

ON A NEW FORM OF GALVANOMETER.*

BY PROF. JAMES BLYTH, M.A., F.R.S.E.

The object of this short communication is to describe a method of measuring electric currents by means of an instrument whose scale is graduated to equal divisions, and whose deflections are, from the intrinsic nature of the instrument, proportional to the current strength through all ranges.

In principle the instrument depends upon the mechanical action exerted by a magnetic field upon a movable conductor carrying a current. In construction it is essentially similar to the well-known apparatus, due to Faraday, for showing the continuous rotation across the lines of magnetic force of a horizontal radial conductor carrying a current and having slipping contacts at its centre and circumference. The construction will be understood from the following description:—

Two bundles of permanently magnetised steel wires are made up in the form of cylinders having narrow axial holes. These are fixed with their axes in the same vertical line, separated by a narrow gap, and so that the north poles of the one set of magnets face the south poles of the other. In this gap the magnetic field is sensibly uniform and the lines of force vertical. Inserted in the gap is a thin circular disc of wood or vulcanite, having a central mercury cup and a concentric circular mercury trough at a short distance from it. A stout brass rod is provided, having a short thick copper wire rigidly attached at right angles to its lower end. Its upper end passes freely through the axial hole in the upper magnet, and is rigidly attached to the lower end of a long fine torsion wire of steel or silver, whose upper end is fixed to a suitable support. The lower end of the brass rod dips into the central mercury cup, and the outer end of the copper wire (bent down a little at right angles) dips into the concentric canal of mercury. Stout copper wires are led from the central cup and canal to binding screws suitably placed so as to form the terminals of the instrument. The upper end of the brass rod, which projects a little above the upper magnet, carries a long pointer, which moves over a horizontal circular disc, graduated either to degrees or to show amperes directly. This disc is fixed with the torsion wire passing freely through its centre. The whole is so enclosed as to be free from air current.

The action of the instrument will be easily understood. Suppose a current sent through it. As is well known, the electromagnetic force acting on the radial current will tend to make it rotate in a horizontal plane with a uniform force. This rotation will go on till a certain angle is reached, when

* Paper read before the British Association at the Aberdeen meeting, September, 1885.

Digitized by Google

the moment due to the electromagnetic force is balanced by the moment due to the torsion of the wire.

Let i = the current strength,
a = the length of the radial wire,
N = the magnetic induction,
A = the torsion constant,
θ = the angle of equilibrium,

we have $\frac{1}{2} ia^2 \mathrm{N} = \mathrm{A}\theta$; or $i = \frac{2\,\mathrm{A}}{a^2 \mathrm{N}}\,\theta$,

showing that the current strength is proportional to the angle of deflection.

The instrument admits of several modifications. I have constructed two in addition to the above. In the one the permanent magnets are replaced by similarly-placed electromagnetic coils, through which the current to be measured passes. In this case the square of the current strength is proportional to the angle of deflection. In the other the fixed magnets are dispensed with, and instead a cylindrical bundle of magnets is fixed coaxially to the brass rod, but insulated from it, so that it rotates along with the rod and radial wire. In this case the radial wire projects from the middle of the length of the magnet bundle, while the lower end of the brass rod is prolonged so as to dip into a mercury cup at a considerable distance below the lower end of the bundle. Owing to the influence of the exterior part of the circuit leading from the mercury canal to the cup, the equation for this case is a little more complicated. With proper arrangements, however, the deflection can be shown to be proportional to the current strength.

In the instruments constructed for practical use the mercury cup and canal are so made, on the unspillable ink-bottle principle, as to preserve the mercury in case of being knocked over or even inverted.

MESSRS. PAXMAN AT THE INVENTORIES.

On Saturday evening last, at the invitation of Messrs. Paxman and Balls (Messrs. Paxman and Co.), a party of scientific gentlemen was entertained at dinner at the Inventions Exhibition to welcome Sir Philip Cunliffe Owen upon his return to what may be termed active duties, after a long and serious illness.

The occasion of the dinner was an acknowledgement of the very remarkable success achieved by Messrs. Paxman and Co. with the steam engines of their construction by which the machinery for lighting the Exhibition by electricity has been driven. The popularity and success of the Exhibition has been largely due to the very extensive adoption of the electric light, and, indeed, without this splendid light much of the attractiveness of the Exhibition would have been entirely wanting, and many of the chief features could not have been carried out.

The success of the electric light at the Inventions is of far greater importance than at first sight appears. Three millions of the public, more or less, have thus seen that the *fiasco* of electric lighting companies' bubbles was not through the failure of the light, but through the impotence of those who undertook to develop it. There is now no doubt as to its flexibility, for here it is seen adapted to interiors, exteriors, and fairy land effects. One of the most important features in any electric light system is the motor driving the dynamos. The latter may to a certain extent regulate, but failure of the motor cannot be compensated by any regulation of the dynamos. It must not be forgotten that originally Messrs. Davey, Paxman and Co. undertook to provide motor power at a very short notice, and a due meed of praise should be awarded, not only for their success at the Inventions, but for their success from the commencement of their work. The Executive have had a wonderful chance in their hands, but so far have failed to take advantage of it. An almost perfect monograph could have been obtained on electric lighting by this time. Suppose that it had cost the Executive £10,000, what of that? The public pay, and gladly pay. In our estimation not a revolution of an engine or a dynamo should take place without a record. Coal should be weighed, water measured, dynamometers and photometers everywhere. The electric light, in fact, should here be one gigantic scientific experiment, and the results rigidly obtained and verified.

Engines for electric lighting purposes must be capable of working with almost absolute uniformity of speed for a great length of time, and must be thoroughly trustworthy as not liable to failure in any sense, even for a few minutes. All the larger engines in the electric lighting department are by Messrs. Paxman and Co., and the perfection of their work has shown itself in remarkable contrast with a number of small high speed engines which were admitted into this department for driving some machines direct. Altogether Messrs. Paxman and Co. have provided about 1,200 horse-power in the electric lighting department, and they have also provided steam by means of a number of very fine locomotive boilers supplied from their works, which are capable of giving off 1,300 horse-power, thus making a total of 2,500 horse-power. These boilers have been called upon to perform much heavier work than was intended, in consequence of the heavy consumption of steam by some of the small high-speed engines, and through the failure of some of these much extra work has been imposed upon the large engines of the Colchester firm. The high excellence of the design and workmanship, and the economy of fuel consumption by these engines has, however, enabled them to perform this work without any difficulty. They are all fitted with Paxman's well-known automatic expansion gear and governors, and several of them are on the compound system, by which great economy of fuel and steadiness of running are ensured.

The unqualified success of the Colchester engines in different parts of the world has been fully confirmed by a most severe test in the recent Fisheries and Health Exhibitions, and also in the Inventories, and the executive committee have warmly acknowledged their indebtedness to Messrs. Paxman and Co., who are to be congratulated on a success which can only be attained by the best designs, materials, and workmanship, combined with a thorough knowledge of what is required. It may also be mentioned that this firm have not only received a gold medal at this Exhibition, but also at the two previous ones.

But to return to our immediate subject. A hearty welcome was given to Sir Philip Cunliffe Owen, who, in replying to the toast, stated that the preliminary work in connection with next year's Exhibition was well advanced, and that the space was fully occupied.—Sir F. Bramwell replied on behalf of the executive committee, and Sir F. Abel on behalf of the lighting committee, and both spoke in high terms of the manner in which the firm of Messrs. Paxman and Co. had fulfilled all demands made upon them.

THE DISTRIBUTION OF ELECTRICITY.*

BY PROF. GEORGE FORBES.

LECTURE I.—INTRODUCTORY.

When asked to give a course of lectures on the distribution of electricity, I was very pleased to accept the task, because I felt that such a work was much needed. Numbers of engineers have worked out very fully numerous problems in electrical distribution for their own wants, but no classification of systems has been attempted, and no work has been published to assist the engineer in drawing out specifications and selecting between systems.

I also felt that a principal reason why public electric lighting had made so small progress was the difficulty of planning a system of distribution, and the probability that an expensive system proposed to-day would be superseded by a more economical system next year.

The low pressure system, called multiple arc distribution, is enormously expensive, and necessitates the engine house being in the centre of the populous district lighted, and this is seldom feasible. A high pressure system gets over this difficulty, but we can hardly say that any such system has yet been brought to practical perfection. This is what is wanted for large central station lighting, although much can be done even on the expensive low pressure plan.

At first I proposed to make these lectures extremely popular. But as I progressed I found that I should sacrifice too much by avoiding technicalities, and I felt that the time I have spent on their preparation would have better fruit if I addressed myself more directly to brother engineers, but still in language clear enough to be understood by a non-technical audience.

I shall use the parliamentary term "pressure" in these lectures, signifying difference of electric potential between the two conductors. Those who have had most to do with large practical installations know best what serious items are the cost of conductors and the purchase of a site. The latter would be enormously diminished if the works could be at a distance. It is my duty in these lectures to see how far in each system of distribution the cost of conductors can be diminished; and wherever economy clashes with other facts, and introduces new engineering difficulties, it will be my duty to show how these engineering difficulties may be removed.

One thing I must insist upon. If the economical considerations lead us to a large conductor, we must recommend that large conductor. No financial questions of a difficulty in raising the money may be allowed to influence the engineer in recommending a smaller conductor than his calculations have proved to be the most ecomical in the end.

You all know the different systems which have been proposed for lighting. You know how arc lights have been distributed in series, and how incandescent lamps have been put on multiple arc in large stations.

* The Cantor Lecture of Professor George Forbes, delivered on February 2nd, 1885. From the *Journal of the Society of Arts*.

Digitized by Google

More especially you are acquainted with what has been done in America in this matter. In some cases only has a special system been thoroughly worked out; and in very few cases, I fancy, have different systems been relatively compared and pursued so as to bring out the most economical conditions possible.

Besides these different systems I have spoken of—the series and multiple arc systems—you are aware that the latter, the multiple arc, is divided into a number of different modes of distribution. You have all heard people talking about the network system, the system with three mains, and also of lines-of-centres distribution. These are different modes of multiple arc system. And so also we have another one, which is called the multiple series system, which has been used to a certain extent, and very successfully used, but which has very radical defects in it which have prevented its general adoption; at the same time, many distinguished engineers believe that, in the future, there may be a possibility of making this system efficacious, and of removing the defects which are in the way. The objection to the ordinary multiple system, where all the lamps are connected to two massive mains, or to a number of wires which are so connected together as to make two massive mains, is the enormous cost of the conductors.

Besides the difficulty that the Electric Lighting Act is unworkable, as every unprejudiced person must admit that it is, there is no doubt another fact which has largely hindered electric lighting, and that is the enormous cost of the mains. And not only that, but the multiple arc system introduces another serious expense. It becomes essential with such large mains to have our central station and our engines in the centre of the district which is being supplied. Now, in a thickly populated neighbourhood, such as it would be economical to light on the multiple arc system, it is very difficult to get a site for your engine and dynamos, and this has been acknowledged by those who have tried to undertake the system in London to be one of the most serious objections to the multiple arc system. Thus at every point we see that it is of the utmost importance that engineers should devote their attention to economy in the construction of their mains, to enable us to have a good supply after the most economical system of mains which is possible, whether that system be multiple arc or multiple series, or any other of the modifications which have been proposed. It is at present the earnest hope of thousands and thousands of the inhabitants of our great towns that they may have electricity supplied to their houses from central stations, just as gas is at the present time. They have been prevented hitherto from obtaining such a supply, partly by the cost of production and supply, and partly by the jealousies of municipal authorities acting through Parliament, and who have undertaken gas speculations. The public who want the electric supply will not endure this much longer, and it becomes a matter of importance for electricians to see how far they are able to reduce the cost of production and supply.

Production.—The question of production is one which has been very fully discussed. The dynamo machine affords the most economical means of production, and will probably continue to do so. If ever it be superseded, it can only be by a step in our knowledge entitled to the name of a great scientific discovery. Such discoveries do not come at our bidding. They are evolved in the laboratory of the patient scientific inquirer, and seldom in the workshop of the speculative inventor. In selecting our dynamo, cost of manufacture and maintenance, and cost of production of electrical energy, are the chief items to be considered. For a central station with 10,000 lamps we want to have about 1,000 electrical horse-power in the circuit. We may use high-tension machines in parallel, or low-tension machines in series, until we get in the external circuit 7,500 amperes and 100 volts (if such be the class of lamp we are using), or we may use a single machine to produce the same effect. It is better to use a large number of machines, so that they may be each removable and able to be replaced by another when repairs are necessary. But it is a matter of indifference what class of machine we employ (high tension in parallel, or low tension in series), except so far as cost is concerned. We have simply to choose the machine which gives the greatest output of energy in the circuit at the least expense.

I have drawn attention to this because it is important, and because few people have thought of combining low tension machines in series. And I have confidence that the simplicity of construction of these machines, their cheapness and economy of maintenance, and their infinitesimal internal resistance, will lead them to be generally adopted.

The question of primary batteries must be laid on one side as being quite too costly. If a battery were made practical in which coke or charcoal should be consumed instead of zinc, we might discuss the matter. In 1880, I made a number of partially successful experiments in this line, but with no very definite result. If, on the other hand, the residual products of a battery were valuable, and there was unlimited demand for them, some progress might be made. And yet we have no reason for hope in this direction. Secondary batteries being dependent entirely upon the dynamo, are connected with the supply rather than with the production of the current.

There are other systems, such as that which utilises alteranate currents combined with the induced current distributors on the plan perfected by Messrs. Gaulard and Gibbs. This also is rather a question of supply and distribution, and will be left to a later stage for discussion.

Leaving now the question of the production of electricity on one side, the next point to be considered is its distribution and supply. But before attacking this problem directly, I should like to make a comparison of it with the similar problem with respect to gas.

Comparison with Gas Distribution.—The production of gas is a somewhat extensive laboratory experiment enlarged to a commercial scale. The distillation of coal, and the subsequent treatment of the gas by condensers, scrubbers, and lime purifiers, previous to its admission through the regulator and station meter to the gas holder, is really a complicated process compared with the production of electricity. In its distribution through mains to the houses of individuals, the problem is very similar to the problem for electricity. A certain pressure is given to the gas at the central station. With this pressure it must be forced through the mains, and must be delivered to the gas jets of consumers at a definite pressure. The pressure must not vary seriously with the number of jets in use, nor with the position of a house in the district. There must be no leakage in the pipes, or as little as possible. In all these points electricity has its analogue. Moreover, a difference of pressure will establish itself if the flow of gas and the resistance of the pipes to this flow are large; and the larger the pipes the less is this resistance. Hitherto the analogies are very striking. There are, however, two points of difference. First, in gas distribution the resistance to the flow of gas is not proportional inversely to the area of the pipe, so that while with electricity the resistance of 100 parallel wires is the same as that of one wire 100 times the section, this is not the case with gas, where the hundred pipes have much more resistance than the simple pipe of a hundred-fold section. Secondly, the cost of gas mains is not proportional to their sectional area, and still less is it proportional to the current of gas it has to carry. With electricity, on the other hand, the cost of mains always increases at least in proportion to the current. The consequence of these facts is, that the cost of mains is an incomparably more important matter in the case of electricity than in that of gas. This is what renders the distribution of electricity so important and worthy of study by the electrician. Upon the arrangements made under this head depends very largely the question whether or not electricity is as cheap a means of lighting as gas.

While comparing gas and electricity, it is surprising to see how great a difficulty has been met in introducing the latter. When gas was introduced the public had no experience of, nor occasion for confidence in, a general supply, and the laying of pipes was a leap in the dark. There was no knowledge of the size of pipes required, there was little means of even guessing at the probable consumption. At the present time a public supply of light is well understood and appreciated, and we know well what currents our wires will carry. Moreover, from the known gas consumption, we can form a more accurate estimate of the probable demand for electricity. Then, at the same time when gas was introduced, the burners were infamous (merely a hole in the top of a closed tube), and the flame was smoky and sulphurous, consumed the oxygen, poisoned the air, and blackened surrounding objects, while its smell was odious and unwholesome. It was not known how to prevent leaks, and leaks meant explosions. The inexperience of the public was certain to leave cocks turned on—hence explosions again, and deaths from suffocation by gas. Gas gave a naked flame which is a constant source of danger, while to-day the incandescent light cannot set light to anything. Yet, in spite of all these advantages, the difficulty of introducing electricity has been far greater than was that of introducing gas. The electric light must contend against a monopoly. Gas had a fair and open field. Our Legislature has favoured the monopolists; the legislators for gas encouraged its development. Gas met with financial speculators just as electricity has done. The monopolists who have sprung into existence are the one deterrent cause.

Distribution of Electricity.—Passing now to the subject of these lectures, it will be well if we give a general survey to-day of the various points with which we have to deal, and of the different plans of distribution, which must afterwards be considered in detail.

The first thing to be noticed is that, in order to give electricity a fair chance in competing with, or supplementing, the gas supply, the cost of one of its most expensive parts, *i.e.*, the conducting mains, must be reduced as low as possible. Various schemes have been proposed with one advantage or another. Some systems have been devised whose speciality is that they do not allow the potential to vary much. Other systems have specially in view the avoidance of total darkness if an accident should occur at any point. At present it is essential that these considerations should be second to economy. Let us first get the most economical system, and all things else shall be added hereafter. Now, in attempting to reduce the size of our conductors, we meet with three difficulties:—1. With small conductors energy is wasted in heating them, and this may become very considerable. Thus, while capital outlay on copper is saved by small conductors, the annual consumption of coal is increased, and large engines and dynamos are required. 2. With large currents this heat may be sufficient to injure the insulation. It also increases the resistance of the conductors; and if the conductors be underground, the heat may become unpleasant to foot passengers. Clearly, the conductors must be large enough to prevent such troubles. 3. There is a loss of potential in the mains, which is greater where these are smaller. This loss is also greater in proportion to the number of lamps fed by the main. The fall of potential with one lamp might be one-tenth of a volt, and with 100 lamps it would be 10 volts. So large a variation under varying conditions of consumption cannot be permitted, and the conductors must be large enough to prevent any such variations.

I propose now to say a few words on each of these heads, in order to prepare the way for criticising different systems of conducting mains.

Now, let us first look at the problem with a few figures before us, to see on what scale we are dealing. Suppose that we are using a conductor of a square inch section to carry 1,000 amperes. The resistance of 100 yards of that conductor of pure copper would be 0·0024 of an ohm. Now, the energy which is used up is given you by the calculation C^2R divided by 746. That is equal to 3·2 horse-power used up in every 100 yards of our conductor for every 1,000 amperes. Now, what is the cost of this electrical horse-power per annum? It is usually considered safe to say a horse-power costs £10 per annum, but, owing to the period in which electricity would be used, this is not a safe figure. Let me begin by considering £20 as the

Digitized by Google

cost of horse-power. £64 is the cost of the total horse-power. We have wasted in four years in every 100 yards £256 ; in 20 years £1,280 is wasted in that conductor. Now, if I double the size of my conductor, I have the quantity of power wasting reduced to £640. The question comes to me, would it cost more than £640 of capital to lay down an extra 100 yards of a similar section ? No, it would not ; and, therefore, it is economical to double my conductor. And so we go, step by step, until we find that the gain is just equal to the extra expenditure of capital in the laying down of conductors, and then we have arrived at a satisfactory arrangement. You will easily see if you work this out. Now this is an important point, in fact one of primary importance. It was first approached by Sir William Thomson in an address to the British Associacion, in 1881, in which he read a paper on "The Economy of Metal Conductors of Electricity," and, in that most interesting paper, he arrived at the conclusion that the interest spent upon the capital of the conductors should be equal to the value of the energy which is wasted annually in these conductors.

The first question which becomes a trouble is, what are we to consider the cost of electrical horse-power ? There are two ways of looking at this problem, and we will just glance at them independently. First, let us take the case of an installation which has been carefully estimated for ; and let us see there, after the whole of the buildings, distributing and supply plant, and everything has been laid down, what is the cost of each horse-power of electricity, if you like to call it so. To give you a perfectly unbiased example, I have taken the figures, kindly furnished me by Mr. Crompton, of a large installation for which he carefully prepared estimates. I find, on looking into this, that in this case the cost of electrical horse-power—of course depending on the number of hours used during the year—if it was for 1,000 hours, the cost of horse-power came to about 5d. ; for 2,000 hours in the year, 3·5d. ; and for 3,000 hours only 3d. ; and that means for the year in these three cases it would be 5,000 pence, 7,000 pence, and 9,000 pence. Now, the next question that comes before us is, what is the number of hours we are supposed to use our electricity ? There is very little doubt that about 1,000 hours is probably a fair average consumption for people in a town ; but I think it very likely that, at any rate in the first installation set up, a certain selection will be possible, which will raise the average a little higher. For my own purposes at present, I am going to assume 1,500 hours ; if you prefer another value, you can work it out yourselves to suit it. That will be the average cost of those two, which comes almost exactly to £25 a year. Now, if you work out the cost of the energy wasted in a 1,000 yards conductor, you will find, I think, that the following figures are energy wasted in the conductor for 3½in., 4½in., 4in., 5in., 5½in., 6in., and 6½in. ; the amount is £22·8, £20, £17·8, £16, £14·5, £13·2, and £12. Therefore, the gain in passing from any one to the next is 2·8, 2·2, 1·8, 1·5, 1·3, and 1·2. These are the gains which there are in increasing the size of the conductor.

Up to this point it is all plain sailing, a matter of plain calculation. The next thing is, What is the interest on the capital which is expended ? This of course depends on the way in which the mains are laid, and different people have different ideas about how they should be laid. Many people lay mains at present with stranded cables. For my own part I cannot see what is the object of doing this ; it is the most expensive form in which you can produce your copper, and really nothing is to be gained. It seems to me simply to arise from the fact that cables we used previously were submarine cables, and certainly they are of advantage there ; but why they should be used on land, where there is no strain, I see no earthly reason. Others think they should be laid in massive bars of semi-circular shape, covered with bituminous compound ; others in flat sheets laid in troughs. At any rate, every person differs from every other, and consequently every person must have a different value for his cost of copper. But I have taken it as an example simply, and you need not take the value I use. Take the £100 a ton as the cost of adding an additional amount of copper to our mains after the troughs and so on have been laid. In that case the interest upon it depends upon the percentage which we allow. Now, what are we to allow ? Ought it to be 5, 7½, or 10 ? That, again, is a question for the engineer to determine for himself. But allow me to point this out, that when we are increasing the size of our mains, really we ought to be diminishing the percentage allowed for maintenance. The wear and tear is less, heating is less, the danger to insulation is less ; everything leads us to believe there is a less cost of maintenance with a large conductor than with a small one. This is a very important point. Each one must judge for himself whether to take 5, 7½, or 10 per cent. He will find with 5 per cent. the annual cost is 1·27, at 7½ per cent. 1·91, at 10 per cent. 2·55 ; so that what we have to do is to find that size of conductor which should equal the interest which we happen to consider the right interest. Supposing 5 per cent., then we have 1·27 settled, which gives 6 inches ; 7½ per cent., 1·81, about 4 or 4½ inches ; and 10 per cent., 2·55 ; between 3·5 and 4 inches for a thousand amperes. I have gone through this example carefully just to give you a clear conception of the way in which the problem is to be worked out, but I think you may very safely say that the consumption I have taken is too large. It is perfectly true that this estimate to which I have alluded includes the cost of buildings, dynamos, boilers, and other machinery, the mains, and also the annual cost of coal at 18s. per ton. Well, all these points do come in, therefore it is a question for each one to consider for himself how far these things are to be divided in this way. It may be said by some, however, that it is desirable only to look upon our plant as being fixed, and supposing we want to carry extra current on the same size of conductor, would it be wise to do so or not ?

We may ask, "With a working station, what would be the extra cost for energy wasted if we increased the current for the same section of wires ?" The answer might be given that everything is in place and paid for, except an extra engine and dynamo, and the cost of coal, oil, waste, and petty stores for the extra energy. The cost of a mechanical horse-power so reckoned is, say, 0·75d. per hour with coal at 21s. the ton, say 1·00d. for an electrical horse-power per hour, including loss of transformation, besides the cost of the dynamo, *i.e.*, 1500d., or £6·250 per horse-power per annum of 1,500 hours. The cost of dynamos is £20 per 1,000 watts of maximum output, or £7. 18s. per horse-power, which, at 15 per cent., is £1. 2s. 6d. per annum. Thus the whole annual charge per horse-power, in this way of looking at it, is :—

Power	6·250
Dynamo	1·125
Total charge	7·375

Now, we have seen above that when a conductor of one square inch section carries a current of 1,000 amperes the loss of energy per 100 yards is 3·2 electrical horse-power, which is £23·599 per annum. Our Table now becomes the following :—

Section in sq. inches.	Cost of waste energy.	Gain for 1·10in. increase.	Extra cost of mains at 5 per cent..
2·50	£9 440	£0·863	£0·635
2·75	£8·577	£0·711	£0·635
3·00	£7·866		
3·25	£7·261	£0·605	£0·635
3·50	£6·743	£0·518	£0·635

It is not fair to allow more than 5 per cent. on the extra copper, as there is no extra attention required ; in fact, probably less attention, owing to the smaller development of heat. This gives the maximum economy at 3 to 3·25 inches the 1,000 amperes. Where the cost of an electrical horse-power is 0·8d. in place of a penny (exclusive of interest and depreciation in the dynamo) the economical size comes out 2·5 square inches to the 1,000 amperes.

(To be continued.)

BRITISH ASSOCIATION MEETING, 1885.

ADDRESS TO THE CHEMICAL SECTION, BY PROF. HENRY E. ARMSTRONG, PH.D., F.R.S., SEC. C.S., PRESIDENT OF THE SECTION.

(Concluded from page 402.)

The current belief among physicists would appear to be that the dissolved electrolyte—the acid or the salt—is almost exclusively primarily decomposed (Wiedemann, "Elektricität," 1883, II. 924). We are commonly told that sulphuric acid is added to water to *make it conduct*, but the chemist desires to know why the solution becomes conducting. It may be that in all cases the "typical compound" is the actual electrolyte—*i.e.* the body decomposed by the electric current—*but the action only takes place when the typical compounds are conjoined and form the molecular aggregate*, for it is an undoubted fact that HCl and H_2SO_4 dissolve in water, forming "hydrates." This production of an "electrolytical system" from dielectrics is, I venture to think, *the* important question for chemists to consider. I do not believe that we shall be able to state the exact conditions under which chemical change will take place until a satisfactory solution has been found.

F. Kohlrausch (*Pogg. Ann.*, 1876, 159, 233) has shown that, on adding sulphuric acid to water, the electric conductivity increases very rapidly until when about 30 per cent. of acid is present a maximum (6,914) is attained ; conductivity then diminishes almost as rapidly, and a minimum (913) is reached when the concentration corresponds with that of a monohydrate (H_2SO_4, OH_2) ; from this point conductivity increases somewhat to (1,C31 at 92·1 per cent. H_2SO_4), and then again falls, and is probably zero for the pure acid ; on adding sulphuric anhydride to the acid conductivity again increases. Solutions of other acids and of a number of salts—chiefly deliquescent and very soluble salts—also exhibit maximum conductivity at particular degrees of concentration. In no other case has the existence of two maxima, such as are observed in solutions of sulphuric acid, been established ; but probably this is because the experiments either have not been, or cannot well be, carried out with pure substances or very concentrated solutions. Solutions of less soluble salts increase in conductivity as the amount of salt dissolved increases.

Kohlrausch has suggested, as an explanation of the influence of the "solvent" on the conductivity of an "electrolyte," that in a solution the ions which are being transferred electrolytically come less frequently into collision than would be the case in the pure substance. There is therefore less opportunity for the formation of new molecules, and the ions are able to travel farther before entering into combination.

Regarding the question from a chemist's point of view, however, I cannot help thinking that this explanation is scarcely satisfactory or sufficient; and I cannot resist the feeling that the production of electrolytically conducting solutions from dielectrics is in some manner dependent upon the occurrence of chemical action. If the composition of the solutions of

Digitized by Google

maximum conductivity be calculated,* it will be seen that they contain but a limited number of water molecules; thus the solution of sulphuric acid of maximum conductivity (at 18°) contains 30·4 per cent. of acid, and therefore has the composition $H_2SO_4 : 12·4\ H_2O$ (approximately); for nitric acid the ratio is 1 : 8; for acetic acid it is about 1 : 17. Now, it is highly remarkable that the solutions of maximum electric conductivity are also very nearly those in the formation of which nearly the maximum amount of heat is developed; this will at once be obvious on comparison of the curves given by Thomsen ("Thermochemische Untersuchungen," Vol. III.), and by Kohlrausch. In the chemist's experience, the point of maximum heat development is usually near to the point of maximum chemical change, and I think, therefore, that we are justified in concluding that, even if electrical conductivity be not a maximum at a particular concentration on account of the presence of a particular hydrate (belonging to the class of molecular aggregates) in maximum amount, at all events the "structure" of the system is especially favourable, and the "chemical influence" exerted by the one set of molecules upon the other is at a maximum at the point of maximum conductivity. The fact that the amount of sulphuric acid required to form a solution of maximum conductivity increases with temperature—

Temp.	0°	10°	20°	30°	40°	50°	60°	70°
Per cent.	30·2	30·9	31·7	32·5	33·5	34·1	34·5	35·4

and also the fact that the maxima and minima of conductivity tend to become obliterated with rise of temperature (Kohlrausch), are both in accordance with the view that conductivity is in some way dependent upon chemical compsoition, as the effect of rise of temperature would be to cause the dissociation of hydrates such as I have referred to. The increase in conductivity of aqueous solutions with rise of temperature would appear to be against the view here put forward; but it is probable that this may be largely due to diminution in viscosity and increase in the rate of diffusion.

Our knowledge of the binary metallic compounds, which are generally admitted to be electrolytes *per se*, also affords evidence, I think, of an intimate relation between chemical constitution and "electrolysability." It has been pointed out (comp. L. Meyer, "Theorien d. mod. Chemie," 4th ed. p. 554) that whereas all the metallic chlorides and analogous compounds which cannot be electrolysed are easily-volatile bodies, the electrolysable metallic chlorides, &c., are fusible only at high temperatures. A careful discussion of the various known cases does not, however, justify the conclusion that decomposition takes place, or not, according as the temperature at which the body assumes the liquid state—and at which, therefore, there is full opportunity given for electrolysis to take place—is high or low, especially as recent observations show that electrolysis may take place prior to fusion. But it is especially noteworthy that many of the chlorides, &c., which are electrolytes, undoubtedly contain more than a single atom of metal in their molecules; indeed, after careful consideration of the evidence, I am inclined to go so far as to put forward the hypothesis *that among metallic compounds only those are electrolytes which contain more than a single atom of metal in their molecules.* No difficulty will be felt in granting this of cuprous and stannous chlorides, and even of cadmium, lead, silver, and zinc chlorides; but opinions will differ as regards the metals of the alkalies and alkaline earths.† Assuming the constitution of metallic electrolytes to be such as I have suggested, it is not improbable that on electrolysis a part only of the metal is determined to the one pole, the remainder being transferred along with the negative radical to the opposite pole. Hittorf, indeed, has already put forward this view in explanation of the remarkable results he obtained on determining the extent of transfer of the ions in aqueous and alcoholic solutions of the chloride and iodide of cadmium and zinc.

Again, an argument in favour of a connection between chemical constitution and electrical conductivity is the fact that carbon, sulphur, selenium and *phosphorus* each exist in conducting and non-conducting modifications, as it can scarcely be doubted that the so-called allotropic modifications of these elements are differently constituted.

It appears, as I have already said, to be the current belief that when aqueous solutions are submitted to electrolysis, as a rule the dissolved substance, and not the water, is the actual electrolyte. Without reference to the question I have raised as to the constitution of an electrolyte, it appears at least doubtful whether this view can be justified by appeal to known facts; at all events, I have failed to find satisfactory evidence that such is the case. Moreover, as sulphuric anhydride dissolves in water with considerable development of heat, it would appear that more work has to be done to separate hydrogen from sulphuric acid than to separate it from water; on this account we might expect that the water rather than the acid would be decomposed. Are not perhaps both affected according to the proportions in which they are present? The marked variation in the extent to which the negative ion is transferred to the positive pole, as observed by Hittorf, when solutions of different degrees of concentration are electrolysed, would appear to support this view. The difference in the products, according as dilute or very concentrated solutions of sulphuric acid are used, may also be cited as an argument that the chemical changes effected vary with the concentration; but, on the other hand, it is quite possible that the observed differences may result from the occurrence of purely secondary changes. Ostwald has recently put forward the view that one *or more* of the hydrogen atoms of certain acids are split off according to the concentration of the solution.

*Formula.	Formula Weight.	% in solution of max. con.	Composition in approximate mol. ratios.	Conductivity.
HNO_3	63	29·7	1 : 8	7330
HCl	36·4	18·3	1 : 9	7174
H_2SO_4	98	30·4	1 : 12·4	6914
H_3PO_4	98	46·8	1 : 6	1962
$C_2H_4O_2$	60	16·6	1 : 17	15·2
KOH	56	28·1	1 : 8	5995
NaOH	40	15·2	1 : 12·7	3276

† We may regard as evidence in support of this explanation the fact that neither beryllium chloride, which fuses at 600°, nor mercuric chloride is an electrolyte, as both of these, at temperatures not far removed from their boiling points, exhibit the simplest possible molecular composition. Clarke's recent interesting observations on mercuric chloride and iodide do not, I think, suffice to prove that these compounds are electrolytes; it is more than probable that electrolysis is preceded by the formation of mercurous compounds. Even an aqueous solution of mercuric chloride does not conduct appreciably better than water (Buff).

I call attention to this because I conceive that it has a most important bearing on the discussion of the nature of the chemical changes which occur during the dissolution of metals. Formerly it was said that when zinc acts upon dilute sulphuric acid, the zinc displaces the hydrogen of the water and the resulting zinc oxide dissolves in the acid, forming zinc sulphate; the modern explanation advocated by most chemists has been that the metal directly displaces the hydrogen of the acid; in fact, that this is the nature of the change whenever an acid is acted upon by a metal. If in a solution of sulphuric acid, of whatever strength, the acid be the actual electrolyte, I imagine that we are right in accepting this modern view; but if the water be the electrolyte, we must, to be consistent, return to the view that the oxide—more probably in most cases the hydroxide—is the primary product. And if it can be shown that during electrolysis both water and acid, according to circumstances—concentration, E.M.F., &c.—undergo change, it will be necessary to teach that in a similar manner the action of metals on acids is no less complex. Our views on the action of metals on concentrated sulphuric acid, and on solutions of nitric acid of various strength, must also materially depend on the interpretation of the behaviour of these acids on electrolysis with varying electromotive forces.

Having thus fully explained why I venture to think that Helmholtz's definition that "electrolytes belong to the class of typical compounds, not to that of molecular aggregates" is somewhat open to question, it now becomes necessary to make some slight reference to the constitution of these so-called molecular aggregates. Although opinions differ widely as to the definition to be given of a typical or atomic compound, and of a molecular compound or aggregate, the majority of chemists appear to agree that we must recognise the existence of two distinct classes of compounds. Prof. Williamson, in his address to this section at the York meeting (1881), entered at length into the discussion of this question, and in very forcible terms objected to the recognition of molecular combination as something different from atomic combinations; in this I, in the main, agree most fully with him. He further said that he had been led to doubt whether we have any grounds for assigning any limits whatever to atomic values, and he adduced a number of cases which, in his opinion, afforded illustration of a capability of elements to assume greater atomic values by combining with both negative and positive atoms than with atoms of one kind only; for example, he cited the compounds K_2CuCl_4 and K_2HgCl_4 as proof that copper and mercury may assume hexad functions; the compound K_2AgI_3 as an illustration that silver may act as a pentad; and the compounds $KAsF_6$ and K_2AsF_7 were regarded by him as evidence of the heptadicity and nonadicity of arsenic.

I have long been of opinion that the experimental investigation of this question is of great importance, and I believe that it must ere long attract the attention it deserves. The problem will be solved, not by discussions on the fertile theme of valency, but by determining the structure—the constitution—of bodies such as were referred to by Prof. Williamson.

My own view on the question is a very decided one. So far as the mere definition of valency is concerned, I entirely agree with Lossen; and, as I have said, I hold with Prof. Williamson that in all compounds the constituents are held together by atomic affinities, and atomic affinities only, but I believe that the formation of so-called molecular compounds is mainly due to peculiarities inherent more especially in the negative elements—*i.e.*, the non-metals and metalloids, and not in the positive elements—the metals; in other words, to the fact that, as was first pointed out, I believe, by Lothar Meyer, the negative elements tend to exhibit a higher valency towards each other than towards positive elements. The view I take, then, is, that in the majority of so-called molecular compounds the patent molecules are preserved intact in the sense in which a hydrocarbon radical, such as ethyl, is preserved intact in an ethyl compound, being held together by the "surplus affinity" of the negative elements. Thus I would represent the compounds K_2CuCl_4 and K_2HgCl_4 as containing copper and mercury of the same valency as the metal in the parent chloride, and regard them as compounds of the radicals ($CuCl_2$), ($HgCl_2$), and (KCl); a view which may be expressed by the formulæ

$$Cu\begin{matrix}Cl\,.\,ClK\\Cl\,.\,ClK\end{matrix} \qquad Hg\begin{matrix}Cl\,.\,ClK\\Cl\,.\,ClK\end{matrix}$$

The arsenic compounds referred to may be similarly represented

$$F_4AsF\,.\,FK \qquad F_3As\begin{matrix}F\,.\,FK\\F\,.\,FK\end{matrix}$$

We do not hesitate to attribute to the so-called double cyanides this order of structure, without in any way supposing that the metal changes in valency. Evidence that the "constituent radicals exist unchanged in molecular compounds" is afforded by facts such as that ferrous and potassium chlorides, for example, form a compound which obviously is still ferrous, being of a green colour, which would hardly be the case if the valency of the iron were increased; and that in like manner the compounds formed from stannous chloride manifest all the properties of stannous derivatives.

Whatever be the nature of chemical affinity, it is difficult to resist the conclusion that the "charge" of a negative radical especially is rarely, if

Digitized by Google

ever, given up all at once, that its affinity is at once exhausted. It would also appear that the amount of residual charge—of surplus affinity—possessed by a radical after combination with others depends both on its own nature and that of the radical or radicals with which it becomes associated. Differences such as are observed in the composition and stability of the hydrates of the salts of an acid—the sulphates, for example—clearly point to this. Other illustrations are afforded by the manner in which chlorhydric acid yields chlorhydrates of some metals and chlorides of others.*

It is noteworthy, however, that often those elements which from the ordinary point of view are regarded as possessed of feeble affinities are those which manifest the greatest tendency to form molecular compounds. Thus, it is commonly held that of the three elements, chlorine, bromine, and iodine, chlorine has the highest and iodine the lowest affinity, and this view accords well with the recent observations of V. Meyer on the relative stability of their diatomic molecules at high temperatures; but nevertheless we find that the compound which HI forms with PH_3 is far more stable than that of HBr or HCl with this gas; and it is well known that mercuric *iodide* has a much greater affinity for other iodides than have mercuric bromide and chloride for the corresponding bromides and chlorides.†

The recognition of the peculiarity in the negative elements to which I would attribute the formation of molecular compounds must, I think, exercise an important influence in stimulating and directing the investigation of these compounds and of compounds other than those of carbon; in the near future the determination of the structure of such compounds should occupy an important share of the chemist's attention. It will perhaps afford a clue in not a few cases which are not altogether satisfactorily interpreted in accordance with the popular view of valency. I may instance the formation of (?) polymeric metaphosphates, of complex series of silicates and tungstates, and of compounds of hydrocarbons with trinitrophenol. It may even serve to explain some of the peculiarities of the more complex carbohydrates.

It is one of the most clearly established of the "laws of substitution" in carbon compounds that negative radicals tend to accumulate; numerous instances are afforded by the behaviour of paraffinoid compounds with chlorine, bromine, and oxidising agents, and by that of unsaturated paraffinoid compounds when combining with hydrogen bromide and iodide. The special affinity of negative elements for negative is not improbably the cause of this accumulation. A similar explanation may perhaps be given of some of the peculiarities which are manifested by benzenoid compounds.

I would even venture to suggest that in electrolysing solutions the friction arising from the attraction of the ions for each other is perhaps diminished, not by the mere mechanical interposition of the *neutral* molecules of the solvent—in the manner suggested by Kohlrausch—but by the actual attraction exercised by these molecules upon the negative ion in virtue of the affinities of the negative radicals.

One result of increased attention being paid to the investigation of problems such as I have indicated will probably be that we shall be called upon to abandon some even of our most cherished notions. I would suggest, for example, that it may become necessary to regard nitrogen peroxide not as a mixed anhydride of nitrous and nitric acids, but as a compound of two NO_2 groups; its conversion into nitrite and nitrate affords no proof of its constitution, as chlorine peroxide, ClO_2, which exhibits no tendency whatever to combine with itself, also yields both chlorite and chlorate. A greater shock may result from a conviction arising that not only carbon dioxide, but sulphur dioxide, and perhaps even sulphur trioxide, dissolve in water, forming *hydrates*—$SO_2{\cdot}OH_2$, $SO_3{\cdot}OH_2$—not *hydroxides*. In recent times, in discussing questions of this kind we have perhaps often been led to attach too much importance to the argument from analogy; it is not improbable that, especially in the case of compounds other than those of carbon, chemical change involves change in structure more frequently than we are apt to believe.

It is possible that a precise estimate of what, for want of a better name, I have spoken of as residual affinity, may sooner or later be obtained, if the view Prof. Lodge has propounded in his paper "On the Seat of Electromotive Forces in a Voltaic Cell" be correct, that the cause of the Volta effect is the *tendency to chemical action* between the bodies in contact; that, for example, chemical strain at the air-contacts is the real cause of the apparent contact force at the junction of two metals in air. Prof. Lodge, if I understand his argument, appears to assume that the air effects are in some way dependent on the presence of "dissociated oxygen atoms." I think this is probably an entirely unnecessary assumption. Of late years, no doubt it has been the fashion to attribute the occurrence of changes of various kinds to the presence of products of dissociation, but probably to a very unnecessary extent. Recent investigations to which I have alluded show that there are other factors of extreme importance; for example, that water must be present in order to render a mixture of carbonic oxide and oxygen explosive. Again, the observations of V. Meyer and Langer have shown that, whereas chlorine *violently attacks* platinum at low temperatures, it is *without action* upon it at temperatures between about 300° and 1,300°, but then *again begins to act* upon it, the action becoming violent at 1,600° to 1,700°. I have little doubt that the action at low temperatures is dependent upon the presence of moisture; if it were due to dissociated chlorine atoms, the action should increase with rise of temperature without break. In short, I see no reason to assume that oxygen at ordinary temperatures consists of other than diatomic molecules. Assuming Prof. Lodge's view to be correct, the strain exists in virtue of the attraction which the oxygen molecules exert upon the metal molecules. On this assumption, I can well understand that the method of calculation followed by Prof. Lodge will not uniformly lead to satisfactory results. The "heat of combination" is not necessarily a measure of "affinity." The values are in all cases algebraic sums of a series of values, scarcely one of which is known, and, as I have already pointed out, the affinities of the molecules are by no means always of the same order as the affinities of the constituent atoms; for example, in all probability oxygen-stuff has a higher absolute affinity than sulphur-stuff; chlorine-stuff a higher absolute affinity than iodine-stuff, yet iodine and sulphur compounds more often than not seem to exhibit more residual affinity than chlorine and oxygen compounds. So that, from Prof. Lodge's point of view, chlorine would have the higher and iodine the lower contact value; whereas, from my point of view, the reverse might often be the case. I point this out because it appears to me that we here have an opportunity of testing the question experimentally; and seeing that it is possible practically to prevent chlorine from attacking metals by excluding moisture, I do not take the hopeless view that Prof. Lodge and others seem to hold regarding the possibility of settling the important question of pure contact *versus* chemical action by appeal to experiment. I may also point out that according to my hypothesis it is possible that the metals may exert a considerable attraction for each other, especially those having monatomic molecules; many alloys are undoubtedly compounds; possibly not a few are compounds of the "molecular aggregate" class.

To return now for but a few moments to the subject of chemical change and its intimate connection with electrical phenomena. One application I would make of the views here put forward would be to explain the superior activity of bodies in the *nascent state*, and in particular of nascent-hydrogen. Briefly stated, I believe it to consist in the fact that nascent hydrogen is hydrogen in circuit—hydrogen in electrical contact with the substance to be acted upon. The experiments of Faraday and of Grove afford the clearest evidence that in order to bring about action between hydrogen and oxygen at ordinary temperatures it is merely necessary to make them elements in a voltaic circuit. The difference in the effects produced by "nascent hydrogen" from different sources is, I imagine, attributable to the variations in E.M.F., which necessarily attend variations in the constituent elements of the circuit.

It is not so easy, however, as yet to explain some of the changes which take place at high temperatures. Mr. Dixon's experiments have proved that a mixture of carbonic oxide and oxygen is non-explosive, but that explosion takes place if moisture be present, the velocity of the explosive wave depending upon the amount of water present. When the mixture of the two gases is "sparked" change takes place, but only in the path of the discharge. Mr. Dixon considers "that the carbonic oxide becomes oxidised at the expense of the water, the hydrogen *set free* then becoming reoxidised." M. Traube, who in a series of papers has called attention to the importance of water in promoting oxidation, has suggested that the oxygen and carbonic oxide together act on the water, forming hydrogen peroxide and carbonic acid: $CO + 2OH_2 + O_2 = CO(OH)_2 + H_2O_2$; and that the peroxide then reacts with carbonic oxide to form corbonic acid: $CO + O_2H_2 = CO(OH)_2$. The carbonic acid, of course, is resolved into carbon dioxide and water ("Berichte," 1885, p. 1,890). Traube actually shows that traces of hydrogen peroxide are formed during the combustion. It appears to me that the water may exercise the same kind of action as it (or rather dilute sulphuric acid) exercises in a Grove gas battery, and that its hydrogen does not become free in any ordinary sense. The production of hydrogen peroxide is not improbably due to a secondary simultaneous change.

Unlike a mixture of carbonic oxide and hydrogen, a mixture of hydrogen and oxygen is violently explosive. If we assume that in both cases the reacting molecules are electrolysed by the very high E.M.F. employed, and that the atoms then combine, it is difficult to explain the difference in the results. Does it arise from the fact that hydrogen is an altogether peculiar element? Or are we to attribute it to an influence which water itself exercises upon the formation of water from hydrogen and oxygen—as in the Grove gas battery? It is noteworthy that the velocity of the explosive wave in electrolytic gas, according to Berthelot and Vieille, is a close approximation to the mean velocity of translation of the molecules in the gaseous products of combustion calculated from the formula of Clausius (H. B. Dixon, *Phil. Trans.*, 1884, p. 636). And this is also true of mixtures of carbonic oxide and oxygen, and of nitrous oxide and oxygen with hydrogen. May we therefore assume, as the velocity corresponds with that of the products, that the water exercises the important office of inducing change throughout the mass, and not that the hydrogen is peculiar? I am tempted here to suggest that perhaps the "induction" observed by Bunsen and Roscoe in a mixture of chlorine and hydrogen is due to the occurrence of a change in which a something is produced which then promotes reaction between the two gases. I here assume that there would be no action between the pure gases.

If I have allowed myself to flounder in among these difficult questions it is not because I feel that I am justified in speaking with authority, but

* The name chlorhydric acid is here applied to the compound $HCl(OH_2)x$—probably $x=1$—which, according to Thomsen, is present in an aqueous solution of hydrogen chloride. It would be an advantage if we ceased to speak of HF, HCl, HBr, HI, as acids, and always termed them hydrogen fluoride, chloride, bromide, and iodide respectively. The names hydric chloride, bromide, &c., might with equal advantage be altogether abandoned; hydrochloric acid is objectionable, as suggesting a relation to chloric acid. The names fluor-, chlor-, brom-, and iodhydric, as applied to the *acids* present in aqueous solutions of the hydrides, are especially appropriate as indicating that they are compounds containing the radical water—that they are hydrates; indeed, it would be well to restrict the use of hydric and hydro- to bodies of this kind, and to speak of hydrides as hydri-, not as hydro-, derivatives. It would then be possible to give comparatively simple names even to complex hydrates.

† Thomsen gives the values in heat units as—

$HgCl_2$, 2KClAq	= −1380
$HgBr_2$, 2KBrAq	= 1640
HgI_2, 2KIAq	= 3450
$HgCy_2$, 2KCyAq	= 8830

Digitized by Google

in the hope that I may be the "fool," and that the "angels" who are well able to discuss them will be led to do so without delay; for chemists are anxiously awaiting guidance on matters such as I have referred to.

Attention must, however, be directed to the study of electrical phenomena by the recent publications of Arrhenius and of Ostwald (*Journal für Praktische Chemie*, 1884, 30, 93, 225; 1885, 31, 219, 433), and especially by the statement put forward by the latter that the rate of change under the influence of acids (in hydrolytic changes) is strictly proportional to the electrical conductivities of the acids. There cannot be a doubt that these investigations are of the very highest importance.

I trust that in the discussions which we are to have on molecular weights of liquids and solids, and on electrolysis, there may be a free exchange of opinion on some of the points here raised. My reason for selecting these subjects for discussion in this section will have been made sufficiently clear, I imagine. Last year, in the Physical Section, the idea assumed shape which had long been latent in the minds of many members of the Association, that it is unadvisable, as a rule, to encourage the reading of abstract papers, which rarely are, or can be, discussed. Two important discussions were *introduced* by Profs. Lodge and Schuster. We must all cordially agree with Prof. Lodge's remarks on the importance of discussing subjects of general interest at these meetings. It appears to me, however, that even a more important work may often be accomplished if the discussion consist of a series of papers which together form a monograph of the subject. I have endeavoured to carry this idea into practice on the present occasion, and a number of friends have most kindly consented to assist. Unexpected difficulties have arisen, and probably we shall none of us succeed in doing all we might wish. I trust, however, that the section will approve of this first attempt sufficiently to justify my successors in this chair in adopting a similar course.

I much regret that is impossible for me to attempt any review of recent work in chemistry. Not a few really important discoveries might be chronicled, and the patient industry of many who have toiled long to win results apparently insignificant should have been mentioned with high approval. A few remarks I will crave permission for, as regarding the general character of the work being done by chemists, and regarding that which has to be done.

Complaints are not unfrequently made in this country that a large proportion of the published work is of little value, and that chemists are devoting themselves too exclusively to the study of carbon compounds, and especially of synthetical chemistry. We are told that investigation is running too much in a few grooves, and it is said that we are gross worshippers of formulæ. Most of these outbursts are attributable to that pardonable selfishness which consists in assigning a higher value to the particular class of work with which one happens to be engaged or interested in than to any other line of investigation; too frequently they result from want of sympathy with, if not absolute ignorance of, the scope and character of the work complained of. It must not be forgotten that chemical investigation, like other investigation, is to a large extent the work of genius; the rank and file must necessarily follow in the order of their abilities and opportunities; hence it is that we work in grooves. The attention paid to the study of carbon compounds may be more than justified both by reference to the results obtained and to the nature of the work before us; the inorganic kingdom refuses any longer to yield up her secrets—new elements—except after severe compulsion; the organic kingdom, both animal and vegetable, stands ever ready before us; little wonder, then, if problems directly bearing upon life prove the more attractive to the living. The physiologist complains that probably 95 per cent. of the solid matters of living structures are pure unknowns to us, and that the fundamental chemical changes which occur during life are entirely enshrouded in mystery. It is in order that this may no longer be the case that the study of carbon compounds is being so vigorously prosecuted; our weapons—the knowledge of synthetical processes and of chemical function—are now rapidly being sharpened, but we are yet far from ready for the attack. As to the value of the work, I believe that every fact honestly recorded is of value; an infinite number of examples might be quoted to prove this. No unprejudiced reader can but be struck also with the improvement in quality which is manifest in the majority of the investigations now published; at no time was more attention given to the discovery of all the products of the reactions studied, and to the determination of the influence of changes in the conditions. As regards our formulæ, those who look upon the outward visible form without proper knowledge of the facts symbolised, and who take no pains to appreciate the spirit in which they are conceived, are undoubtedly misled by them. The great outcome of the labours of carbon-chemists has been, however, the establishment of the doctrine of structure;* that doctrine has received the most powerful support from the investigation of physical properties, and it may almost, without exaggeration, be said to have been rendered visible in Abney and Festing's infra-red spectrum photographs. Some of us look forward to the extension of the doctrine of structure not only to compounds generally, but even to the "elements." The relationships between these are in so many cases so exactly similar to those which obtain between carbon compounds, which we are persuaded differ merely in structure, that it is almost impossible to avoid such a conclusion, even in the absence of all laboratory evidence.†

As the field of view opens out before us, so does the vastness of the work to be accomplished become more and more apparent; and Faraday's words of 1834 may be quoted as even more appropriate than a half-century ago:—

"Indeed, it is the great beauty of our science, CHEMISTRY, that advancement in it, whether in a degree great or small, instead of exhausting the subjects of research, opens the doors to further and more abundant knowledge, overflowing with beauty and utility, to those who will be at the easy personal pains of undertaking its experimental investigation."

* I venture here to direct attention to an extension of the acknowledged theory of structure suggested (by myself, I may say) at the close of the discussion of the van 't Hoff-La Bel hypothesis of isomerism in Miller's *Chemistry*, Vol. III. 1880 edition, p. 993. The same view was soon afterwards independently put forward by Dr. Perkin.

† F. Exner in a recent paper (*Monatshefte für Chemie*, 1885, p. 249) "On a New Method of Determining the Size of Molecules" actually put forward an hypothesis as to the structure of elements.

FIRST REPORT OF THE ELECTRICAL SUBWAY COMMISSION, NEW YORK.

The following is the full text of the Electrical Subway Commission's report to Mayor Low:—

Brooklyn, September 15, 1885.

Hon. Seth Low, Mayor of Brooklyn:—

The undersigned, appointed by you as Commissioners of Electrical Subways for the City of Brooklyn, organised as a Board on the 9th day of July, and have since held twenty-nine meetings, mostly private, and devoted to the study of the problems presented to the Board by the law under which it was created. At a considerable number of public sessions, and also by a voluminous correspondence, the views and proposals of experts and inventors have been examined; and the Board has, moreover, made itself acquainted, as far as practicable in so brief a period, with the experience of other cities having electrical subways in this country and in foreign countries. The president of the Board has made a personal examination of the various underground conduits and systems in use at Washington, D. C., and has consulted freely with those who, during the past few years, have been conducting experiments with electrical subways in that city. Neither these investigations nor the knowledge previously possessed by the individual members of the Board have rendered it possible at this early stage to announce a solution of the problem of underground electrical conductors throughout the City of Brooklyn which shall be thoroughly practicable and at the same time entirely satisfactory and complete. One solution has, indeed, been proposed by eminent authority. The General Committee on Underground Communication, composed of telegraph and telephone managers, the Governor of the State and the Mayor of the City of New York and others, referred the subject of electrical and mechanical devices to a sub-committee, of which a distinguished electrician, President Henry Morton, of the Stevens Institute of Technology, was chairman, and this sub-committee reported in March, 1884, that nothing would be as good as a properly constructed tunnel of sufficient size to admit the passage of workmen and access to the wires within it; this tunnel to be connected with conduits of sufficient capacity for lateral wires. Another sub-committee of the same general committee reported that there was no law of the State under which a company could construct such a tunnel and conduit system, with the view of leasing the space or the conductors, and it seems to be admitted that no existing company would undertake it for the accommodation of its own wires. That the cost would be very great is evident, and the probability is that it would be greater in Brooklyn than in New York, if the attempt were made to cover with such a system all the area of the city, since the shape of our City of Brooklyn would not permit so easily the distribution of lateral conduits from one main central tunnel.

So far as the Board has been able to learn no extensive tunnel system has anywhere been constructed for the accommodation of electrical conductors. In London, where the tunnels of the Metropolitan Underground Railway have been utilised, and in Paris, where the large sewers have served the same purpose, these subterranean channels, already existing, could be turned to account without cost, and these cases constitute no precedent applicable to a city where tunnels and suitable large sewers do not exist. Such opportunities, and likewise the opportunities offered by the structures of elevated railways, should be utilised, of course, wherever practicable. But it does not follow that nothing more can or should be done until somebody constructs a vast system of tunnels and branches. Even if that were certain to be the ultimate plan (of which this Board is by no means assured), tangible relief may be obtained in the meantime from plans less ambitious and comprehensive.

The sub-committee already mentioned examined between May 7, 1883, and March 15, 1884, about six hundred proposed plans and devices. Since the latter date many new ones have been brought forward. Their number, variety, and complexity would render the task of this Board almost interminable if that task were to be an exhaustive scientific examination of every theory or device submitted to it, coupled with experimental tests of such promising ideas as had not received the seal of successful practice. But this Board conceives its duty under the law to be to promote in every possible way relief from the evils which the law was designed to remedy, and it has therefore been from the outset desirous of approving some plan by which a beginning could be made, provided only that such a plan should be reasonably free from mechanical or other objections, and that it should not be of such a nature as to exclude improvements dictated by further experience. The consideration of the subject with a view to immediate practical action has been much simplified by the establishment of certain conclusions, based upon actual conditions in the City of Brooklyn, as well as recognised principles of electrical engineering; and it is to state these conclusions and explain in plain and non-technical language the consequent action of the Board that the present report is designed.

1. The purely electrical questions connected with underground electrical conductors are not yet satisfactorily solved. The general experience is that such conductors cost more in the beginning and less for current maintenance than overhead wires, but that they do not last as long. No

Digitized by Google

substance used as an insulator underground has proved invariably and perfectly permanent. The expensive gutta percha covered wires employed so widely in Europe have been deemed (apart from their high cost) the best subterranean conductors; and yet wires of this kind—the same as those used by the British Postal Telegraphs—which had been for years in the underground service of the Western Union Telegraph Company in New York, have, within a few weeks past, developed a curious disease of the gutta percha coat which rapidly destroys their insulation. If material so long and so thoroughly known and tested is thus liable to fail, obviously it would not be safe to trust to materials not known or not tested by prolonged experience, no matter how confident their inventors might be of their special virtues. The practical conclusion drawn by this Board from the above proposition is that solid conduits—that is, conduits consisting of groups of wires solidly bedded in insulating material (such as asphaltic concrete or the like), should not be extensively adopted in the present state of knowledge and experience. By this it is not meant that experiments might not be cautiously tried with some such method, but such experiments should be limited in extent and prolonged in duration. Only successful operation for some years could overcome the unfavourable presumption created by past experience. In such solid conduits the single conductors have hitherto almost invariably failed, sooner or later, for one reason or another, or for no assignable reason, and when they do fail the whole agglomeration of wires and cement is useless. Repair is impossible, and the digging up of the mass to replace it is far more difficult and costly than the original excavation. In Washington, Philadelphia, New York, even in Brooklyn, there are to-day sections of underground conductors laid on this plan and abandoned in despair, but not removed. The immediate problem is thus simplified by excluding for the present solid conduits, and leaving such only as permit the renewal and removal of wires and cables.

2. It is not primarily the duty of this Board to solve electrical problems for the benefit of the electrical companies, and in judging of any system of underground connections proposed by such a company the Board is concerned with its electrical features only so far as they affect its repairs or changes, and the disturbance of the city streets which those may involve. That is to say, questions of detail concerning insulators, conductors, preventives, or remedies for induction, &c., may be safely left to the companies themselves, their interest being to secure and maintain an efficient service in these respects, provided always that the system proposed be one which will permit experiment, repair, renewal, and change without excavation. If the streets must be dug up every time an old cable or wire fails or a new one is to be tried, then it is part of the duty of this Board to know beforehand what sort of conductors, insulators, &c., will be used in any proposed system, and to approve only that system which promises in these respects the greatest efficiency and permanence. Otherwise these considerations concern the electricians and business managers of the companies only. The problem is thus further simplified by restricting it for the present to conduits only.

3. Such conduits, unless they were large tunnels, could in all probability not carry the wires for electric arc lights. No discussing of the electrical disturbance produced by currents of high intensity upon neighbouring conductors will be undertaken. Nor does the Board here pass a scientific judgment upon various suggested remedies. A number of plans have been submitted to the Board involving the collection of telegraph, telephone, and arc light wires in the same conduit, of small dimensions. In some cases the inventors evidently do not realise the difficulties and dangers involved; in other cases they offer ingenious remedies and protections not yet tested in practice. But this Board is not willing to approve such plans in the present state of electrical science. It is convinced that prudence requires that the electric arc light conductors should be, in the words of the New York sub-committee already referred to, "widely separated from each other, from all other classes of conductors, and from the walls of the conduit." The second of these requirements is the most important, and it simplifies the duty of the Board by dividing one problem into two, which can be separately solved. A large tunnel being deemed at present impracticable, the low tension (telegraph, telephone, &c.), conductors and the high tension conductors must be provided for in different conduits.

4. Approaching now the subject of underground conductors for telegraph and telephone service, the Board finds that the most important, and in some respects the most difficult, part of the problem in the City of Brooklyn is presented by the telephone service. The New York and New Jersey Telephone Company, operating nearly all the telephones within the city limits, owns over two-thirds of the electric conductors of all kinds strung overhead in Brooklyn, and occupies, either alone or in conjunction with the other electrical companies and with the city departments, nearly three-fourths of the poles supporting such conductors. This company, in round numbers, has 2,400 subscribers in Brooklyn, 1,900 of whom require special separate wires, the remaining 500 being grouped upon circuits, so that one wire serves several subscribers. In a few large business blocks in the neighbourhood of the City Hall subscribers are so numerous and are so likely to be always numerous, in spite of individual changes, that the wires distributed to such buildings may be regarded as permanent, and there is no difficulty in arranging for their distribution from subways without the use of aërial supports. But over the larger part of the city, particularly among residences, telephone subscribers are sparsely scattered. To require that connection should be made wholly underground with each of these would be certainly to raise the cost of the telephone service to exorbitant figures, and probably to destroy the service altogether, for the earning capacity of a telephone wire is limited to a fixed sum. No amount of business done over the wire within the city limits increases the income of the company. The charge in Brooklyn at the present time, for instance, is, for a residence, 60 dols. per annum, and the subscriber contracts for only twelve months at a time. In the spring and fall large numbers of persons change their residences and have their telephones moved; at all times new subscribers are coming in and old ones falling out. Changes due to these causes have been known to amount to several hundreds in a month, and as the business is extended these changes will become still more numerous. If complete underground connections were insisted upon in all cases, the telephone company would be obliged either to exact from its residence subscribers a heavy initial payment to cover the cost of the first connection, or a long contract of service, or both; or else it would decline to serve such subscribers. In practice, either of the two former alternatives would probably be the same as the last, since, if the company did not decline the subscriber would. In the opinion of this Board the resulting limitation of the telephone service in Brooklyn would be a serious injury to the city. That service is one of the last invented agencies of civilisation by which this city is rendered a desirable place of residence. The means of easy communication between Brooklyn and New York, or between distant portions of this city and its business and official centres, promotes its territorial extension and the increase of residence in its beautiful outlying wards. If handsome dwellings are no longer confined to the Heights, it is because of such conveniences as the bridge, the surface, elevated and rapid transit railways, and last, but destined not to be least, the growing telephone system. The existence of such a system, therefore, is a benefit to others than its subscribers for the time being, just as the existence of gas and water supply in a given street enhances the value of property on that street, even of houses not yet supplied, or of vacant lots where no houses stand.

Another consideration, however, has impressed itself upon this Board. Assuming that it were mechanically and commercially practicable to make all telephone connections completely subterranean, and that the telephone company could satisfactorily adjust the question of cost with its subscribers, the perpetual digging up of the streets and sidewalks of Brooklyn to make and unmake such connections might become a more intolerable nuisance than the aerial wires. If telephone subscribers were so numerous and so distributed that a main conduit were required in every street, this evil would be reduced to a minimum, though it would still exist. If every house contained a permanent subscriber, or if every house owner maintained the telephone service as regularly as the gas or water service, the evil would disappear. But such conditions neither exist nor impend. In the present actual condition of the Brooklyn telephone system, a combination of main subways with overhead conductors for terminal distribution is the only thing that can reasonably be undertaken.

Such a combination has been in operation for some years in Washington, D.C., where the cables from the main subways are carried at convenient points to poles, whence the single wires are distributed to subscribers. Washington, fortunately for this plan, possesses numerous lanes and alleys, in which such poles can be placed and thus be removed from the main thoroughfares. In Brooklyn, for the most part, such lanes are wanting. In permitting such a system here it would be the duty of the Board to exercise a constant vigilance of detail, with the determination of abolishing, as fast and as far as possible, all poles whatever, and of securing the location in the least objectionable places of such as seemed temporarily indispensable.

Immediately upon the organisation of the Board the New York and New Jersey Telephone Company proposed to lay in Washington-street a box conduit of creosoted wood to contain in separate compartments cables of 25, 50 or 100 wires which would be drawn in through manholes located at convenient points, and would terminate at distributing poles. The Board declined at that time to commit itself to the approval of this plan, and required of this company, as of all others operating in the city, the preparation of maps and other information necessary for a full investigation of the subject. A map showing the location of every telephone subscriber and wire in the city was prepared by the company, and the minor details of its plan, which was subsequently proposed again on a larger scale, were thoroughly discussed between the Board and the experts of the company.

As the result of these inquiries and conferences the Board has adopted the following resolutions:

Whereas the New York and New Jersey Telephone Company has submitted to this Board a plan of construction for an underground conduit to contain electrical conductors, which plan the said company proposes to carry out immediately on the following lines, viz.: On Fulton-street, from De Kalb-avenue to the City Hall, and below the City Hall, either on Fulton-street or on Washington-street, to points to be hereafter determined by this Board, the said conduit to consist of a partitioned box of creosoted timber, and the wires and cables contained therein to be connected for terminal distribution with overhead conductors at such places and to such extent only as this Board may permit;

And whereas the representatives of the Western Union Telegraph Company and the Gold Stock Telegraph Company have signified their concurrence in the said plan and their willingness to place their conductors along the said routes in the said conduit, and the said New York and New Jersey Telephone Company has agreed to give in the said conduit sufficient accommodation for the said wires, and also for the wires of the police and fire departments of Brooklyn;

And whereas the said plan of construction appears to this Board practicable, and promises to remove from the said streets a large number of the telephone and telegraph wires and poles which now encumbered them; therefore,

Resolved that this Board hereby approves the said plan of construction, subject at all times to such modifications as shall from time to time by this Board be made, and subject also to the rules and regulations not inconsistent therewith, prescribed or to be prescribed by the municipal authority having control of said streets. Provided that the number, nature, location and extent of all aerial conductors to be connected with the said subway, and of their poles or other supports, shall be determined hereafter by this Board, the present general approval of the said plan, in advance of the

Digitized by Google

determination of details, being given by this Board in order to permit making of contracts for the materials required.

A few words in further comment on this action will complete what the Board deems it advisable to say at this time. The plan thus approved is subject to the continual control of the Board; and the approval thus given does not prevent the Board from continuing a patient examination of all other suggested plans. Since this conduit, however, will permit the experimental use of any kind of cable which the telephone or telegraph companies may prefer, the choice of such cables has been left by the Board, for the present, to the companies, and the latter have already determined to try several varieties. Persons having special conductors or insulators to recommend are therefore referred to either of the above-named companies. At the same time this Board will be glad to receive at any time from such persons statements concerning proposed conductors, &c., and will arrange for personal hearings whenever they shall seem to the Board desirable. But, pending the tests to be made by the companies, the Board does not propose to institute practical tests of new conductors. With regard to the conduit itself, the Board is satisfied that timber properly creosoted will be sufficiently durable, and this material having been proposed by the companies referred to, the Board has not felt called upon to suggest any other and more expensive one. Creosoted wood is said to be injurious to gutta percha coating brought into contact with it; and it is not unlikely that wires covered with gutta percha would have to be further protected if used in this conduit. But lead pipe containing insulated wires can be placed in it without fear of injury from creosote or moisture. Such lead cased cable could be, in the opinion of the Board, drawn into the conduit through the manholes, even if the latter were placed at greater distances apart than will probably be the case. The position and detailed construction of the manholes, together with other details of the system, will be determined hereafter, with careful reference to the local conditions on each block affected.

The objection to box conduits, that they may give opportunity for the accumulation of explosive mixtures through leakage from the gas pipes, has been duly considered, and the Board believes that effective provision can be made for the prevention of such accumulation in this conduit. A conduit of this character has been successfully operated in Brooklyn during the last nine months. It lies in Court-street, from the City Hall to Pacific-street; contains in cables 450 telephone wires, of which 250 are now in service, and the remainder are being rapidly brought into connection with aerial distributing conductors. This conduit has so far given no trouble, and has not been opened since it was laid. It is intended to open it, and carefully inspect its condition, and such an inspection may determine some points of detail in the larger system of the same general character now to be constructed.

In regulating the terminal distribution connected with the proposed conduit the Board will follow no general and invariable rule, but, considering each locality separately, will strive to reduce to a minimum the necessary amount of aerial conductors, and to cause these to be supported wherever practicable otherwise than upon poles in the streets.

INDIA OFFICE SPECIFICATION.

Specification for certain Component Parts of Standard Iron Telegraph Posts for the Government of India.

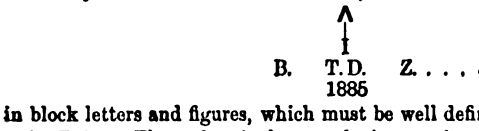
1. All the component parts are to be of the best materials and workmanship, and to be made in accordance with the drawings and patterns, which may be seen on application to the Superintendent of the India Store Depot, Belvedere-road, Lambeth, S.E.

2. *Sole Plates.*—The sole plates to be made of the best grey metal, cleanly cast and blackened. To test the fitting of the screws, 1 per cent. of the sole plates shall be screwed on to the sockets. In the event of any misfit the whole may be screwed on. By misfit in this case is meant a sole plate not entering on the screw of the socket sufficiently to take 1¼ complete turns. The thickness of the corrugated web to be 3-16 of an inch.

3. *Sockets.*—The sockets to be made of the best grey metal, cleanly cast and blackened, and in order to ensure the concentricity of the cast-iron sockets, the contractors shall have the bearings of the core barrels and seatings of the moulding boxes, with which they are made, turned and bored respectively. Five per thousand of the rough castings will be broken at the expense of the contractor, to determine their accuracy in this respect.

4. *Caps.*—The caps are to be made of the best annealed malleable cast iron. The socket in the cap is to be rimered out and gauged for size. A manufacturing margin of 1-16th of an inch, either upwards or downwards, will be allowed for the entrance of the gauge. A ring and plug gauge, corrected to the stand at the India Store Depot, will be supplied to the manufacturer, on his tender being accepted, and is to be returned to the Superintendent of the India Store Depot on the completion of the contract.

5. Each sole plate, socket, and cap is to have its distinguishing letter, the India Government mark, the letters T.D., the name of the contractor, and the year of manufacture cast on it, thus:—



in block letters and figures, which must be well defined.

6. *Tubes.*—The galvanised wrought-iron tubes are to be of B. B. Staffordshire iron, equal in quality to pattern No. $\frac{2845}{H}$ at the India Store Depot. Samples of the iron proposed to be used are to be submitted for the approval of the superintendent of the India Store Depot before the manufacture of the tubes is commenced. The letter distinguishing the size of a tube is to be punched out of the metal of the outside hoop at the bottom of the tube before it is riveted on. The inner strengthening rings of the tubes are to be driven home hard, the drawings merely showing their normal position.

7. The rivets for the galvanised wrought-iron tubes must be of such a quality that they will stand riveting cold.

8. The wrought-iron tubes and malleable iron caps to be well galvanised with pure zinc, which must be evenly deposited and free from spots.

9. The Superintendent of the India Store Depot, or his deputy, may be present during the whole process of making the component parts specified in the schedule, and they shall have every facility for seeing them during all stages of their manufacture, but samples of the finished work are to be forwarded for approval, free of expense, to the Superintendent of the India Store Depot, from time to time, as he may direct.

10. To ensure that all the component parts fit, there is in the drawings a dotted line called the "fitting line." When the posts are taken for testing purposes the Superintendent of the India Store Depot or his deputy will choose at random the component parts to be fitted together. On their being so fitted, should they find that any one component part in the total quantity either does not reach, or passes, this "fitting line" by more than 2in., they shall gauge one per 1,000; if they find another misfit they shall gauge 10 per 1,000, and a third out of gauge will cause the whole quantity to be gauged. In such case the portions to be gauged are the outer upper diameters of the sockets, and the inner lower, and the outer upper diameters of each tube, except tube A, which must be gauged for inside diameters at both ends.

11. The following table gives the minimum breaking weight and minimum weight at which each size of a complete post of two galvanised tubes and a socket may take a permanent set of a curve with a versed sine of half an inch:—

Size.		Breaking Weight.	Weight for Working Load and Permanent Set of not more than half inch.
Tube.	Socket.		
		lbs.	lbs.
A, Z with	Z	400	274
A, B ,,	B	500	344
B, C ,,	C	840	576
C, D ,,	D	1,500	1,033
D, E ,,	E	2,400	1,650

These are the actual pulls or dead loads at the line of wires when the posts are in working order or vertical, but, as the whole are to be tested horizontally, two-fifths of the average weight of the two tubes, taken in even pounds, is to be deducted for the overhanging weight of the post itself.

12. The component parts being ordered singly, the tests for minimum breaking strength, and also for working strength and permanent set, are to be determined exactly according to the foregoing table, and, where needed, the necessary lengths to make out the full length shall be furnished for purposes of testing by the contractor. The strength of the A 5ft. and of the Z tubes shall in all cases be at least equal to that specified for the B, C posts, both for the minimum breaking strain and also for the working strain giving the permanent set.

13. One per 1,000 of the galvanised tubes will be tested up to destruction. Should they not all give the required test, one per 100 must be tested to the minimum breaking strain. If then one per 100 should break at less than the minimum breaking strain, 10 per cent. of the quantity submitted for examination must be tested to the minimum breaking strain, and, if it be found from this that more than one per cent. has broken at less than the minimum breaking strain, the whole must be absolutely rejected.

14. The tests will be conducted as follows:—The tubes and sockets to be tested shall be fitted together, and the whole laid horizontally, so that the total weight shall rest upon a support at the ground line of the socket, viz., one foot from the bottom of the lower galvanised wrought-iron tube, and no part of the support is to be brought nearer the bottom of the lower tube than one foot, a shackle or strap holding down the socket at the bottom end, the post being thus supported on its working fulcrum. The test load shall then be hung on at the line of brackets, or one foot from the top of the post.

15. In testing for permanent set, the tubes and sockets shall be fixed in the same way as described above, and the working or dead permanent set test load, as shown in the above table, shall be hung on the post at the line of brackets, or one foot from the top end, and with this load the permanent set, measured as a versed sine from a chord stretched from the bottom to the top of the galvanised wrought iron portion of the post, after the weight is removed, shall not exceed half an inch.

16. The testing shall be performed by the Superintendent of the India Store Depot or his deputy, for which purpose the contractor must supply all necessary machinery, apparatus, a complete set of gauges and templates, convenience, labour and assistance of every kind required for the purpose, without making any claim or charge for the same, it being distinctly understood that these expenses are included in the prices stated in the tender. All tubes or sockets broken or otherwise destroyed in

Digitized by Google

testing, and any additional lengths required, as mentioned in paragraph 12, to be at the expense of the contractor. All testing apparatus, &c., to be under the control of the Superintendent of the India Store Depot, or his deputy, during the period of examination.

17. The galvanised caps to be packed in cases made of 1in. (full) deal, with two battens each top and bottom, and to be bound with 1in. hoop iron. Each case to contain 25 of the A or B size, or 10 of the C size. The packing to be done to the entire satisfaction of the Superintendent of the India Store Depot or his deputy. Instructions for marking the cases will be forwarded by the Superintendent of the India Store Depot when the stores have been approved. Should any damage be discovered on the arrival of the stores in India, which may be attributable in any way to defective packing, the contractor will be held responsible for any loss that may arise therefrom.

18. Proper accommodation, under the control of the Superintendent of the India Store Depot or his deputy, must be provided by the contractor for the storage of approved, and the distinct and safe custody of rejected, stores, until finally disposed of.

The following is the schedule to the specification :—

Standard Iron Telegraph Posts, Component Parts.	Pattern. No. at India S. Dept.	Quantity required for				Weight of each part.
		Calcutta.	Bombay.	Madras.	Total.	
	For make	No.	No.	No.	No.	ct. q. lb. oz.
Caps, A	A 1884	—	—	2,700	2,700	0 0 2 6

,, ,, E	E ,,	150	50	180	380	0 2 2 0

The quantities marked * are required in advance of the rest. The tender should state the earliest date by which the quantities so marked can be delivered, and also by what date the contract could be completed.

Tenders, addressed to the Secretary of State for India in Council, with the words "Tender for Parts of Telegraph Posts" on the envelope, must be delivered at the India Office, Westminster, S.W., before 2 p.m. on Tuesday, the 20th inst.

LEGAL.

Hatchett's Hotel v. Verity and Sons.

In the Chancery Division, on the 6th instant, before Mr. Justice Mathew, vacation judge, Mr. Warmington, Q.C., applied on behalf of the plaintiffs to continue an interim injunction originally granted by Vice-Chancellor Bacon and renewed by Mr. Justice Mathew on 25th September, restraining the defendants from presenting a petition for the winding up of the plaintiff company. He said the grounds of his application were that the claim of the defendants was disputed, and that the company was not insolvent. The real object of the defendants was, by the winding-up process, to put an undue pressure on the company. Messrs. Verity and Sons were electricians, and under a special contract with the company, they undertook to supply the hotel in Piccadilly with the electric light. They were to do the work to the satisfaction of the architect, which had not been done. The company had found the defendants £1,000, and the latter now claimed a further sum of £1,134. The company said the defendants had no title to sue, because they had not completed the contract ; secondly, because what they had done had been improperly done, which was supported by an affidavit from Mr. Joel, electrician ; and, thirdly, because the company was not insolvent.

Mr. Bramwell Davis, for the defendants, said the plaintiffs had not offered any security for the debt.

Mr. Warmington said the ordinary course for the recovery of a debt was to bring an action.

The Judge, to the plaintiffs' counsel : Can you offer half the amount of the debt as security ?

Mr. Warmington said he was in the judge's hands.

Mr. Davis said the work was done according to the state of the science of electricity at the time the contract was entered into ; but the learned judge knew that the science was advancing from day to day. The lighting of the hotel was completed in January, and had been continued ever since. He also urged that statements which had been made at the meetings of the hotel company tended to show that the company was insolvent. He said the defendants only wished to be secured for the debt. He would leave the matter in the judge's hands ; but he thought the company should offer £800 as security.

The Judge directed that that amount should be deposited in court in the joint names of both parties, and said he would refer all the matters in dispute to arbitration, with liberty to apply to himself in court in case of any difficulty arising. Costs would be reserved, to be disposed of in chambers after the arbitration.

UNIVERSITY COLLEGE OF NORTH WALES, BANGOR.

SESSION 1885-6 will open on FRIDAY, OCTOBER 2.

DEPARTMENTS OF PHYSICS, CHEMISTRY, AND BIOLOGY.

Physics .. { *Professor*, A. Gray, M.A. / *Demonstrator*, D. M. Lewis, M.A.

Chemistry { *Professor*, J. J. Dobbie, M.A., D.Sc. / *Demonstrator*, G. Macgowan, Ph.D. (Leipzig).

Biology .. *Lecturer*, R. W. Phillips, B.A., B.Sc.

The Classes and Laboratory Courses of this College are arranged to suit the requirements of Students preparing with a view to the Practical Applications of the above Sciences, as well as of Students preparing for University and other Examinations. Two years of the Three Years' Course required for Graduation in Science at the University of Edinburgh may be taken at this College, and the Lectures in Chemistry and Botany are recognised by the Universities of Edinburgh and Glasgow as qualifying for the Medical Degrees of those Universities.

The extensive Laboratories (Physical, Chemical, and Biological) are fully equipped for Study and Research, and in the Physical Department special attention will be given to the Teaching of Electrical Engineering. A special course has been arranged in this subject. For Plans and Description of Physical and Chemical Laboratories, see *Nature* for February 26, 1885.

Laboratory Fees (per Term).

	Physical Laboratory	Chemical Laboratory	Biological Laboratory
Six Hours per week	£0 17 6	£1 1 0	£0 17 6
Twenty-four or more Hours per Week	2 15 0	4 4 0	2 15 0

Proportional Charges for more than Six or less than Twenty-four Hours per Week.

A considerable number of Scholarships and Exhibitions are open for Competition at the beginning of each Session, and several are awarded at the close of each Session on the result of the year's work.

For full Information see the College Calendar, which may be had (price 1s. 6d.) on application to the College Secretary.

NOTES.

IN LIQUIDATION.—The firm of Oppermann Brothers is in liquidation.

NOTICE OF INTERRUPTION.—The cables of the Direct Spanish Telegraph Company are interrupted.

THE NEW TELPHER LINE.—The new Telpher line at Glynde, Sussex, is to be opened to-morrow (Saturday).

THE ANGLO-BRUSH COMPANY.—We are informed that Major-General C. E. Webber has joined the board of this company.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 9th inst. amounted to £3,121.

NEW CABLE STEAMER.—A new cable steamer, to be called the "Mirror," is being built for the Eastern Telegraph Company by Messrs. Napier, of Govan.

EARTHQUAKE IN SPAIN.—A telegram from Granada states that a strong shock of earthquake was felt there on Wednesday morning. No damage is reported.

GRUMBLERS!—The four American operators who went to Siam not long ago complain that they have nothing to do but draw their pay. Send that country right along here!

BOURNEMOUTH AGAIN.—We understand that the directors of the Shaftesbury Hall Company, Bournemouth, have been considering the desirability of lighting the hall with the electric light, but after a lengthened discussion they have decided in favour of gas.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 9th October, were £2,470, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

HARD LINES.—Female telegraph operators in Germany receive £48 a year, and no holidays. When one remembers the length of the words they manufacture in the Vaterland, one can have some idea of the drawbacks to the telegraphic profession in Germany.

A NEW POST OFFICE.—A large post and telegraph office has just been erected in Belfast. The telegraph instrument room is 101ft. by 52ft. and 35ft. in height, and every arrangement has apparently been made to ensure the comfort of the staff. The cost is estimated at £23,000.

ELECTRIC LIGHTING OF A TOWN IN SWEDEN.—It is said that the Thomson-Houston Company has received an order for electrical apparatus for lighting the entire city of Hermosand, Sweden. The city possesses a valuable water-power, which will be used for driving the dynamo machines.

TRUTH STRANGER THAN FICTION.—A writer in a gas contemporary at last admits, what we for long have stated, that "the electric light is at once the most formidable foe and the best friend of gas." The cry for more light is being heard, and is having its effect. The cry for a better and purer light will be followed by a like result.

THE ELECTRIC LIGHT IN GUATEMALA.—There are now about fifty lights burning in the city, the dynamo being run by a steam engine as a temporary arrangement until the turbines are ready for work. This department, together with the electrical apparatus at Zapote, is in the charge of an experienced mechanical engineer.

IN PERU.—The Peruvian electric lighting people are vigorously pushing their business in Peru, S.A., and expect to have all the business portion of Lima lighted by the latter part of next month. The electric company is in receipt of information from a number of Peruvian cities stating that as soon as the Lima plant is in operation orders will be forwarded for complete electric lighting plants.

A SON OF SCIENCE.—It is with great pleasure that we are able to chronicle an interesting event. On Wednesday morning at Broomhill, Tunbridge Wells, and under the electric light, a son and heir was born to Sir David Salomons, who is well known in connection with the electrical branch of science. If the son inherits the tastes of the father, he could not well have had an earlier introduction to electricity.

THE COREAN TELEGRAPHS.—It is said that different lines of telegraphs are to be constructed in Corea under the superintendence of Chinese officials. The preliminary surveys were commenced some little time ago between Gensan and Seoul, and at various points on the Chino-Corean frontier. The length of the lines actually undertaken is over 400 miles.

A PERMANGANATE OF POTASH CELL.—A modification of the Leclanché, called Roberts's permanganate battery, has been brought before the public. The solution consists of permanganate of potash, bichromate of potash, table salt, and sal-ammoniac. The *Electrical World* seems to think that this battery will burn solution and not zinc. If so, we will buy a few in anticipation of the millennium. The E.M.F. is given at 1·8 volt, and the internal resistance at ·7 ohm.

A LUCKY FLUKE.—It is said that Lilian Norton, the well known singer, was married about sixteen months ago to Mr. Frederick A. Gower, who lost his life recently. A few months ago she petitioned the Court for a divorce from her husband. A few days before the trial Gower's counsel secured a postponement of the trial so that he could go to Paris. Soon after his arrival there he accepted the invitation of a friend to make a balloon ascent, with the melancholy result with which we are familiar. Mrs. Gower has now gone to Paris to claim his estate, which is large.

A NEW PRIMARY BATTERY.—We are informed that Messrs. Woodhouse and Rawson have in hand, and are about to bring out, a new primary battery for domestic electric lighting, of which great things are expected. As, however, we have not yet had facilities offered us for inspecting the invention, we can say nothing as to its merits. Descriptions of it which appear in print are apparently on mere hearsay testimony, as it has, we have reason to believe, not yet been examined or tested by any independent authority.

INTERCOLONIAL CABLEGRAMS.—With regard to the negotiations between the Australasian Governments relating to a reduction in the telephone rates, a reply has recently been received to the effect that the New Zealand Government were ready to comply with the request, providing that the Government of Victoria would contribute a share of the cable subsidy. To this proposal the Victorian Government had replied, expressing their willingness to furnish a quota of the subsidy if New Zealand would do likewise with regard to the Tasmanian cable.

THE OVERHEAD WIRES AT WATFORD.—The Watford Local Board at any rate do not seem to be in love with overhead wires. At their last monthly meeting the clerk read a paper respecting an application which had been made for permission to erect posts in the district of the Board to connect Bushey Hall with the Post Office by telegraph. It was suggested, however, that the Board should not allow any more posts to be set up. The chairman said they did not want electrical wires; they were a horrible nuisance wherever they

Digitized by Google

were. The matter was subsequently referred to the Highway Committee for investigation.

THE CHANNEL FLEET.—During the stay of the Channel Fleet in Stornaway Bay quite a sensation was caused by a display of the electric light from one of the ships. Although the night was dark, the brilliancy of the light showed everything quite distinctly, not only in town, but for miles around. The Fleet lay at Kirkwall all day on the 9th inst., and was visited by large numbers of people. In the forenoon the men of the "Iron Duke" engaged in gun drill. In the evening the "Minotaur" and two other vessels were lighted by electric light.

THE PROPOSED INTERNATIONAL EXHIBITION AT LIVERPOOL.—The proposed Exhibition of Navigation, Travelling, Commerce, and Manufacture, to be held in Liverpool next year, will, it has been decided, receive a large installation of the electric light. The grounds also will be illuminated by electricity, and there will be a fountain display, &c. Considering the dense population of Liverpool and the district within fifty miles—estimated to be larger than that of London and a radius of the same extent—the number attending the Exhibition is expected to be very large. It is intended to open the Exhibition about the middle of May next, and to close it at the expiration of six months.

THE TELEPHONE AT CHISWICK.—At an ordinary meeting of the Chiswick Local Board, held recently, the United Telephone Company asked permission to erect three ground poles on the north west side of Little Sutton-lane, bordering on Chiswick Park Club.—The chairman said the clerk and engineer to the company were in waiting to explain the proposed direction of the wires, and give any other information, and perhaps it would be better to call them into the room at once.—This suggestion was adopted, and the representatives of the company, having interviewed the Board, were told that their proposals would be practically agreed to, it being understood that a public call room would be made in or near the Vestry Hall.

ELECTRIC LIGHTING AT THE LEICESTER EXHIBITION OF THE SANITARY INSTITUTE OF GREAT BRITAIN.—The main hall of the Health Exhibition Building at Leicester is brilliantly lighted by five arc lamps of 4,000 candle-power each, arranged in a row down the centre of the hall; in the annexe are two more of these lights, and another is placed outside the building. The arc lamps used are the Crompton-Crabbe. The incandescent lamps are run off an Elwell-Parker machine, and are 40 in number, of the Woodhouse and Rawson type, this firm having put down the installation. One of Messrs. Marshall and Sons' portable engines, of 12 nominal horse-power, and fitted with Hartnell's patent automatic expansion gear, drives the lamps with perfect steadiness.

PRECAUTION.—An amusing story is told by the Milan journal *Pungolo*. It appears that a merchant of Turin who had correspondence in the French Department of Bouches du Rhone, received at his private house at Pinerolo a telegram from Marseilles. Upon reading it he discovered to his great annoyance that it must have been delayed some twenty-four hours. He called upon the telegraph clerk to account for the delay, and the honest man at once confessed that the despatch had indeed lain for a day and a night in his office. He went on to explain that as it had come from a place where cholera is known to be raging, he had felt himself bound, in compliance with the regulations of the Italian sanitary authorities, to disinfect it by exposing it to the fumes of burning sulphur.

SOME AMERICAN ITEMS.—A test of electric headlights for the Northern Pacific Railroad was made at Brainerd, Minn., on Sept. 18, it is said with perfect success.—It is reported that the new electric railway of Toronto, using the system of the Vanderpoele Electric Manufacturing Company of Chicago, is a success.—Newark, O., has contracted for electric lighting.—The Edison Company are running about 165,000 incandescents altogether.—There are now about 3,000 electric lights in the city of Philadelphia, public and private, the larger portion of them being owned by four companies, the Brush, the United States, the Thomson-Houston, and the Excelsior.—The electric light is to be introduced in the Nulhegan Lumber Mills at North Stratford, Conn.—The Sun Electric Lighting Company has been organised, with head-quarters at Chicago.

THE TELEPHONE AND FIREDAMP.—According to a contemporary, the telephone is said to be capable of making known the presence of firedamp in the atmosphere of a mine. This is the outcome of an interesting discovery in the matter of weather prediction. It has been found—so at least says our contemporary—that when two iron rods are placed seven yards or eight yards apart, and connected by an insulated wire, in the circuit of which a telephone is placed, indications of an approaching thunderstorm may be heard twelve hours in advance. A low buzzing sound is first heard, which becomes more and more loud and distinct as the storm approaches. Every change in the atmosphere is distinguished by different sounds more or less intense. When applied as a firedamp indicator this apparatus reveals by altered sounds the change which has taken place in the atmosphere by the escape of firedamp into it from the strata of the broken mine.

"TANNERGRAMS" AT WEST HARTLEPOOL.—At a recent meeting of the West Hartlepool Commissioners the truism that man is a dissatisfied animal was once more put in evidence. The matter of "tannergrams" happening in the course of the meeting to crop up, one of the commissioners said that now they had got the sixpenny telegrams he thought they should approach the General Post Office with a view to getting branch telegraph offices—one if not two. His impression was that if they had one in Milton-street and the other at the Stranton Post Office, or somewhere in Belle Vue, they would be found of infinite service. He moved that the authorities be petitioned. Another member suggested that an office for the cemetery district be added. The motion was put to the meeting and carried. However desirable these new "tannergrams" in offices may be, it is difficult to see their utility in a cemetery. What they should have there, in order to keep up the unities, is a good Dead Letter Office.

IRON POLES.—An American contemporary says that a metallic telegraph pole has been adopted by the Canadian Government for its telegraph lines on the North-Western prairies. The pole is constructed of malleable galvanised iron, and is 1½in. in diameter at the top and 2½in. in diameter at the bottom, and weighs less than fifty pounds. The bottom of the pole is set into a claw-plate, upon which the earth is closely packed to a height of about 2ft. Then another plate is put into place around the pole, and the earth packed upon it to the level of the ground. The claw-plates take a hold in the ground at once, so that the pole becomes solidly fixed immediately after being set, which desideratum is only obtained by the ordinary wooden pole after it has been in the ground for at least a year. A recent test is said to have shown the great strength of the pole, as a heavy No. 6 Government wire was strung and the poles subjected to the

Digitized by Google

greatest possible strain, but without moving them in the least.

THE LIGHTING OF MINES.—The following is one of the clauses of the "Suggested Reforms in Coal Mining," submitted by Mr. Ellis Lever, of Manchester, to the Parliamentary Committee of the Trades Union Congress, which held its annual meeting at Southport not long ago:—"The necessity of using safety lamps in all mines or seams which admit gas, in however small a quantity, has been on many occasions abundantly proved. Real safety lamps of the best type only should be used, and in no case should the working miner be obliged to provide or to clean the lamp he uses. This should be done exclusively at the cost of the colliery proprietor. Inferior and notoriously bad lamps should on no account be allowed in any mine. All lamps should be officially tested and stamped by a Government representative before being used. Upon the better lighting of mines depends largely the safety of the miner's life and limbs, and every assistance should be given to invention in the direction of the electric system of illumination."

LIGHTING OF A SAVINGS BANK.—We understand that the Maxim-Weston Company have just completed their contract with the Government for the lighting of the Post Office Savings Bank, Queen Victoria-street. The original contract was for three gas engines of 40 horse-power each (indicated) and 700 lamps. Finding, however, that the engines were capable of running a greater number of lamps than what was originally intended, an alteration has been made in the installation whereby the authorities will be able to run nearly double the number of lamps. The dynamos used are of the Weston shunt-wound type, similar to those used on board the "Gallia," at Messrs. Rally Brothers, Manchester; and a number of other places. The lamp is the new Weston wavy filament, and, according to recent tests, thirteen of these lamps can be run so as to give a good light with only one horse-power effective. We are further informed that arrangements are now being made, by taking in an adjacent basement, to enable the plant originally intended to be largely increased.

THE ELECTRIC LIGHT IN CHEMNITZ.—The installation of arc lamps at Chemnitz, Saxony, possesses some points of novelty. The arcs are of the differential type, and take from eight to nine amperes. When the full light is not wanted they hang inside six side lanterns covered with transparent red calico. To each of the six sides is hinged below a triangular piece of the same material, each of these pieces bearing on a curved hook a brass ball. These balls press the six pieces together by their weight and close the pyramidical space below the lantern under the upper case. If the lamp is to give its full light it is lowered, when, by its weight, it presses the triangular pyramidal sides apart and descends. When it is to be raised again the cylindrical top of the lamp comes first in contact with six bars, which are fastened to the apex of the sides of the pyramid and bent outward. The pyramid opens and allows the lamp to enter the lantern, whilst the bars slide over the lamp globe, which is of strong glass, bringing the pressure of the balls to bear against the lamp, and thus securing its ascent in the central line.

THE SWAN SAFETY LAMP.—This lamp consists of the lamp proper and a secondary battery. The weight of lamp and battery together is 6¾lb., the cylindrical case containing the cells measuring 8 by 4 inches. The light given, for twelve hours' use, is equal to half a standard candle; but, by reducing the time of lighting to eight hours, the current may be increased, and a light obtained equivalent to three-fourths of a standard candle. A single charge provides for a whole day. Mr. Swan holds that the electric lamp is absolutely safe. If it is neither so light nor so cheap as the ordinary lamp, it is in both respects at least practicable, and the working cost will probably not be more than that of the ordinary lamps. As regards weight, he is not without hope of being able to reduce it. It requires no air; and there are, unfortunately, times after an explosion of fire-damp when the air of a pit is so foul that no oil lamp will burn in it. With a Fleuss apparatus for breathing and the electric safety-lamp, the work of exploration, which can hardly be otherwise accomplished, may be carried on, and this, it is reasonable to hope, will be attended with the saving of life.

THE DEFENCES OF NEW ZEALAND.—The Government of New Zealand have evidently determined, now that they have taken up the question of defences, to place them on a satisfactory footing. It is intended to arm the various forts now erected and in course of erection with the Brennan controllable torpedo recently adopted by the Admiralty. All the necessary apparatus, in the shape of powerful stationary engines and plant for ejecting the torpedoes, has been ordered. In addition each harbour will be protected by an elaborate system of submarine mines. The electric light having been proved to be an indispensable adjunct to modern warfare, each fort will be furnished with a complete set of searching lamps and apparatus. Three sets of plant (two of which are of the most powerful class in existence) have been ordered from Messrs. R. E. Fletcher and Co., electrical engineers and contractors, of Dunedin, in addition to those lamps which that firm have already constructed and supplied to the Defence Department. These sets of plant will be similar in design and capacity to those in use on the "Colossus" and other ships of the British Navy. Mangin projectors will be used, and the two larger lamps will be actuated by "Victoria" dynamos of the Anglo-American Brush Corporation's make.

A NEW TELEGRAPH COMPANY.—A new company, entitled the West African Telegraph Company (Limited), was registered on the 29th ult., with a capital of £1,000,000, in £10 shares, to carry on the business of telegraphy in all branches and in all parts of the world, power being taken to use all known systems or any system which may hereafter be discovered; and to purchase or cause to be manufactured wires and cables of all kinds for telegraphs, telephones, or other purposes. The subscribers are:—Abraham Scott, 157, Leadenhall-street, merchant, 50 shares; John Miles, 32, Paternoster-row, publisher, 100; G. Henderson, 7, Mincing-lane, merchant, 50; Matthew Gray, Lessness Park, Abbey Wood, Kent, engineer, 100; Robert Kay Gray, C.E., 106, Cannon-street, 25; Neil Bannatyne, 15, Earl's Court-square, merchant, 50; Wm. James Tyler, 106, Cannon-street, secretary to a company, 25. The number of directors is not to be less than five nor more than nine; qualification, shares or stock of the nominal value of £500; the subscribers are to appoint the first; remuneration, £2,000 per annum, with an additional £500 for every complete 1 per cent. dividend or bonus in excess of 6 per cent. per annum. The company takes power to acquire and carry out Government, municipal, or other concessions, relating to telegraphs or otherwise.

BLOWING UP THE FLOOD ROCK.—On the 10th inst., at 11:15 a.m., the explosion of Flood Rock at the Hell Gate entrance to New York harbour, took place by means of an electric current from the shore of Long Island. Three hundred

Digitized by Google

thousand pounds of dynamite and rackarock were used, the rock having been honeycombed with galleries wherein the explosives were placed. A Reuter's telegram, dated New York, October 10, 6:0 p.m., says :—The explosion took place at 11:13 a.m., and apparently has completely destroyed the rock. It is believed that as soon as the necessary dredging is done the greatest obstacle to navigation in the East River will be removed. The shores were crowded with the people who gathered to see the effect of the tremendous explosion. When it took place the water was violently agitated immediately near the rock, but only for a moment. An immense volume of water, with large fragments of stone and wood, rose to a height of 150 to 200ft., trembled aloft for a second, and then sank into the river. The shock was slightly felt on the shores, but a tremble was felt throughout the city and for miles away. No damage was done to the surrounding property. General Newton's little daughter, a young lady eleven years old, pressed the button which started the electric current and thereby caused the explosion.

Hair and Electricity.—Those of our readers whose interest in electric lighting has made it at times difficult for them to keep their hair on will appreciate the following :—At the annual meeting of the American Dermatological Association, at Greenwich, Conn., remarks were made by various doctors who gave their experiences in removing hair from the face by electricity. Quite a large and important business is done in this line, especially among ladies. The only remedy is to kill the root of each hair, which must be done separately, by means of an electrical needle and battery. Dr. Fox said: In the case of a young woman with a heavy beard, he had removed, by actual count, eight thousand hairs. This process had required two or three years. Since then it had been necessary to remove only a few dozen hairs. The president, Dr. Hardaway, had performed the operation of electrolysis for ten or twelve years, probably longer than any other member of the association. He used the irido-platinum needle, which had the advantage of being bent, and was not likely to pass through the follicle wall. The moment the follicle was entered, there was an escape of sebum. One case, that of a woman with a heavy black beard, had been entirely relieved. Electrolysis with a fine needle afforded a method of getting rid of freckles. The plan was to dot the surface covered by the freckle with the needle.

Gas Journals and the Electric Light.—Here is a specimen of the fair and impartial criticism we are accustomed to at the hands of our gas lighting contemporaries :—"Several interesting matters in connection with the electric lighting business came up for discussion at the recent meeting of the National Electric Light Association. Mr. Leggett, of Detroit, read a paper on the tower lighting system as used in that city. Of course the writer claimed that the scheme was a grand success. 'It produces,' he stated, 'an artificial moonlight effect; and walking or driving by night is possible without constant apprehensions as to obstacles ahead.' Continuing, he said: 'Detroit is a city of from 160,000 to 180,000 inhabitants. Its business section occupies about one square mile. Around this is a belt about one mile in width, forming the residence portion of the town. Formerly 3,782 gas and naphtha lamps were used; while large areas, amounting to two square miles, were not lighted at all.' The Brush Company are paid 95,000 dols. a year for lighting the city, using ninety towers for the purpose. Well, they ought to light the place thoroughly for this sum. The 3,782 gas-lamps, at 16 dols. each, would only come to 60,512 dols., a vast difference. Another gentleman, speaking of the incandescent electric light, said 'We have to-day an infant seven years old, which, I think, is going to strangle gas with one hand and petroleum with the other.' Gas men will doubtless be glad to know that we shall have a companion in misery." The remark anent the same number of gas lamps is refreshing. Does the writer mean to infer that the candle-power is also an equal quantity ?

The West African Cables.—An important addition to the network of telegraphs spread all over the globe is about to be made along the West Coast of Africa. A new and improved cable, constructed by the India Rubber, Gutta Percha, and Telegraph Works Company, under the superintendence of Mr. Gray and his sons R. K. and Matthew, is now on its way on board the company's telegraph ship "Silvertown" to the French settlement at Dakar, there to connect with the existing Spanish line from Cadiz, and to extend in the first instance to Bissao, Bulama, and Conakry. From that it is intended to continue the line to St. Thomé, in the Gaboon country, to the mouth of the Congo, Loanda, Benguela, Walfisch Bay, and the north-western boundary of Cape Colony. So far the West African Company is acting on concessions from and in the interests of the French, and more especially of the Portuguese Government. As pioneer and tender to the "Silvertown," the "Buccaneer" goes out with Mr. J. Y. Buchanan, of the "Challenger" expedition, Mr. Rattray, naturalist, and Mr. Murray, who was also engaged in the "Challenger." Soundings and submarine testings, mechanical and chemical, will be taken of a range of ocean bed left unexplored by the great English expedition, and there can be little doubt that most interesting additions will be made to our knowledge of marine botany and zoology. There is happily no reason to dread the attacks of the microscopic-borer *teredo navalis*, whose partiality for dining off, or rather in, the gutta-percha coating of the wire sometimes sets free the electric current, and so destroys for a time work costing hundreds of thousands of pounds. *Teredo navalis* thus makes a meal the costliness of which dwarfs into insignificance that of the most luxurious banquets of Roman emperors.

Electricity and Ships' Compasses.—Commander Hudson calls attention, in a short article in the *Nautical Magazine*, to a possible action of electric light wires on ships' compasses. He thinks that while knowing the effect of the ironwork of the ship on the compasses, "we have an uncertain and unrecognised element of danger" in that the compasses, "placed in close proximity to the deck beams, will be liable to be acted upon by electric currents whose force and direction are continually changing as switches are turned on and off." The author gives in this article a ludicrous example of the incompetent electrical engineer, one, however, which might have caused considerable damage. Bad workmanship and ill-designed systems will prove a curse to the honest electrical engineer. The work on many ships is lamentable. In addition to the action on ships' compasses, there is another element of danger in the plan of connecting one wire from the dynamo with the ship's frame to earth. But here is Mr. Hudson's tale :—"The insulation of the feed wires in the saloon of a vessel fitted in this way being interrupted, to discover the position of the fault without unnecessarily taking down the linings, a temporary wire was led as a test wire from the dynamo in the engine room along the upper deck and down through the companion doors to the saloon. The saloon house was built of steel. Whilst the dynamo was running the saloon door accidentally closed, the insulating wire was cut through, and the wire coming in con-

Digitized by Google

tact with the steel of the house formed a new circuit, the result being a flash of blue flame, the fusing of the wire, and the setting on fire of the board. Any one who had seen the utter look of astonishment and unpremeditated bolt on the part of the electrical engineer would have been quite convinced how little the danger attending a system of lighting in this manner was realised."

THE ELECTRIC LIGHT IN A LONDON CLUB.—As before mentioned in our columns, the Naval and Military Club, Piccadilly, has earned the distinction of being the first club in London with sufficient confidence in electricity to adopt it as its means of lighting. The engineers and contractors for the work are Messrs. B. Verity and Sons, of Covent Garden, London, who also have the contract, among others, for the lighting of the New Constitutional Club, Northumberland Avenue. Considerable difficulty was at first experienced in procuring suitable space for the electric machinery, but with the removal of some old stables in the rear a substantial engine house, with every requisite, has been erected by the contractors. Two steel multitubular boilers, with engines of the compound type, and fitted with automatic gear, have been specially manufactured by Messrs Davey, Paxman, and Co. The two substantial dynamos worked off the large fly-wheels have been manufactured in New York by Mr. Edison, at a special slow speed, for this club, and have come up with the high anticipation formed of them. Either of the engines or dynamos are sufficient for the whole present electric lighting of the club, and they are coupled up so as to give the most complete confidence. Added to this there are a set of 50 large accumulators, not only as a safeguard against any possible stoppage of the machinery, but also for supplying the light when the engines are not working. The lights are at present fixed throughout the whole of the club proper, and in some other departments—notably, the kitchens. In the principal rooms they are mostly fixed in elaborately etched and cut glass vases of Adams design, suspended from the ceiling, and cast a soft and well-diffused light round. The work of laying the wires has been a difficult one, owing to the character of the decoration and the necessity of the wires being completely hidden. Switches are provided for turning on and off the various rooms in sections, and the requirements of the insurances have been met by not only putting safety fuses on the one electrical pole of the wire, but on both positive and negative. All the wires are covered with no less than four separate coatings of insulation, and are protected by ornamental wood mouldings. The incandescent lamps used are of the Edison type. We hope that this important installation may soon be followed by many others of like character.

THE ELECTRIC LIGHT AND THE HASTINGS TOWN COUNCIL.—At a recent meeting of the Hastings Town Council the following report was taken as read :—The committee have had under consideration a renewed application from the secretary of the Hastings and St. Leonards Electric Lighting Company for permission to fix overhead wires for the supply of electricity between the company's works in Earl-street and Robertson-street. The committee have referred the matter for inquiry to a sub-committee, who have consulted with the electrician of the Eastbourne Electric Light Company, and have received from him a report containing the terms upon which he considered the application might be granted, with due regard to the public safety. This report has been submitted to the committee, and having fully considered the same, they recommend that the application be granted on the following conditions, viz. :—1. The wires used for crossing streets to have a tenacity of not less than 20 tons to the square inch, and weigh not more than 30lb. per 100 yards. 2. All main thoroughfares to be crossed at right angles, or as nearly so as circumstances will permit, and the wires to be shackled off on each side of the street, so that the space should be as short as possible. The supports, whether chimney stacks or poles, to be quite sound and well secured, and the wires run so that they cannot swing or rub against any angle of a wall, chimney stacks, &c., with any probable force or direction of the wind. 3. All wires crossing streets to be run at such a height as not to impede any fire escape in use, or likely to be used, in the borough. 4. All wires crossing streets or other public places, and their supports, to be examined periodically twice or thrice per annum, by some competent person on behalf of the Corporation, and the company to make any repairs or alterations which then, or at any other time, are necessary for public safety or to fulfil the above conditions. 5. The crossing places of streets to be settled by the borough surveyor or other competent person acting in conjunction with the Electric Light Company's engineer. 6. The company to undertake to stop the electric current in the event of a serious fire in a house supporting a wire or wires. 7. The periodical inspection of the wires to be at the expense of the company. 8. The wires to remain only during the pleasure of the council. 9. The posts for carrying the wires not to be put up in any public street without the express sanction of the council. Mr. Alderman Hennah rose to move the adoption of the report. He thought it would really be a good thing for the town to have these wires overhead, as, considering all restrictions put on the company in granting the privelege, the town would be in no way committed. The question would of course be raised about the danger, but he thought they had got over that by the shackling of the wires as suggested, and the condition of crossing the streets at right angles, so that in case of accident the wires would not come in contact with those down below. It had been suggested there would be some danger from the electric wire in cases of its breaking, but the electrician assured them that such was not the case, and that when a wire broke, unless they picked up both ends the current was broken, and there was no danger whatever. The question was also asked him (the electrician) whether, in case of an electrical storm, there would be any danger to the property to which the wires were attached, and the reply was that if there was the least danger of the kind it was not the property in contact with the wires, but to the machinery where the current was generated.—Mr. Weston begged to second the report. The committee which had been appointed to consider the matter had taken the opinion of a first-class electrician, and had then taken such precautions as they considered advisable for the safety of the public and the general interests of the town. In adopting that report, too, they would be assisting a public company, which had been struggling for some time to extend its operations by further lighting by electricity, which had been so satisfactorily done up to the present point.—Mr. Brown would like to ask the town clerk whether, in giving this sanction, they were likewise giving sanction to pass over houses and make fast to chimney-stacks of private property ?—The Mayor : You don't ask that seriously, do you, Mr. Brown ?—Mr. Brown : Yes, I do ; whether you have control over private property, or the streets alone ?—The Mayor : Certainly not.—Mr. Brown referred also to the 9th part, with reference to the putting up of posts in the streets only with the sanction of the Corporation, and said he hoped they would never give permission for the putting up of posts in Robertson-street, or any other streets for the carrying of wires, or any other purpose whatever. All he wanted was to know.—The report was then adopted.

OLD CABLE STORIES RETOLD.—VII.

BY F. C WEBB.

(Continued from page 66.)

THE RED SEA AND INDIA CABLE OF 1859-60.

On the 14th February, on going ashore, we learnt that the Suakim-Aden section failed gradually until it broke down altogether on the 6th February, and as far as could be judged the fault was about half way on the section. Mr. Brunton and Mr. Forde came off to H.M.S. "Retribution" to ask for H.M.S. "Cyclops" to go up the Red Sea, and for the "Retribution" to take me to Muscat to test. "Cyclops" question was agreed to; but before "Retribution" question came on Mr. Newall arrived on board, and Mr. Brunton and Mr. Forde left.

On the 15th Mr. Brunton and Mr. Forde arranged with Mr. Newall to repair the Suakim and Aden section in the "Imperidor," which ship had still 400 miles of surplus cable left in her; Mr. Mayes, R.N., and Mr. Long were to go in her to watch proceedings. Mr. Brunton gave me a note, requesting me to hold myself in readiness to go to Hellania, the island of the Kooria Mooria group where the station existed, and to Muscat in H.M.S. "Cyclops," which ship he would apply for immediately.

During the ten days I was in Aden there were various festivities, in honour of the cable, on board the men-of-war (English and French), and the cable ships, and ashore at the military mess. On the 16th I see by my diary that there were races, of which, not being a horsey man, I have not the slightest remembrance. The officers of the "Cyclops" on this day dined with Mr. Long, the superintendent of the station. On the 17th the commodore gave a grand dinner to Mr. Newall, &c. I learnt that the Cosire and Suez section had also failed on Feb. 5 (two days before the Suakim and Aden section failed), but they had no idea where the fault was.

It is said that on the average it only rains once in five years at Aden, but when it does it is done thoroughly. The water accumulates on a plateau of table land, and pours down a ravine in the rocks. At the site of the tanks, especially constructed to collect the water, the ravine has been dammed up. Two ancient circular water tanks have also here been discovered and cleared of *débris* that had been washed into them. A heavy storm of rain, however, in May, 1859, brought such a flood of stone and water down that the new works were partly destroyed, and one of the ancient tanks was half filled up with stones. Five inches of rain fell in three hours.

On the 19th Mr. Newall gave a dinner on board the "Imperatrix;" the commodore and others went. I heard that Mr. Newall, in returning thanks when his health was toasted, asserted that "the cable would last for one hundred years!".

On the 23rd the "Imperidor" and "Imperatrix" left at 9 a.m. to repair the Aden-Suakim section. I tested this section roughly, and made the fault about 130 nautical miles from Aden. On the 24th I tested Aden-Kooria Mooria section. In the evening one of the cable ships spoke to Aden from off Perim. On the 25th I shifted from H.M.S. "Retribution" to H.M.S. "Cyclops" (6-gun paddle wheel corvette), Captain Pullen.

On the 26th I tried to get further tests of the Aden-Kooria Mooria section, but was stopped by a German gentleman, named Weyrich, because he said it would interfere with his testing the Aden-Suakim section. On the 27th I tried again to test, with the same result.

I went on board the "Cyclops" at noon, and at 7:30 p.m. we left for the Kooria Moorias with a small Indian navy schooner called the "Constance" in tow. The lieutenant in command of this small craft was said to be very eccentric, and one of his eccentricities nearly had rather serious results. He took it into his head one morning, when lying in harbour at Aden, to fire round shot at some seagulls on the beach, and nearly shot the Brigadier commanding at Aden, who was out for his morning walk, and was greatly astonished at a bang from the little schooner, and then by a round shot bounding along within a few inches of his legs.

Nothing particular occurred on our passage from Aden to Hellania, the principal island of the Kooria-Mooria group (where we arrived on March 4), except that we saw a large shoal of dolphins playing at leap-frog. Mr. Nichols was the local superintendent in charge of the station at Hellania, and Mr. Sannemans, from Messrs. Siemens and Halske, was in charge on the part of Messrs. Newall, Liddell and Gordon. I landed next day, and the "Cyclops" went off to Gibli, another island of the group, where there are guano deposits. I got my batteries and instruments ready at once. The "Constance," commanded by Lieutenant Cookson, I.N., was now anchored off the island for protection, but the marine artillery guard were still on the island.

Lieutenant Cookson came ashore and had tea with us, and I could see nothing in his manner to denote any eccentricity of character. On the 7th I tried to test, but was constantly stopped by Aden persisting in sending messages. On the 8th I again tried to test, but Mr. Long kept sending *long* messages, first to Hellania, then to Muscat, and then to Kurrachee. At last, in evening, I got a few tests of Aden-Hellania section. On the 9th I cut off Aden to enable me to use office batteries, and tested Hellania-Muscat section. At 3 p.m. joined up to Aden and asked them to let me have line at 7 p.m.; but at 7 they were transmitting to Kurrachee, and continued to do so until 9 p.m. Then Mr. Long sent a long message to me saying that they had been waiting for me at instrument since 7 p.m., and that it was not their fault, &c. The "Cyclops" arrived from Gibli this day, and was to sail the next day for Muscat. On the 10th, after some trouble, I got Aden to let me test. At noon Aden took line, saying they wanted it for one hour only. At 1:30 I called and wanted line, but Aden said they were in the middle of a Government message. I said I could not help it, I *must* have the line. Then there was a long argument between Long, De Conde, and I, and at last I got line and finished testing about 7 p.m., and about 10 p.m. got some test-message slips for proof of speed of working.

At 11 p.m. I took passage in the "Cyclops;" Mr. Sannemans also came, and the Marine Artillery Guard were also embarked, leaving the station to the care of Lieut. Cookson and the "Constance." I do not know whether he fired any more round shot at the shore, but the monotony of the situation would excuse even grape and canister. Commodore Edgell said that anyone who stopped there a year ought to have a pension of a £1,000 a year for the rest of his life. On the 11th, at 4 a.m., we started for Muscat, where we arrived on the 15th. I went ashore at 9 a.m., and tested Muscat to Hellania section. Mr. M'Gill was in charge for the company, and Mr. Buffleb of Messrs. Siemens and Halske, on the part of Newall, Liddell, and Gordon. On the 16th I made tests of Muscat-Kurrachee section, and at 10 p.m. started in the "Cyclops" for Kurrachee, Mr. Buffleb taking passage also in the ship. Arrived in Kurrachee on the 20th, when I began making test from the telegraph office at Manora Point of Kurrachee-Muscat section. I slept at office, and finished tests of section by half-past three p.m. I then wanted to get some tests right through to Aden, but, after a great deal of sending and squabbling, Muscat said that they could not get Hellania, so I had to give it up. On the 23rd I left for Bombay, and arrived there on the 26th, where I found my old friend the "Retribution." In the evening I went on board the Indian navy paddle-wheel frigate "Punjaub," then in full commission. This magnificent ship and her almost sister ship, the "Assaye," were sold in 1863 to Mr. John Willis, of London. The engines of both ships were taken out, and they were converted into sailing ships, the "Punjaub" being rechristened the "Tweed." Mr. Willis sold the "Assaye" to a Captain De Busch, and then (wonderful are the ways of Governments) the Government chartered both ships for laying the Persian Gulf cable. The "Tweed" was designed by Mr. Oliver Lang, of Woolwich Dockyard, at the time he was designing the present royal yacht, the "Victoria and Albert," and it was said that she had exactly the same lines as the royal yacht. She was built at Bombay Dockyard, of teak, with close timbers, like all wooden men-of-war, and was launched at night, as the night tides are a few inches

Digitized by Google

higher than the day tides. She was one of the five sailing ships that took out the first Persian Gulf cable, the "Assaye" being another. The "Assaye" was lost on the west coast of Ireland on her way home, but the "Tweed" was one of the two ships that took out the second Persian Gulf cable. She gained the first prize at the Havre Maritime Exhibition, and is probably the finest sailing ship in the British merchant service, and the Parsee shipwrights of Bombay dockyard, who look upon her as their pet child, are justly proud of her. The brass in her engines fetched £5,000. When smoking a ciger on board her I little thought that I should have to cut her and the "Assaye" about in 1863, and be on board the "Assaye" in charge of cable laying in 1864 and fit the "Tweed" up again in 1868 for cable laying. I left Bombay for Aden in the "Ottawa" on the 27th March at 10 p.m., and arrived at Aden on April 4th at 10 a.m. I found that the "Imperidor" and the "Imperatrix" had been at Aden about the 29th of February, and had cut out seven miles of cable from the Suakim-Aden section, and laid it down again. On March 2 they had gone back to the other side of Perim, and had cut and found a fault near Suakim, and had gone there. During the time of their passage to Suakim Aden spoke to Suakim, and then the cable failed again.

When the vessels arrived at Suakim the staff were greatly astonished to find that Aden had been able to speak to Suakim, and would scarcely believe it. The "Imperatrix" had then left for Suez, where she embarked some of the Royal Artillery with Armstrong guns for China. The "Imperidor" went to work again, and had many difficulties, fell short of coals, returning to Aden on March 29 to coal; she left again on March 31. In the office at Aden they could not get Hellania up to the time I left in the "Ottawa" for Suez. This is all I can tell of the repairing operations, which I believe finally resulted in their inserting about 300 miles of new cable in the section. The line was for about a day workable from Kurrachee to Suez. It was one of the days between March 20 and March 23 inclusive, for a message from me at Kurrachee to my wife in London passed right through, and was one of the few messages that ever went through from India to England in 1860.

The testing appliances at the stations supplied by Messrs. Siemens and Halske were an immense step in advance of any previously used. The arrangement of the *Wheatstone bridge with high resistances* was a novelty to me, and I of course at once saw the great advantage thus offered to practical electricians, and, with the permission of Messrs. Siemens' staff, I availed myself of these instruments to take my tests, a few particulars of which I here append :—

RED SEA AND INDIA CABLE OF 1859-60.

	Nautical miles.
Weight of copper in lbs.	180
Gutta percha ditto	212

Tests of Aden-Hellania Section (taken by bridge), at Hellania, March 11, 1860.

	Nautical miles.
Length of cable	730
Distance by chart	717
Slack =	13, or 1·8 %.

Copper resistance in Siemens' units :

Z to E	4480
C to E	10160
2 /	14640
/	7320

or $\frac{7320}{730}$ = 10·03 Siemens' units per nautical mile.

Insulation res. C to E	69900 S.U. absolute.
× Length	730 naut. miles.
	2097000
	489300
	51027000

or 51 million Siemens' units per knot, with 60 elements C to E.

Trying rate of working on Morse with Siemens' polarised relay got 28 words in four minutes from Aden,

$= \frac{28}{4}$, or 7 words per minute.

And, again, 19 words in three minutes,

$= \frac{19}{3}$ or, 6·3 words per minute.

Tests of Hellania-Muscat Section, taken at Muscat, March 15, 1860.

	Nautical miles.
Length of cable	493
Distance by chart	488
Slack =	5, or 0·1 %.

Copper resistance C to E 4172 Siemens' units.

$\frac{4172}{493}$ = 8·5 Siemens' units per nautical mile.

Insulation resistance C to E	129000 S.U. absolute.
× Length	493 naut. mile. 2
	387000
	1161000

	15300000
	680000
	73300000

or 73 million Siemens' units per nautical mile.

We should think very little of a line in these days which only gave 70 meg. per nautical mile.

With regard to the machinery and tanks, &c., I cannot speak, as I did not go on board either cable ship. I have, however, a large and complete drawing of the brake employed, given me by Mr. Newall; but it would be impossible to describe it in writing alone. I shall some day, I hope, exhibit it, with many others of machinery I have used, at a lecture on the subject of cable engineering. The cable was never repaired in all its sections, and some years later a quantity of the cable was recovered in the "Sir James Duke," under the superintendence of Mr. L. Clark, assisted by the late Mr. J. C. Laws.

The cruise, by what I gathered from the staff on its return, was not a pleasant one as regards personal comfort, the accommodation being simply execrable. Major Green, at Muscat, I have heard, said that he would sooner go into general action than live one week on board the ship. The discomfort was, however, borne with great good humour and patience by the staff, three of whom have since died, viz., Mr. J. C. Laws, Mr. Alexander, and Mr. Suter. The latter, who was my assistant in the "Old Monarch," died during the expedition at Aden, and is buried there.

Some of the cable was recovered, and the "Sir James Duke" had her screw taken out at Aden, and sailed for England, the late Mr. Alexander being on board. She took a fabulous time to get home, and stuck about the Cape for several months, hundreds of ships passing her. Like a second "Flying Dutchman,"

Digitized by Google

the captain "tried in vain his oath to keep" to get home in three months. Mr. Alexander gave me an account of the voyage home. After the first month they had nothing but salt provisions—except some very long-legged, bony fowls—and the captain had but one story, which he began regularly to tell after his first *post-prandium* glass of grog, till poor Alexander got so sick of it that he would bluntly interrupt the captain at the very first word by a "Suppose we go on deck, Captain." On arriving off Falmouth Mr. Alexander went ashore in the pilot boat, rushed to an hotel, and ordered supper. The waiter brought in *a fowl*, which so incensed my poor friend that he hove it at the astonished waiter's head, and then ordered baked potatoes and champagne; and this was about the last incident connected with the Red Sea and India cable of 1859-60.—*R.I.P.*

HISTORY OF THE INCANDESCENT LAMP.—III.*

Twenty years ago Swan commenced to experiment with carbon filaments in exhausted globes, but for want of an economical means of producing the current and a good vacuum such experiments necessarily led to nothing practical. The experiments were resumed in 1877, when the dynamo had opened an entirely new field. The discovery of the Sprengel pump gave a ready means of obtaining a far more perfect vacuum.

Swan had the good fortune to make the acquaintance of Mr. Stearn, who had already attained to a place among the first authorities on the question of high vacua.

All the various attempts towards the practical application of the carbon-incandescent principle had two great obstacles to contend with, which baffled every exertion made to overcome them. One difficulty consisted in the rapid wear and consequent breakage of the carbon; the other in the obscuration of the lamp by a sort of soot. These two phenomena appeared with such a uniform consistency that the opinion was soon formed that the blackening of the glass bulb was the result of the volatilisation of the carbon under the influence of enormous heat.

Swan fortunately attached no great significance to these experiments. He knew, in fact, that the conditions under which all the earlier experiments had been made were not such as to render possible the attainment of an even approximately perfect vacuum. Swan saw perfectly well that the first thing to be done was an experiment to raise the carbon to a white heat in a perfect vacuum, and under conditions more favourable than before. In furtherance of this idea he in 1877 sent Mr. Stearn a number of pieces of carbon made from carbonised cardboard, requesting him to have them mounted in a glass bulb, to be then exhausted as perfectly as possible. Mr. Stearn undertook this difficult operation with the greatest willingness, and carried it out with singular skill. Mr. Stearn described this experiment as follows in an article kindly placed at the disposal of the writer:—

"The first result of our combined labours was obtained on the 3rd November, 1877. A strip of carbonised paper was fixed between the platinum wires (as shown in Fig. 1), the

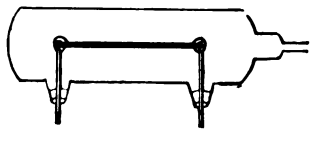

Fig 1.

opposite ends of which were passed through the side of the glass and sealed into it. The resistance of the carbon was so great that twenty Bunsen cells were required to raise it to a red heat. This first experiment failed, as the carbon at the first passage of the current was broken with the momentary strain when the carbon was exposed to a higher temperature than that employed in carbonising it.

"This risk was avoided in the next experiment by stretching the carbon filament less tightly between the conducting wires. In the next attempt with carbonised paper small pieces of platinum foil were connected with the carbon strips by means of electrolytically deposited copper, as shown in Fig. 2.

Fig. 2.

"The lamp shown in Fig. 3 was now constructed. This consisted of a thin carbon stick of circular section, in platinum holders, which were connected with the platinum wires passing through the glass. The latter was sealed up after a long exhaustion by means of a Sprengel pump. During the years

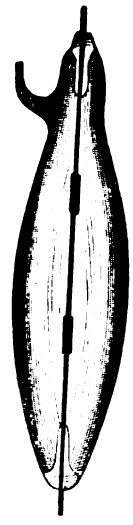

Fig. 3.

1878 and 1879 we made experiments with these and other forms of carbons, and the result was patented in England on the 2nd of January, 1880 (Swan's patent 2nd January, 1880).

"A lamp of the kind shown in Fig. 4 was exhibited at a meeting of the Newcastle-on-Tyne Chemical Society, on the 18th of December, 1878, and the same subject was also discussed on the 27th of March at a meeting of the same Society (vide *Chemical News* of April 18th, 1879, and June 27th, 1879). On the 3rd of February, 1879, and on the 12th of March of the same year, this lamp was exhibited in action at numerously attended lectures delivered by Mr. Stearn in Newcastle

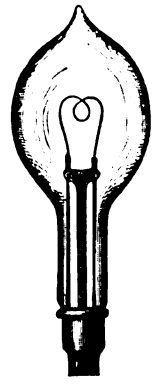

Fig. 4

and Gateshead, the chair being taken by Sir William Armstrong. These lamps were composed of nothing but glass, platinum, and carbon, and were hermetically sealed after the most perfect exhaustion with a Sprengel air pump."

One of the most important problems was the question how to free the carbon conductor during the process of exhaustion from the noxious gases contained in it. "Edison," Mr. Stearn goes on to say, "thought that he could claim for himself alone the credit of having achieved this object (*vide* English Patent, No. 562, Feb. 9, 1881). But it must be remembered that as

* Abstract of an article by Prof. Dr. Rudolf Lewandowski in *Zeitschrift für Elektrotechnik*.

Digitized by Google

early as 1878 other experimenters recognised the necessity of purifying the carbon from the gases contained in it, although, instead of gases rich in oxygen, they passed in a gas neutral in oxidising properties. Sawyer and Mann (Cheeseborough Patent, Nov. 28, 1878) employed a method by which the carbon was heated by the current, and then allowed to cool in an atmosphere of nitrogen. Sawyer and Mann introduced at the same time another most important improvement in the construction of the incandescent lamp, described in the above-mentioned patent. This was a process to give strength and uniformity to their slender conductors by filling up their inequalities and irregularities by the deposition of carbon obtained by electrically heating them in a bath of liquid or gaseous hydro-carbon.

It is now admitted that Sawyer and Mann were answerable for these improvements.

Lane-Fox in his patent enunciates the principle, already established by King, that the dimensions of the conductor must vary according to circumstances, in the following

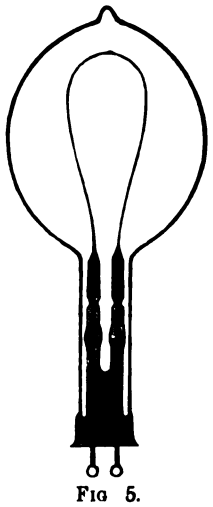

Fig 5.

words :—"The length and thickness of the spiral depends on the intensity of light required and the electromotive force to to be employed."

We have here certainly something definitely stated as to the dimensions of the conductor; but it is a fact, as may be seen from the diagram (Fig. 5), that Lane-Fox in his incandescent lamp, patented in 1878, employed a carbon filament for his conductor, and that he has a share in the patenting of a carbon filament lamp. Lane-Fox worked almost contemporaneously with Mr. Swan on the application of carbon to incandescent lamps, and in another patent, No. 1,122, of the 20th March, 1879, he states the unavoidable necessity of using high resistances, where high electromotive is to be used for lights of low intensity.

We have thus seen that the fundamental principles of the present incandescent lamp were known as far back as 1845, but twenty years more elapsed before these principles were developed into the manufacture of the present type. It is indisputable that the first patent for an incandescent lamp of the form now generally adopted was taken out by Lane-Fox, in 1878. This patent, however, must not be referred to the principles laid down by Starr, which found expression in the patent taken out by King, but should be considered on its merits of more or less novel details of construction.

That Du Moncel's somewhat severe remarks were justifiable is clear to the most casual student of the history of the incandescent lamp. Events, too, have vindicated his predictions, for Edison's lamps, with carbon filaments of the kind already mentioned, quite failed to justify the hopes reposed in them. But such and similar disappointments were wholly unable to discourage the eager genius of Edison, and only spurred him on to new achievements. On the 16th September, 1880, two months after the patenting of Swan's lamp, with its filament of specially prepared cotton, he took out a patent for the materials used in the present Edison lamps. This consisted of thin bamboo strips of the well-known shape shown in Fig. 6.

The success of Swan and Edison stimulated other workers in electricity towards the construction of carbon incandescent lamps. Maxim, Lane-Fox, Müller-Northomb, Puley, Burnstein, Woodhouse and Rawson, Gatehouse, and most recently Herr M. Von Bernd followed one another in a tolerably consecutive series, their lamps being all in essential principles comparable to those of Swan and Stearn and Edison, these principles having become recognised for the last ten years as alone suitable for the purpose, the distinctive characteristics of the various types being confined to degree of finish in construction, shape of bulb and material, shape and thickness of carbon filament. We may cite as an interesting fact that a few months ago a young electrician, Herr Max Von Bernd, of Wiener-Neustadt, has succeeded in replacing broken filaments by a very simple process, and thus repairing worn-out lamps, a discovery promising to be of great value in reference to the cost of maintenance of the incandescent lamps.

Thus, thanks to the laboriously accumulated experience of these indefatigable workers, has the science of electric illumi-

Fig. 6.

nation achieved a consummation which will open out a way for it to the palace and the cottage, and insure an increasing field for its universal application.

LITERATURE.

Arithmetical Physics. Part II. B. Magnetism and Electricity. By C. J. Woodward, B.Sc. Simkin, Marshall and Co.

We have had occasion to refer to previous works of this series as being written with a special object. This object is to assist students in preparing for examination. Although we hold, with Prof. Crystal, that the present examination mania is more of a curse than a blessing, and that books written for examination purposes are not equal in value to those written for educational purposes, we are bound to admit that most of these books serve a useful purpose. A student may have, and frequently has, a fair grasp of principles, yet be utterly unable to apply the principles, or to investigate their application by rigid mathematical scrutiny. The man who can only vaguely generalise is almost worthless. Qualitative analysis in electrical matters must be accompanied by quantitative measurements to be of practical use. Such books as this of Mr. Woodward are admirably adapted to initiate the student into the mysteries of quantitative work.

Errata.—In Sir W. Thomson's article on "Multiplying Potential" in our last issue, in the fifth line of text, for "n and the" *read* "$n+1$;" and in the eighth line, after the word successively, *insert* "and at short intervals of time."

Brazilian Submarine Telegraph Co.—The Directors of this Company will, at the general meeting on the 29th inst., recommend a final dividend of 3s. per share, payable on 30th inst., making 6 per cent. per annum for the year ended 30th June. £12,000 has been placed to reserve.

THE COMPOUND WINDING DISPUTE.

Although it would be improper and impertinent to offer here any opinion upon the legal aspects of this latest conflict among electric lighting patents, the facts of the case are of sufficient interest to be set forth in due order, and the consequences of legal action in the matter are of such serious moment that we do not hesitate to express our opinion as to the inexpediency of resorting to that mode of settlement. It is a costly process at best, and as we had occasion to observe in regard to electric lamps, it can only end in unsettling proprietary rights in general without establishing anybody's in particular. When the dogs are called in to arbitrate between foxes over a contraband goose, whatever becomes of the bird, the vulpines are safe to lose it. And this, we think, without meaning offence to electric lighting engineers, will be their case if they try to affirm with legal precision claims which would very well stand on their own practical merits, but which if too nicely inquired into may prove to be out of date and wholly untenable. The goose may be mauled almost past recognition, but if she is of proved maturity and species known, her rightful place in the farmer's yard can hardly be gainsaid. A number of electrical discoveries have been for many years straying about the common land, unused and almost forgotten. Suddenly their utility is perceived, and after much ingenious pains bestowed on them they are turned to practical account. No wonder that ownership is vehemently asserted by all and sundry who have done anything towards converting a barren theory into a serviceable reality; and no blame to them. But under the circumstances prudence would dictate that there be as little squabbling about the prey as possible, lest the true owner—but we need not finish the sentence.

So far as we can gather, the present dispute arises out of an assertion on the part of the Brush Company that they invented and patented, several years ago, the principle of compound winding for dynamos. It occurred in a patent of numerous claims, where it was suggested for electro-plating purposes. Meanwhile somebody else had worked out, by hard experience and costly experiment, that the principle was good for dynamos for electric lighting; and, adapted in a certain manner, machines of great power and popularity have, for three or four years past, been constructed on this principle, covered of course by patent. It then naturally occurs to the Brush patentee that something, too, could be made of the similar principles embodied in his miscellaneous patent; and in due accordance with Patent Law all the rest of the patent is disclaimed, and this alone let stand. It had never been used apparently; but by virtue of elimination it now becomes a valid independent invention, and the makers of compound-wound dynamos are forthwith warned that they will be infringing this patent if they make any more. This is curious; but everything is curious where Patent Law comes in. Patent right has sometimes been described as a patent wrong backed by a right lump of money; and we have little doubt that if the latter is forthcoming, tempered by no second thoughts as to consequences, the right, such as it is, will be upheld. But the question at once occurs to us—What would it be worth when established?

Let us consider this point with candour and impartiality. We are not sure that a "principle" can be patented—a theory cannot, unless it has a practical application—and in the case we are considering the application was to a purpose quite different from that to which it is now diverted, to the exclusion of other people who had already applied it to that special purpose. But if a principle can be patented apart from its special application, then it is certain that this principle of compound winding has been patented more than once before, and used in numerous ways. We need not particularise; the fact of its early use, for example, in telegraphy is well known, and the archives of the Patent Office show beyond question that the principle and its applications were matters of patent right long before the Brush "Teazer" was thought of. It does not, of course, follow from this that the Teazer patent has no independent validity; we are not laying down the law; what, however, may be fairly doubted is the possibility of legally widening the scope of this particular device to the exclusion of all its rivals. And we should be inclined to say the same thing of all modern dynamo patents.

These facts tell, of course, with equal force against the patentees of compound winding applied to electric lighting dynamos. Probably they would acknowledge this if their rights, such as they are, were not threatened by patentees whose ideas were certainly behindhand in taking practical shape. As against the original discoverer or discoverers, whoever they may have been, we hold that the claims of all these later rivals are invalid, because their principle was forestalled. Compound winding was long ago used avowedly for the purpose of controlling, regulating, and sustaining a current. As to the application of this method to the requirements of Electric Lighting, if that and that alone is the point now in dispute, it can only be determined in one way, namely, by the test of date; and the Brush claim will hardly stand this test, we fancy. In short, the theory,

Digitized by Google

being old, belongs in the commercial sense to nobody; the practice, being new, belongs, if to anybody, to the first comer. That the idea was suggested, or even utilised, for electro-plating eight years ago has as little relevance as the fact that it was suggested and used for other purposes eighteen years ago. If ideas count for anything, the earliest bars the later; and so with deeds. It is hardly likely, therefore, that the first makers of compound-wound dynamos will abandon their work without a struggle, simply because somebody else had patented an idea which might have been turned to the same account, but was not. If, however, it comes to challenging rights, we gravely doubt whether any exist worth speaking about; and we should advise all parties alike to refrain from proceedings which can establish nothing and may probably disturb a great deal.

CORRESPONDENCE.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I feel myself happy in having obtained a word from Mr. Sprague on this subject. Nevertheless, I confess I am a little puzzled by his letter in your issue this week (Oct. 9). Your correspondent, if I rightly understand him, refers the phenomenon in question to certain considerations connected with the direct currents of induction and the prolongation of magnetism in the core which results from their influence. The action of these currents had not escaped my consideration, but they seemed to afford no explanation of the phenomena. May I ask Mr. Sprague to be good enough to be a little more explicit, and to state for my benefit (1) whether he considers that the prolongation of the magnetism in the core is greater or less when the secondary circuit is closed? Unless he replies that it is *less*, he would afford no explanation of what actually occurs. Meanwhile he has pointed out that the direct currents of induction, to whose influence the prolongation is due, are developed partly in the primary wire and partly in the secondary wire, and I still follow him where he says that the ratio of these two developments of current is "according to" (*lege pro* amounting to?) "the resistance of the secondary circuit." Thus I gather that as long as the resistance of the secondary circuit remains *quasi*-infinite owing to the disconnection of its terminals, the induction will be confined to the primary wire; also that as soon as the secondary circuit is completed it becomes, in its own measure, an available channel for induced currents. Would Mr. Sprague kindly state (2) whether from his point of view this change of relations will lead to greater or less influence upon the core, tending to retard its demagnetisation?

I quite follow your correspondent in the general principles which he enunciates, but I should be glad to learn how he considers these principles are applicable as an explanation of the phenomenon that the spring vibrates faster when the secondary circuit is closed.—Yours, &c.,

Oct. 10th, 1885. E. ALDRED WILLIAMS.

LIFE OF INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think if some of your correspondents on this subject would state what they find to be the life of their lamps, your readers could find the average themselves.

For this purpose I beg to enclose small table, showing what I have found to be the life of the lamps of five different makers, all of which gave way during the past nine months. A dated label was put on each lamp when it was put into the circuit, and as a note is kept of hours lit each night, the life of these lamps was easily ascertained. They are all 50-volt lamps, and were in the same circuit, but were not all put up at the same time. The latter may account for some lasting much longer than others, as the remainder of those in columns 3, 4, and 5 are still burning.—Yours, &c., ENQUIRER.

Edinburgh, 10th October, 1885.

NOTE.—The numbers refer to the various makers:—

DIFFERENCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As a constant subscriber to your journal since its commencement, I regret to see letters appearing in its columns with the apparent object of advertising the writers, and otherwise void of information.

In your issue of the 9th inst. I find a letter, signed "Alfred J. Thompson," referring to *rockets* being used for passing wires over forbidden ground. This gentleman, after asserting that a Mr. Danvers has made a mistake in claiming the novel use of rockets for passing wires as his own idea, proceeds to mention that he has used "bow and arrow, slug sling," &c., as a means for passing wires over forbidden grounds, &c.; and then winds up with the remarkable statement that *rockets* were too expensive an item.

Therefore, so far as Mr. Thompson is concerned, according to his own statement Mr. Danvers has the prior claim.

Perhaps it will astonish Mr. Thompson to hear that "rockets," to my own knowledge, have been frequently used for the same purpose years before the telephone was thought of as being of commercial value.

Apologising for taking up space in your valuable journal, Yours, &c., VERB. SAP.

October 13, 1885.

THE INTENSITY OF THE HORIZONTAL COMPONENT OF THE EARTH'S MAGNETIC FIELD.*

BY THOMAS GRAY, B.SC., F.R.S.E.

Abstract.

The general principle of the method adopted was that of Gauss, with these modifications. In the deflection experiment the magnetometer needle was made so short that in the calculations it could be assumed, without sensible error, to be of zero length, and two deflectors were used simultaneously. The deflectors were placed one on each side of the magnetometer needle, with their axis in a line at right angles to the magnetic meridian, and in position for deflecting the needle; the directions of the line passing through the centres of the deflectors and the magnetometer needle were, first, the magnetic meridian, and, second, a line at right angles to it. The author pointed out that this mode of procedure leads to two equations, which suffice for the determination of the horizontal component of the earth's magnetic field and also of the effective length of the deflector. In these equations he also showed that the length of the deflector entered as a minus term in the one and plus in the other, and thus rendered the observations highly sensitive to possible errors in that term, and enabled a good estimate of the effective length of the different deflectors to be had. Apparatus was described by which the whole cycle of observations, both for this and the oscillation experiments, might be obtained without the necessity of handling the deflector magnets.

The effects of the various corrections on the value of "H" derived from the equations were discussed. Such of the errors as were sensible had been made the subject of direct experi-

ment, and their effect allowed for in the table of values of "H" given in the paper and quoted above.

As the observations necessary for a determination of "H" by this method extend over such a time as may make the diurnal variation sensible, and further to guard against the readings being vitiated by undetected magnetic storms, a magnetic vibrator was kept going throughout the time of the experiment and its period taken from time to time as might be found necessary.

REMARKABLE OCCURRENCE DURING THE THUNDER-STORM OF AUGUST 6th LAST AT ALBRIGHTON.*

BY J. BEDFORD ELWELL.

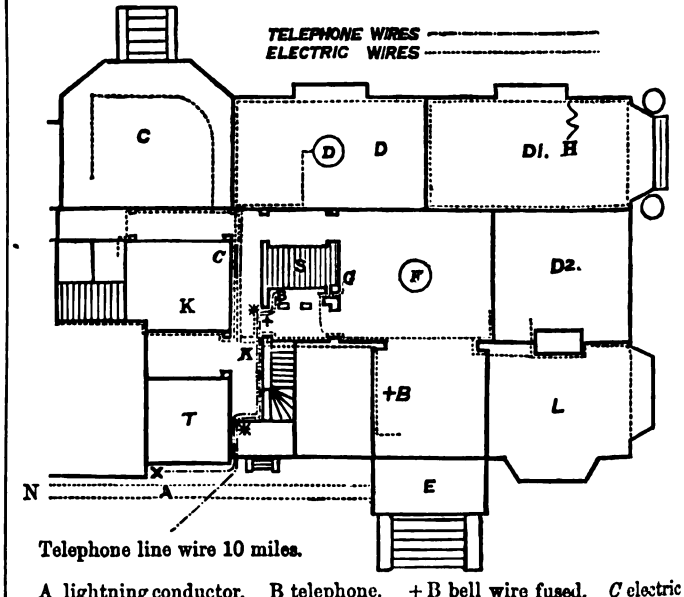
St. Cuthbert's, my residence, is situated at Albrighton, ten miles from Wolverhampton, with which it is connected by telephone. The house has a lightning protector twenty-five years old. The telephone wire very improperly makes earth on this conductor. The storm was at its height about half-past eight in the evening, and we had just retired to the drawing room, there being only a single lamp left alight in the dining room, in the centre of the corona. The telephone bell was sounding with every flash of lightning, when suddenly a report like a rifle-shot was heard in the hall, and at the same instant the servants in the dining room were plunged into darkness by the lamp in the corona flashing up and then going out. (Another lamp was immediately put in, showing the leads were not injured.) Also at the same moment the telephone wires were both fused at points marked * by one of which the wire sometimes used to connect telephone with drawing room through the light switch-board, but not then connected with telephone, passed. This was also fused, and through it the lightning tried to make earth (or *vice versâ*) all over the electric light system, succeeding in one place, in a bed room over the entrance hall, where a bell pull was close to one of the leads. The current struck across, showing an E.M.F. of many thousand volts, and fused the bell wire. None of the lead cut-outs were fused on any of the wires.

On examining the burnt lamp in the dining room it was found to be so blackened that (although it was perfectly clear and bright the moment before, and being a 48-volt Swan lamp could not be overrun from 24 cells) it was with difficulty that the filament could be seen. It was burnt off at *both ends* where the platinum wire joined, *and lay entire* in the bottom of the globe. The glass globe has become a beautiful mirror, by the fine particles of platinum that have been projected against it. A few globules of melted glass or platinum were also rolling about within the globe. A *separate earth plate* has since been put to the telephone, so that nothing of the kind can again happen.

* Abstract of paper read at the Aberdeen Meeting of the British Association.

Details.

The telephone instrument B, in the recess of the main staircase, has both line and earth wire running side by side until both emerge from the house at the corner of the tower, where the earth wire is twisted round the lightning conductor + at A.



A lightning conductor. B telephone. +B bell wire fused. *C* electric light switch board. C conservatory. D dining room. (D) corona over dining table where lamp was blackened. D1 and D2 drawing rooms. E entrance. (F) electrolier in hall. G single lamp in hall alight at the time and not affected. H lamp alight and not affected. K K lamps alight and not affected. L library. N naked wires, on insulators, from engine house to accumulators in a cellar below entrance hall. S staircase. T tower carrying lightning conductor. X telephone earth. N.B.—The corona in dining room is lighted from an upstairs lead, which also feeds four bed rooms in which no lamps were alight at the time.

The lightning conductor, erected 25 years ago, is a copper cable ⅜in. diameter, and about 60ft. long—the tower being about that height—insulated from the building, with the earth end simply buried in gravel, but in a spot where the soil is nearly always moist at the surface (after the storm, the conductor was tested with an ordinary detector galvanometer, and showed a good earth).

The electric light—supplied entirely from Planté-Parker accumulators, 24 in series, placed in a cellar below the entrance hall (in use for nearly three years past without a plate being

Digitized by Google

renewed, or showing any signs of requiring renewal)—is used all over the house, including nurseries, kitchens, and cellars; and the leads, eight in number, all start from the switch-board at C, behind the main staircase, each having its main fuse at the switch-board.

Theatre Wire.—This is a small wire (22 G) running from the telephone at B (but not connected with it at the time) by the side of the telephone wires as far as K, then turning off to the switch-board, where it communicates with the light leads, which are thus used occasionally for the double purpose of lighting and transmitting operatic music from the theatre at Wolverhampton to some of Tayler Smith's connections in the drawing room, to which a telephone receiver may be attached at will, the earth being obtained through the drawing room window (26 G bare wire). The turning on and off of lamps does not affect the telephone.

The above are all the points connected with the matter.

ELECTRIC CONDUCTIVITY OF METALS AND THEIR ALLOYS.*

BY M. LAZARE WEILER.

In the study of all electrical problems, and especially of such as relate to dynamic electricity and its applications, we are brought at the outset to the consideration of conduction. Whether it be a question of light, of force, of heat, of chemical or mechanical phenomena, or, in a word, of any transformation whatever of electricity, it is indispensable to know the quantity of electricity produced at the source, and the amount afforded at the place where it is utilised. The nature of the intervening conductor becomes then one of the principal elements of the problem. In the dynamo-electric machine, which is only a conductor or a series of conductors subjected to magnetic induction, the property of conductivity is an important one. The properties, therefore, of different metals and their alloys, as regards their power of transmitting electricity, afford a subject of exceeding interest.

This question furthermore merits our attention now, for the reason that physicists who have hitherto investigated it have failed to arrive at concordant results, either because of the impossibility of obtaining absolutely pure metals, or by reason of the imperfections of the apparatus or the methods for electrical measurement at the date of their researches. When Mathiessen made his experiments (1863) it was extremely difficult to procure certain metals in a pure state. He mentions the labour necessary to produce 5 or 10 kilograms of pure metal, while now it is a matter of daily occurrence in some manufactories to deposit by electrolysis metals in a pure state by the ton. The processes employed in the establishment of the Nordeutsche-Affinerie, at Hamburg, as well as certain works in Belgium and England, lead to the extraction and separation of the metals from argentiferous copper ores, which contain small quantities of silver and traces of gold, not capable of separation by the older methods. This is profitably applied to ores in which the presence of the precious metals did not formerly affect the commercial value. Under such conditions it becomes easier and all the more necessary to review and complete former researches. This is the work that I have been able to undertake, by aid of the special facilities afforded me by a carefully fitted laboratory and a workshop in which are applied on a large scale processes which were not formerly applied outside the chemist's laboratory. I shall have the honour to resume before you the researches which I have pursued for some years. The results obtained are far from being complete, but they permit us to closely examine certain points of the theory of a subject upon which our ideas are not yet conclusively formed. They afford in all cases useful corrections to the published tables, which are for the most part afflicted with errors. This double claim is, I trust, sufficient to engage your kind attention. Researches relative to the conducting power of different bodies have been pursued only in recent times. Priestley was the first to attempt the determination of the conducting power of metals for a static charge of electricity. There was no precision in his method of comparison. He employed two wires of the same length and diameter, but of different metals, and sent charges through them until one was fused. The fused wire was considered the poorest conductor. Davy applied the same general method with voltaic currents, and succeeded in establishing the law relative to the dependence of electric resistance upon the length and cross-section of the wire. M. E. Becquerel, who has written a memoir on the origin of these researches, gives the table of relative conductivities, as measured by his father, who was the first physicist to engage seriously in this labour. The table is as follows:—

Copper	100	Iron	15·80
Gold	93·60	Tin	15·50
Silver	73·60	Lead	8·30
Zinc	28·50	Mercury	3·45
Platinum	16·40	Potassium	1·33

Since that time Pouillet has given the same measures and added the following table, which possesses a special interest from the fact that it exhibits the influence of the presence of foreign bodies, also of tempering and annealing:—

Palladium	5791	Copper, pure	3838
Silver (963 fine)	5152	Copper, annealed	3842
,, (900 ,,)	4753	Platinum	855
,, (857 ,,)	4221	Brass	200 to 900
,, (747 ,,)	3882	Cast steel	200 to 500
Gold pure	3975	Iron	600 to 700
,, (951 fine)	1338	Mercury	100
,, (751 ,,)	714		

The selection of a unit for comparison in this table is a matter of some interest. Pouillet has chosen mercury for his standard obviously for the reason that, being a liquid, it is the metal most easily obtained in a pure state, and that also, from this same property of liquidity, it is exempt from those variations of conductivity which arise from annealing, hardening, &c.

These considerations prompted the Congress of 1881 to select mercury for the material of the standard of resistance. At a second reunion of this Congress, this selection was approved, and the ohm was defined to be that amount of resistance offered by a column of mercury whose area of section is one square millimetre, and whose length is 106 centimetres, the temperature being 0° centigrade. The important researches of Becquerel, in 1846, led to the determination of the relative conductivity of several metals at the mean temperature of 12·75°. These results are exhibited in the following table:—

	Hammered.	Annealed.
Silver, pure, reduced from chloride	93·448	100
Copper, precipitated by battery and fused	89·084	91·439
Gold, pure	64·385	65·458
Cadmium	24·574	—
Zinc	24·164	—
Tin	13·656	—
Palladium	12·977	—
Iron	12·124	—
Lead	8·245	—
Platinum	8·042	—
Mercury (14°)	1·8017	—

Mathiessen afterwards published in the *Proceedings of the Royal Society* the following table, which has been accepted for practical use down to the present time:—

	Resist. in ohms of wire 1 m. long and 1 mm. diam.	Conductivity.
Silver, annealed	0·01937	100
,, drawn	0·02103	92·1
Copper, annealed	0·02057	94·1
,, drawn	0·02014	94·1
Gold, annealed	0·02650	73
,, drawn	0·02697	73
Aluminum, annealed	0·03751	51·6
Zinc, rolled	0·07244	26·7
Platinum, annealed	0·1166	16·6
Iron ,,	0·1251	15·5
Mercury, liquid	1·2247	1·58
Nickel, annealed	0·1604	12
Tin, pressed	0·1701	11·4
Lead, ,,	0·2526	7·6
Antimony, pressed	0·4571	4·2
Bismuth ,,	1·689	1·1
ALLOYS—		
Platinum 1, silver 1 (drawn or annealed)	0·3140	6·1
German silver (drawn or annealed)	0·2695	7·2
Gold 2, silver 1	0·1399	13·8

* Translated in *Van Nostrand's Engineering Magazine* from a communication to the Société Internationale des Electriciens.

Digitized by Google

An examination of these tables shows a want of accordance not only in the relative conductivities of the different metals, but also in their order. Thus silver occupies the third place in the table of the elder Becquerel, whereas it should have been in the first. Also palladium is in the first place in Pouillet's table, while it should have been placed last. These differences justify the new researches, which are furthermore prompted by that desire for precision which the daily progress in the practical application of electricity renders necessary.

I now proceed to present a *résumé* of my researches in determining the resistance of metals and alloys; then the results of experimenting upon the influence of temperature, and finally, upon the relations more or less intimate between the electric and thermic conductivity. I shall hand to you a set of small bars which have been prepared for these experiments. These bars, as you see, have been cast with a diameter of about 13 millimetres. They have been cut in such a manner as to exhibit the grain of a fracture, and the detached portion has been drawn into wire, upon which the experiments now to be described were tried. In case of the alloys which cannot easily be drawn or rolled, as some of the compounds of silicon or phosphorus, the experiments have been tried directly upon the bars themselves by the method of Sir William Thomson. In conducting the experiments, the bars were supported upon V-shaped rests, placed at an invariable distance apart. These rests were respectively in communication with two resistances composed of two parts, of which one is one-thousandth of the other. A Wheatstone bridge, a differential galvanometer, a battery of four cups, and a contact key complete the apparatus. The measurements, which were very long and minute, and made upon a great number of specimens, were made in part by the writer at the workshop at Angoulême, with the assistance of Messrs. X. Muller and J. Stahl, engineers of the establishment, and partly by M. Duflon, electrical engineer in the measuring room of M. Sciami, director of the Maison Breguet. These latter experiments were those made upon the bars themselves. The number of specimens submitted to your examination is thirty-four. Their conductivities compared with silver and pure copper are given in the following table :—

Silver	100
Copper, pure	100
,, refined and crystallised	99·9
Bronze, silicious, telegraphic	98
Copper and silver alloy, equal parts	86·65
Gold, pure	78
Copper, with 4 per cent. of silicon	75
,, ,, 12 ,, ,,	54·7
Aluminum, pure	54·2
Tin, with 12 per cent. of sodium	46·9
Silicious bronze, telephonic	35
Copper, with 10 per cent. of lead	30
Zinc, pure	29·9
Phosphor-Bronze, telephonic	29
Brass, silicious, 25 per cent. of zinc	26·49
Brass with 35 per cent of zinc	21·5
Tin phosphide	17·7
Gold and silver alloy, eq. parts	16·12
Swedish Iron	16
Tin, pure ; banca	15·45
Antimony-Copper	12·7
Aluminium-Bronze	12·6
Siemens steel	12
Platinum, pure	10·6
Copper with 10 per cent. of nickel	10·6
Cadmium 15, mercury 85	10·2
Bronze, mercurial, dronier	10·14
Arsenical copper, 10 per cent. arsenic	9·1
Lead, pure	8·88
Bronze, containing 20 per cent. tin	8·4
Nickel, pure	7·89
Phosphor-Bronze with 20 per cent. tin	6·5
Copper with 9 per cent. phosphorus	4·9
Antimony	3·88

A large number of experiments were tried upon alloys and compounds not represented in the above series. It will be observed that in the results recorded above resistances are not given in ohms, but conductivities are expressed relatively to a selected standard, which is pure silver. A wire of this metal, one millimetre in diameter, offers a resistance at 0° centigrade of 19·37 ohms per kilometre. Pure silver and pure copper are the best known conductors of electricity. The ease with which silver can be obtained in a pure state would seem to entitle it to the position of standard of comparison. It also oxidizes with greater difficulty than copper, and its oxide is a better conductor. In this last peculiarity there is less chance of error when comparisons are made with silver for a standard. Gold has a conductivity of 78. The alloy of gold and silver calls attention to a remarkable fact. When silver is alloyed with a small percentage of gold, the conductivity immediately diminishes. Two per cent. of gold is sufficient to reduce the conducting power from 100 to 60. An increase in the proportion of gold, however, is attended with a decrease of conductivity at a less rapid rate, the minimum of 16·12 being the conductivity of an alloy of equal parts of gold and silver. If the varying conductivities of the different proportions of gold and silver alloy be represented by a curve, it will be found to take the form of a parabola whose axis is perpendicular to the axis of X, the curve descending from the ordinate 100 for pure silver to 16·12 for the alloy of equal parts of the two metals, and rising to 78 for pure gold. This singular phenomeon seems to indicate that a kind of interference is produced analogous to that when rays of light partially extinguish each other by superposition. This is not an explanation, but a simple analogy.

It should be remarked, however, that it is not true, though sometimes asserted, that in an alloy the electric conductivity is always lower than that of the poorest conductor of the constituents. It is simply demonstrated that the union of two bodies modifies to a great extent their separate conductivities, and this fact ought certainly to lead some time to interesting results. In examining the foregoing table, we find platinum with a conductivity of 10·6. Aluminium, which is distinguished from the other metals by its want of density, has the considerably higher conductivity of 54·2. This is partly compensated for by its low specific weight. But it is a mistake to consider its lightness as a quality fitting it some day for aerial telegraph lines. Its tenacity is rather feeble, and its tensile strength falls from 10 kilograms per square millimetre in the hard metal, to 6 or 7 kilos only in the annealed metal. Iron, steel, lead, zinc, and tin possess low conducting powers, and the results in the table are not insisted upon. It is sufficient to consider them in connection with results previously found. Copper, however, is to be regarded with interest and care, as it, with its alloys, is regarded as the typical conductor of electricity. It possesses when unalloyed and is free from its oxide a conducting power equal to silver. Its cost is low enough to render it available for industrial uses. It is malleable, and some of its alloys possess a remarkable tenacity. It is interesting to note the increase in the conducting power of copper with the improvement in manufacture. In the late discussion upon electric conductors, Mr. Preece exhibited the following table, showing the progress in conductivity of submarine cables :—

Submarine Cables.	Date.	Conductivity.
Dover-Calais	1851	42
Port Patrick-Donaghadee	1852	46
Transatlantic	1856	50
Red Sea	1857	75
Malta-Alexandria	1861	87
Persian Gulf	1863	89·14
Transatlantic	1865	96
Irish Sea	1883	97·9
Pure Copper	—	100

A similar progressive increase in the conductivity of the copper wire, furnished to the Administration Française des Télégraphes, which, after having for many years exacted a conductivity altogether indeterminate, so to speak, has been gradually led to adopt figures quite comparable to the highest in our table. The variation in the conductivity of copper is due to two principal causes: the presence of other bodies, and the presence of a varying quantity of copper oxide. Mathiessen and Holzmann have made a series of interesting experiments bearing upon this subject. Table A exhibits the conductivities of copper of different sections ; table B exhibits the conductivity of copper containing traces of different substances. These results are approximately the same as those we have obtained, and which we have already referred to. Table C exhibits the influence of the presence of copper oxide

Digitized by Google

in the metal. The first five examples are of cold-drawn wire of pure copper.

It may be added as a commentary on the last results that in France pure copper wire is prepared by a special process, which completely eliminates the oxide. Copper thus prepared has the conducting power of silver. It has been measured recently by the telegraphic authorities mentioned above, and with the result of exhibiting a conductivity of 102 by the standard heretofore used, and whose imperfections were thus demonstrated. I cannot remember by what chain of circumstances I was led to study the compounds of copper and silicon, prepared for the first time by M. Henri St. Clair Deville, and apply them practically to the uses of the telegraph and the telephone. Coppers and bronzes prepared under such conditions are much used for aerial telegraph and telephone lines. Their electrical and physical qualities permit us to believe that the time is gone in which iron and steel enjoy the monopoly in such transmission. It is certain, as has been remarked by the eminent electrician in chief of the London Post Office: "Aerial lines should no longer be limited to the single quality of tensile strength. At a time when the apparatus for rapid transmission occupies all the great telegraphic routes, the lines should be made of very good conductors; the surfaces reduced so as to offer the least possible chance for induction, and they ought also to offer but little surface to the wind and snow, and should be practically indestructible." Mr. Preece does not hesitate to conclude that iron and steel wires have had their day, and they will soon be replaced by wires of copper and its alloys. The latter fulfil not only all the required conditions, but when once erected, cost no more than lines heretofore used.

(To be continued.)

TABLE A.

	Conductivity.	Temp. in deg.
1st. Spanish copper from Rio Tinto, containing 2 per cent. of arsenic, with traces of oxides of copper, lead, and nickel	14·24	14·8
2nd. Russian, Demidoff, with traces of arsenic, iron, and nickel oxides	59·34	12·7
3rd. "Tough cake," location not specified, traces of lead, iron, nickel, and antimony oxides	71·03	17·3
4th. ——, traces of iron, nickel, and antimony oxides	81·35	14·2
5th. Australian, Burra-Burra, traces of iron oxide only	88·86	14·0
6th. American, Lake Superior, 3 per cent. of silver, with traces of iron and copper oxide	92·57	15·0

TABLE C.

No.	Mode of preparation.	Conductivity.	Temp. in deg.
1.	Reduced by hydrogen	93·00	18·6
2.	Deposited by battery, not fused	93·46	20·2
3.	Commercial copper	93·02	18·4
4.	Ex. No. 3 remelted in hydrogen	92·76	19·3
5.	The same treated with a jet of hydrogen while fused	92·99	1·75
	(It has been noticed that the conductivity has been raised about 2½ per cent. by annealing.)		
	Copper containing an undetermined amount of oxide	73·32	19·5
	Deposited copper taken from a bar, fused on charcoal, and cast in an atmosphere of hydrogen	93·3	12·8
	Copper same as preceding taken from a porous bar cast in a mould under ordinary conditions	94·8	13
	Deposited copper, treated to cementation with charcoal, and containing silicon with traces of iron and phosphorus	62·8	13

ELECTROMOTIVE FORCES IN A VOLTAIC CELL.*

BY PROF. OLIVER LODGE.†

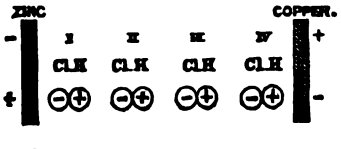
Theories of Wiedemann *and* Helmholtz.

In a recent *Beiblätter*‡, Prof. G. Wiedemann points out that in my summary of views and work in connection with the seat of E.M.F. in the pile I have ignored his theory. I had in fact been mainly concerned with possible explanations of the Volta-effect; while Prof. Wiedemann starts with this as a datum, and on the strength of it explains the action of the pile. Moreover, since most of the theoretical opinions hold on this subject are summarised at the end of the second volume of his *Elektricität*, while his own theory is given in the first volume, along with the account of Volta-force experiments, I had overlooked it. To make amends for this oversight, for which I beg to express my regret, and because I find it difficult to summarise his opinions briefly, I trust I may be permitted to give a rough semi-literal translation of his most conspicuous passages as a help to other students on the subject.

Theory of G. Wiedemann, 1870. (Wied., *Elek.* I., p. 251, *et seq.*)

"We have now to investigate in what way the electrical forces in a closed circuit of two metals and a liquid (*e.g.* Zn. Cu, dilute HCl) are excited. We know that the constituents of the binary compound contained in the liquid separate by the passage of the current in such a way that the one (H) is set free at the copper and an equivalent quantity of the other (Cl) at the zinc, and that the latter combines with an equivalent quantity of zinc to form ZnCl. This process shows that the deportment of the binary body between the metals consists no longer only in a simple overbalancing attraction of its whole mass for one or the other electricity, as in metals, but also in a special action of its constituents. Since the constituent Cl is liberated where the + current enters the liquid, and H where the negative enters, we suppose that each equivalent of Cl in the compound HCl is charged with a definite quantity of negative electricity, which conditions its attraction for the opposite positive electricity. It is the *electro-magnetic element* of the compound. So also must the equivalent H be charged with + E and form the electro-positive element. These charges could be produced by the combination of H and Cl exactly in the same way as they are produced by the contact of zinc and copper. Since the HCl formed is unelectrified, we must suppose that atoms of the + and − constituents contain equal qualities of + and − E.

"If now we immerse a Zn and a Cu plate into the dilute HCl, we can conjecture that the zinc has a stronger attraction for the electro-negative constituent (Cl) than for the H. In consequence of this the molecule of HCl touching the zinc will so lay itself that its electro-negative element is near the zinc and its electro-positive element near the copper. At the same time the molecules thus polarised act by electrical attraction on the constituents of the successive molecules of HCl, arranging the whole row of molecules between the Zn and the Cu plates as in the figure.



"By induction the negative electricity of the zinc-touching electro-negative constituent, chlorine, would act on the E in the zinc in such a way that the near parts will charge themselves positively, the further parts negatively. In the same way the copper adjacent to the electro-positive element (H) of the HCl atom lying against it will receive negative electricity. The positive will remove itself to the remoter regions.

"Thereupon the positive electricity in the zinc would combine with the negative of the next-lying Cl atom, and this latter with zinc to form unelectrical ZnCl. The electro-positive atom H which was formerly joined to that Cl atom would itself unite with the neighbouring atom of Cl belonging to the second atom of HCl, at the same time combining with the electricity contained in this atom; in the same way the hydrogen of the second atom—[the welcome letters *u. s. f.* are now not far ahead, and we will let them serve for the next fifteen or sixteen lines].

"It is evident that in this process there occurs a continual loss of *vis viva*, since the elements of the binary compound rushing up to the metal move with a definite velocity to the metal, and then are reduced to rest, either with formation of ZnCl or by being set free (H). This loss of *vis viva* is the equivalent of the heat which is evolved by the obviously occurring chemical process, which essentially is the solution of an equivalent of zinc in the acid. The same value must likewise be the work applied in effecting the redistribution of electricity.

"When, therefore, electricity begins to flow, work must be done, during the solution of Zn and liberation of an eq. of H from the liquid in the whole circuit, whether it be in the form of heat or of external work, which is equivalent to the heat-production attending that chemical process.

"The electrical shearing-force E is an accelerating force, so its work A in unit time is equal to its product with the quantity of electricity moved in unit time, *m*, and the distance *s* which the same travels, or

$$A = E.\ ms.$$

The product *ms* expresses the quantity of electricity which travels per second through the cross section of the conductor.

* Sequel to Paper on "The Seat of the Electromotive Forces in a Voltaic Cell," from the *Phil. Mag.* for October.

† Communicated by the Author, in continuation of paper in *Phil. Mag.* for March, April, May, and June of the current year.

Digitized by Google

"If we have different combinations, as Zn, HCl, Cu; or Mg, H_2SO_4 or Na Cl, Cu; or &c., we suppose that the same quantity of E travels per equivalent.....[a long appeal to the facts underlying Faraday's law is made to prove this]; hence $ms = \text{const.}$,

$$\therefore A = \text{const.} \, . \, E;$$

or the E.M.F. is directly proportional to the heat generated by the decomposition of an equivalent of the binary compound and the solution of the zinc.

"For the production of steady currents, that electrical force can alone be active which depends on the unequal attraction and polarisation of the atoms of the binary compound in the exciting liquid of the cell; the electrical force at the contact-place of the metals which no mechanical changes can prelude must, on the other hand, be inactive. That this latter, if it perhaps opposed the metal liquid E.M.F. (as by immersion of zinc and lead in KCy solution), is not compensated by a definite part of the tension force, is proved by the aforesaid complete proportionality of the total electrical force (and E.M.F.) in the closed circuit with the said heat-equivalent of the chemical processes. It must then be neutralised in some other way. This would most simply happen on the hypothesis that, by contact of the existing fluid with the metals, the E.M.F. is excited in a double way: first, by an unequally strong attraction of the masses of fluid and metal *as a whole* for the one or the other electricity; and, secondly, by the unequal attraction of the metals for the oppositely electrified components of the liquid. (This double property would be quite analogous to the following: a metal (*e.g.* zinc) can not only attract to itself by adhesion the whole mass of any given fluid (HCl), but also can exert a much stronger attraction for one constituent of the same (chlorine); just also as a magnet attracts iron, not only by reason of gravitation, but much more because of the magnetic polarisation of its individual particles).

"In consequence of the first unequal (mass) attraction for the electricities, the decomposable liquids would behave exactly according to the metallic law of tension, and in a closed circuit of metals and liquids a complete neutralisation of electrical forces (and E.M.F.) would obtain; the second (chemical) action would, on the other hand, alone produce the electrical shearing-force effective in current formation and its accompanying E.M.F.

"We will therefore in the sequel denote the total E.M.F. at the various junctions with strong letters, and that portion of the same of which no part engages in exciting the current by italics in brackets, and by italics without brackets the portion corresponding to the chemical work. In the closed circuit—zinc, sulphuric acid, copper—the whole active E.M.F. would then be

$$\mathbf{Cu/S + S/Zn + Zn/Cu} = Cu/S + S/Zn + (Cu/S) + (S/Zn) + (Zn/Cu).$$

"The experiments of Hankel and others give the total E.M.F. between the metal M and water, which we denote by $\mathbf{M/Aq}$, and which is compounded, according to the foregoing hypothesis, of the E.M.F. excited by the mass action of the water (M/Aq), and that excited by reason of its chemical polarisation M/Aq. If therefore we put into water a copper and a zinc plate, the total potential difference, or E.M.F. between its ends, is $\mathbf{Cu/Aq + Aq/Zn}$. This is the quantity we should directly obtain if we connected the Cu and Zn immersed in water with the same named plate of a zinc-copper condenser, and after breaking the connection determined the charge of the condenser.

"On our hypothesis,

$$\mathbf{Cu/Aq + Aq/Zn} = (Cu/Aq) + (Aq/Zn) + Cu/Aq + Aq/Zn.$$

If we close the circuit by connecting the zinc and copper plate by a copper wire, the force $\mathbf{Zn/Cu}$ adds itself to these E.M.F.'s, and this force removes from the tension series of the metals the following forces $(Cu/Aq) + (Aq/Zn)$; wherefore we get

$$\mathbf{Cu/Aq + Aq/Zn + Zn/Cu} = Cu/Aq + Aq/Zn.$$

But this last is the part of the total E.M.F. applied to the formation of the current. Hence *to the directly found contact-forces between different metals and water we must add the electromotive excitation of one metal on the other in order to get the current-forming E.M.F. in the circuit of a closed cell.*"

So far as I am able to see to the bottom of the foregoing theory its foundation appears to be as follows:—Contact experiments compel us to accept the summation law for the Volta-effects, or total differences of potential,

$$\mathbf{E = Cu/Aq + Aq/Zn + Zn/Cu.}$$

The chemical theory constrains us to admit that the E.M.F. of a cell is the equivalent of the chemical action going on, and thus suggests that it equals the sum of some chemical contact forces; or, in Wiedemann's notation, E ought also to equal

$$Cu/Aq + Aq/Zn.$$

How are these two requirements to be reconciled?

Assume that at every junction there is a total force made up of two portions—a chemical force, such as Cu/Aq, and a physical force, which may be denoted by (Cu/Aq), and write the whole E.M.F. of a cell equal to the sum of these chemical and physical junction-forces,

$$E = Cu/Aq + (Cu/Aq) + Aq/Zn + (Aq/Zn) + (Zn/Cu).$$

We have then only to make the physical forces obey Volta's series law; so that

$$(Cu/Aq) + (Aq/Zn) + (Zn/Cu) = 0;$$

and we get the required relation

$$E = Cu/Aq + Aq/Zn,$$

which harmonises chemical and contact views.

Prof. Wiedemann's reconciliation of contact and chemical theories would thus seem to be somewhat of the same order as the later and less complete one of Fleeming Jenkin, quoted in my paper, § 6; but I cannot help feeling that the theory of Prof. Wiedemann is rather fuller of hypothesis than most other contributions to the subject with which I am acquainted; for it postulates

1. An unexplained difference of potential between metals in contact.
2. A similar difference of potential between the elements of a compound.
3. An unequal attraction of bodies for + and − E.
4. An unequal attraction of metals for chemical elements.
5. A chemical contact-force between metals and liquids, depending on No. 4, not obeying Volta's law.
6. A physical contact-force, depending on No. 3, obeying Volta's law.
7. Proportionality of the chemical contact-forces and the heats of combination.
8. A mechanical falling together of atoms accounting for heat-production at electrodes; and
9. That electrical actions go on between the molecules of a liquid, and between those molecules and metals immersed in it, according to the ordinary laws of electrostatics.

Not all of the above hypotheses, however, are to be regarded as independent: the dependence of Nos. 5 and 6 is stated, and it is possible that some of the others are intended to be likewise dependent, though I do not clearly see how.

In some of these hypotheses, for instance, Nos. 4 and 5, and with considerable differences, Nos. 6 and 7, Prof. Wiedemann's theory bears a resemblance to the views set forth by the present writer in the paper to which this communication is a sequel.

One obvious objection may be taken to the theory on a question of fact. According to it, zinc half immersed in water is negative to copper half immersed in water (see diagram above): but experiment has failed to exhibit anything of the kind; but it is well known that Sir W. Thomson, Prof. Clifton, and others have shown that zinc and copper immersed in water or dilute acid are electroscopically at the same, or nearly the same, potential.

Theory of Von Helmholtz, 1847 *and later.*

There is another theory which I did not indeed ignore, but which I passed over with very insufficient mention, in the paper referred to (see footnote to § 9, *Phil. Mag.*, April, p. 258), viz., the theory of Prof. von Helmholtz, which he first stated in his great memoir of 1847, *Die Erhaltung der Kraft*, and which he has improved and elaborated since (see Faraday Lecture of 1881).

This fascinating theory has a small hypothetical basis, viz., Nos. 3 and 9 of the above list; and on this foundation is erected an explanation of the Volta effect, a theory of electrolysis, and a great part of a theory of chemical combination.

Once grant (1) that every substance has a specific attraction for positive or for negative electricity which can be exerted only through molecular distances, and (2) that the laws of electrostatics may be applied to the charges of atoms in a liquid; and the ease with which a multitude of phenomena are explained is surprising. I do not feel certain that a little too much is not explained; but we can postpone the consideration of possible objections until the theory itself is briefly stated.

Metals, and "electropositive" elements generally, attract positive electricity or positively electrified atoms whenever these come within range, *i.e.*, within some molecular distance of the surface. Potassium and zinc attract strongly, copper and gold feebly. Oxygen, chlorine, and other "electronegative" elements, attract negative electricity in a similar manner.

Bring now two metals, say zinc and copper, into contact, and the superior attracting-power of zinc for positive electricity will at once charge it at the expense of the copper, so that the zinc touching-surface becomes strongly positive, and the copper surface strongly negative. Separate the metals, and they mostly discharge into each other; but a feeble charge remains if the surfaces in contact were large, and if they had been neatly separated; and this is the Volta effect.

Moreover, since each metal has a definite attracting-power depending on itself only, Volta's series law is an obvious necessity.

If one of the substances had been an insulator much less loss need take place while separating them, and accordingly high charges are then found upon them even after separation ("frictional electricity.")

Now, consider similarly two *atoms* in contact, forming, say, a water molecule. The hydrogen will be positively charged, and oxygen negatively. If some atoms should get knocked asunder they retain their charges and therefore tend to unite again, but, while separate, their mutual attractions and repulsions will preserve a uniformity of distribution throughout the liquid—*e.g.* the repulsion of similar charges will prevent a number of oxygen molecules crowding together; and if any cause should remove oxygen atoms from any part of the liquid, the vacancy will be instantly supplied by similar atoms repelled there.

The remarkable thing about the charges of atoms is, however, that they are all equal, and even for different atoms are still the same, or differ only according to simple multiples of some one absolute quantity; so that one atom may have three times as much negative electricity as hydrogen has positive, but not any fractional number. Such an atom may therefore combine with three of hydrogen atoms, and thus be called a triad. Another may be a dyad, &c. A given constant charge belongs to every unit of affinity which the atom possesses; and thus is the fact of chemical equivalence stated, though not accounted for. Faraday's law compels us to believe that atomic charges are thus multiples of one definite electric

Digitized by Google

quantity, but why they should be so we are wholly unable to say. It looks as if electricity were atomic as well as matter; a sufficiently startling idea, as Helmholtz says.

Chemical affinity is thus due to the electrical attraction of oppositely charged atoms; not so much due to the attraction of the atoms themselves. This latter kind of attraction Helmholtz would not indeed deny, and he considers it may account for "molecular" modes of combination; but he regards it as much weaker than the electric forces, and not as effecting definite chemical combinations.

We have ideas now concerning the size of atoms, and can calculate roughly what an atomic charge is. The charge of each atom is but small, but the aggregate charge of an appreciable number of them is enormous. It can be easily reckoned that if you take the opposite electricities out of a milligramme of water and give them to two spheres a mile apart, those two spheres will attract each other with a force of ten tons! Or, again, the electrical attraction of two atoms at any distance exceeds their gravitative attraction 71 thousand billion times. Upon such charges as these even very feeble external electrical influence may exert considerable force, and quite everpower any other kind of chemical affinity.

Plunge, therefore, two platinum plates into the liquid and keep them at some slightly different potential, say a volt or two: their surfaces are oppositely charged, and even this feeble charge may be sufficient to tear asunder the atoms of molecules which come close up to it.* If it is not sufficient, it will at least hold a layer of oppositely charged atoms facing toward it across molecular distance; so that near each plate we have an excessively thin condenser of enormous capacity; but in the mass of the liquid is no such strain, the slightest E.M.F. being sufficient to redistribute the atoms here and to produce perfect equilibrium. If the atoms are torn asunder by the electrode and liberated, fresh ones are continually supplied by the rest of the liquid, the state of strain being constantly re-formed and instantly broken down.

Thus are the phenomena of polarisation and electrolysis explained.

Now insert into the liquid a pair of plates of zinc and copper in contact. By the contact the zinc has become positive and the copper negative, and accordingly the zinc attracts the oxygen (or SO_4 radical) and combines with it: the copper attracts the hydrogen, and does the best it can with it.

This crudely is Helmholtz's view of a voltaic cell.

There is, however, one important detail not yet mentioned. I have spoken as if the work done by an electrode were to tear the atom from its combinations. This is not exactly Helmholtz's view. He adduces arguments to show that the work required to effect decomposition has for its object, not the separation of the atom from the liquid, but the separation of the atom *from its electric charge*. It is to this that it clings, and this that has to be taken from it. If it be made to give up this by a sufficient E.M.F., it is of small or no moment whether the ion be really set free, or be dissolved, or otherwise kept in the liquid. But when the electrode is of such a metal that an ion can combine with it, that ion retains its charge, and accordingly very little E.M.F. is sufficient to decompose the liquid under such circumstances.

Without this statement it might be objected, that when a piece of zinc is plunged into acidulated water, since it has a strong attraction for positive electricity, it ought to attract the positively charged *hydrogen* atoms up to itself, instead of oxygen as commonly supposed. I suppose Helmholtz would admit that it must do this to begin with, when isolated from other metals, on his theory, but that it has no way of separating and liberating atoms because it cannot get rid of their charges. If it be kept at a sufficiently negative potential artificially it can indeed dispose of these charges, and it then does attract and liberate hydrogen. But contact with copper raises it to a *positive* potential, and it then attracts negatively charged oxygen, rather than hydrogen, and combines with it; while the negatively electrified copper seizes hydrogen atoms, tears their charges away from them, and sets them free.

I must confess, however, that I feel a difficulty here. The natural tendency of zinc is, by hypothsis, to attract positive and repel negative atoms; but, while a very feeble positive electrification applied to it is sufficient to reverse this tendency, a comparatively strong negative electrification is needed to enable it to exert that force which by the hypothesis is supposed to be *natural* to it.

In considering a Daniell cell, zinc/$ZnSO_4$/$CuSO_4$/ copper, Helmholtz obtains the energy producing the current, by pointing out that electricity is removed from copper, which only attracts it feebly, and given to zinc which attracts it strongly. Zinc goes into solution and becomes positively charged, while an equivalent of equally positive copper comes out; and since this results in a gain of energy, it follows that electricity must do more work in going to zinc, than in going to copper.

But if zinc attracts electricity so much more strongly than copper, why is it so easy to drive electricity across a copper/zinc junction? And why does no energy manifestation result at the junction from such an operation?

The answer probably is, because of the large charge already existing at the junction; the zinc has pulled as much positive electricity out of the copper as it wants, and there exists at the contact an electrical double layer, whose existence makes it quite easy for extraneous electricity to flow either way across the junction.

But, then, if zinc pulls so much electricity out of a piece of copper with which it is put into contact, where does it all come from? And why does it not leave the copper *strongly* negative instead of only feebly so, as evidenced by Sir W. Thomson's electrified-needle form of experiment? Why, again, does this method of observing the Volta-effect, with the plates permanently in contact, agree so well with the old method of observing it by separation of the plates, if a great but uncertain part of the charge leak back as soon as separation beyond molecular distance is attempted?

These and similar difficulties occur to me in connection with this most interesting theory; and I state them, not with any idea that they are final and unanswerable, but because it is always serviceable to point out the apparent defects of the theory as well as its merits.

It will be seen that, whereas Helmholtz's theory starts with a hypothetical differential attraction of *matter for electricity*, and explains the chemical attraction of matter for matter on the strength of it, my view starts with a differential chemical attraction of *matter for matter* (*i.e.* zinc attracting oxygen more than copper attracts it), and on this basis works out the theory of the voltaic cell and of the Volta-effect.

In electrolysis proper both views may be at one, because here we are concerned with electrical attractions only; but Prof. Helmholtz's has the advantage, because it explains the fact of atomic charges, which mine has to assume. My view of electrolysis has hitherto been much less electrostatic than Prof. Helmholtz's, but also it has been much more vague. A great deal is to be said for the assumption of ordinary electrostatic attraction over molecular distances, and by adopting such more definite ideas I am in hopes of improving my theory further. And though, after all, none of these views can be really absolute, because they begin and end with action at a distance, still electrostatic attraction is a fact, and we know that it can be accounted for by a strain in a continuous medium. Hence phenomena reduced to electrostatics may be held to be provisionally "explained."

But beyond electrostatic attraction some other primary force is necessary; either *chemical affinity*, the attraction of atom for atom, or *electrical affinity*, so to speak, the attraction of atoms for electricity.

Chemical affinity is a fact, however, to be accounted for; but, to enable it to explain everything, the fact of atomic charge must be permitted to likewise go without explanation. These are the necessary data for my view.

"*Electrical affinity*" is not known to be a fact; but if it be granted, everything is explained (barring a few outstanding difficulties), even the fact of atomic charge itself, though not its numerical exactitude. This is the datum required for Helmholtz's theory.

It may thus be said that while the writer's view rests on two admitted facts which it does not attempt to explain, but, assuming them, explains other things from them; Helmholtz's theory rests on one unverified hypothesis, which, being granted, everything else follows; except indeed the numerical *equality* of atomic charges, which has to be regarded as experimentally demonstrated in both theories.

According to my view, the zinc of a cell pulls up the negatively charged oxygen atoms (or SO_4 radicals, whatever the real ions may be) to itself, not because they are electrified, but because they are oxygen. The electrical current produced is a secondary result caused by the chemical action.

According to Helmholtz, the zinc pulls the oxygen atoms because it is itself electrified by contact with copper, and because they are oppositely electrified by contact with hydrogen. The chemical action resulting is a secondary result caused by the electric forces.

Helmholtz's is thus a true "contact theory," and is in many respects like Sir W. Thomson's. Sir William postulates an attraction of zinc for copper, and from this explains the Volta-effect and the production of a current. I am unable to picture to myself exactly *how* the attraction of zinc for copper results in a difference of potential when they are put into contact; but undoubtedly such a force, if granted, would put a supply of energy at disposal which could account for the Volta-effect. And a difference of potential thus set up may result in an electrical decomposition of water and maintenance of current, just as in Helmholtz's theory.

I must confess that I am unable to feel quite comfortable about energy considerations with either of these theories of the voltaic cell; because it seems as if the metallic junction were, after all, driving the current, whatever be said about chemical energy. But in this I must certainly be

---

* It is easy to calculate the surface-density, and the difference of potential, on the above hypothesis, needed to tear asunder oppositely charged atoms attracting each other across molecular distance x. Let it be σ, and let the charge of an atom be q; then

$$2\pi\sigma q = \frac{q^2}{x^2}.$$

Moreover we know that 19,320 electromagnetic units can decompose 18 grammes of water, which allows $536+3+10^{10}$ electrostatic units of each kind of electricity per gramme; so if n^3 be the number of molecules in a gramme of water, the charge of each dyad atom is

$$q = \frac{1\cdot6\times10^{13}}{n^3}; \quad \text{or} \quad 1\cdot6\times10^{-11} \text{ probably.}$$

Hence,

$$\sigma = \frac{1\cdot6\times10^{13}}{2\pi n^3 x^2}; \quad \text{or} \quad 3\times10^{-12} \text{ probably;}$$

and, the difference of potential between either plate and liquid being given by $4\pi x\sigma$, the whole difference of potential between the electrodes is

$$V = 8\pi x\sigma = 6\cdot4\times\frac{10^{13}}{n^3 x}; \quad \text{or} \quad \cdot0064 \text{ electrostatic units probably,}$$

or 1·92 volt.

In reckoning the approximate numerical values above, I have assumed that $n=10^8$ and that $nx=1$. The resulting decomposition force comes out, quite accidentially as far as I am concerned, very near that needed to decompose acid-water. But I need hardly point out that *order of magnitude* is all that is really calculated in these figures; and that not only decimals but even numerals, prefixed to the power of 10, have very little meaning. The value of x may perhaps vary somewhat for different substances; and as to the value of n, though that is definite enough, it is very probable that it ought to be something more like 2×10^8 than what I have above assumed it.

It is at any rate satisfactory that the electrostatic hypothesis should give, as a polarisation E.M.F., a number so entirely comparable with actual results.

Digitized by Google

wrong; that is to say, there must be some thorough way of reconciling these, by such men advocated, views with energy considerations, though I am unable satisfactorily to perceive it.

Both these contact-theories, in explaining the Volta-effect, ignore the existence of the oxidizing medium surrounding the metals. My view explains the whole effect as a result of this oxygen bath, and of the chemical strain by it set up. The other theory, which likewise took account of the atmosphere is the old chemical one; but this leaves the aspect of the matter exceedingly vague. The strictures applied to it by Prof. Helmholtz (Faraday Lecture, 1881) are well deserved:—

"The so-called chemical theory of Volta's fundamental experiment was rather indefinite; it scarcely did more than tell us—here is the possibility of a chemical process, here electricity can be produced. But what kind, how much, to what potential, remained indefinite. I have not found in all the papers which have been written for the defence of the chemical theory a clear explanation why zinc opposed to copper in liquids, where zinc really is oxidized and dissolved, becomes negative, and why in air and other gases it becomes positive, if the same cause (viz. oxidation) is at work."

To the chemical *strain* theory, held by me, none of this remark is in the least applicable. This theory *does not say* that zinc opposed to copper in a liquid is negative. It says that, changing the surrounding medium from air to acid-water, makes scarcely any difference; and that accordingly connecting zinc and copper by a drop of water leaves them with the same respective potentials as they had before. The strain of oxygen-atoms towards a metal exists whether in air or water, but it can produce no effect in either case until at some point the oxygen be swept away by contact with another metal. Then instantly the chemical forces are able to do work, and to produce, if in air or other dielectric, the Volta-effect; if in acid or other electrolyte, the voltaic current. The metallic contact equalises the potential of the two metals in the one case; in the other it perpetually *fails* to equalise their potential. The equalisation of an otherwise disturbed potential is its only effect.

And no indefinitiveness exists as to either the kind or amount of the Volta-effect as so produced, for I have shown fully that *a* Volta-effect can be calculated in absolute measure for any pair of clean metals immersed in any medium, from purely thermo-chemical data; but whether this effect is the real one or not is at present a matter of opinion.

These so-calculated effects undoubtedly agree in some cases with experimentally observed ones; but whether they all so agree, and, if not, the extent to which they are erroneous, are matters mainly for future experiment to decide; and upon such agreement or disagreement between calculation and experiment my theory definitely stands or falls.

THE DISTRIBUTION OF ELECTRICITY.*

BY PROF. GEORGE FORBES.

LECTURE I.—INTRODUCTORY.

(Continued from page 416.)

I have now gone fully into the question of the most economical size of conductors. But it is one of prime importance in the whole of our problem; and, in conclusion, I will furnish you with a table which I find to be of great use.

The engineer can choose his facts for himself absolutely, can choose what he considers to be the right value of the electrical horse-power every year for the number of hours he proposes to run. He can also choose the cost of copper which he thinks it will suit him to lay. Having done that, he proceeds in this manner: I will take as an example copper costing £100 a ton; take 7½ as the rate of interest; I look along the column of Table II*b*. (p. 441) until I find £100, look down until I come to 7½, and find the figure ·316. I then look to the top of the Table II*a*. (p. 441), and I have £8 a year, say, for my electrical horse-power. I look along the column of £8 a year until I find the figure nearest to ·386, and I find that it comes to a place beneath the number 2·7; in that case 2·7 would be the square inches which are required for the main on those conditions imposed by the engineer himself. I have given another table (p. 441) for continual reference, showing the resistance of 100 yards and various other facts, also the current which will heat the wire.

Before leaving the subject of the cost, allow me once more to impress upon you that I consider this matter of primary importance, and no consideration must ever lead the engineer to deviate from the strict rules which regulate the cost. It may be in some special cases not always practicable to regulate our wires to carry the current exactly at this rate. It may be because it is easy to get a stock of conductors at slightly different size, or it may be inconvenient to be always varying the estimate in the size. But these principles must be gone into for every part of the scheme, and in our practical application we must stick as closely to our results arrived at there as we possibly can. It is no use for the engineer to say that financial people will not bring forward the money for these costly mains. The engineer, in my way of looking at it, has no right to look at what the financiers want to do. He must tell them honestly what is the most economical thing to do. If the financier wants to lay out capital in a particular direction, knowing that he will be causing a waste of energy, the engineer ought to have nothing to do with such matters. He ought honestly to give the value of the current which is most economical.

I have dealt now fully enough with the first cause that prevents us from diminishing the thickness of our conductors. The second cause why we should not reduce too much is the heating of the conductors. There are in this three injurious facts; in the first place, it spoils the insulation; the insulating power of the material diminishes by being heated, and the material itself becomes injured; moreover, when it is hot, it usually becomes soft, and the conductors can sink into it, and thus become decentralised. And in the second place, the conductors themselves are injured, because their resistance is increased by the increase of temperature, and these increases of temperature, mark you, are very considerable. And in the third place, the increase of temperature may be very serious, and may actually be objectionable along the streets. I have here a small piece of cable which shows the decentralising action of bituminous compound. This has been lying for six or eight months in a cool part of a cool room, always lying in the same position. I believe when I got it it was perfect, but in a cool place it gradually sunk, and now it is very decidedly out of centre. An old experiment which I used to show when I held my chair at Glasgow illustrates the viscosity of objects. It was first suggested to me, and I first saw it done, by Sir William Thomson in his laboratory. A block of hard brittle pitch—or shoemakers' wax would serve the same purpose—is set with a bullet on the top and corks underneath; in six months the bullet will have sunk into the pitch, and the corks will have risen several inches up through it. This simply shows you how such bituminous compounds must be carefully watched, and how very objectionable is any viscous material in the way of decentralising the conductor.

Now, as to the question of heating conductors, I will not take up much of your time this evening, because I have already, in a paper which I read at the Society of Telegraph Engineers last year, gone into the question very fully. It used to be supposed by some that if the currents in different wires were proportional to the section of the wire, the heating would be the same in all. This is not so, and when we look into the matter we could not expect it to be so. Heat is generated in a wire at a steady rate, and, if the temperature of the wire has reached a stationary condition, the same quantity of heat is carried off from the surface of the wire.

I showed by experiment, in 1882*, that to give the same heating in different wires (when these wires are small) the diameters of the wires should be nearly proportioned to the currents they have to carry.

I will show you by a simple experiment that if the currents should be proportional to the section, the thicker wire would get hottest. Here I have two wires of the same length; one is ten times the thickness of the other. I unite their ends in parallel and send a current through. The current splits up into two parts proportioned to the section of the wires. Both wires get hot, but the thick one hottest, as you see by its white incandescence, whilst the other is not luminous.

I only draw your attention to the question now because there is an important point which, I am glad to say, needs correction. A discovery has been made of an error near the end of the paper which might be misleading, and which probably has misled some. I will give you a corrected edition of it.

Here is the table to which I have referred. It gives you underground conductors. I have recommended sheets of copper for underground conductors, because the temperature is far less raised when you have a thin conductor.

Width in inches, of copper conductor, 1 cmr. thick.	Cross-section in square inches.	Current to raise surface temperature 10° C.
		amperes.
3·2	0·25	250
12·7	0·98	1,000
38·1	2·95	3,000
63·5	4·92	5,000
127·0	9·84	10,000
889·1	68·88	70,000

This is a most important point. We have absolute control over the temperature; by widening out our sheet we have diminished temperature, and can make the heat of conductors subservient to economy.

It is not essential that copper sheet should be used. The same mass of copper put into rods, or wires side by side, would produce the same effect if the average thickness of copper continues to be one centimetre, and these rods might be insulated in any way, or put in pipes. The depth at which these are laid does not affect the heat of the surface of the pavement so long as the depth does not exceed two feet, but the temperature of the conductor itself is greater at the greater depth.

It is satisfactory to find that the considerations of heating the insulation and heating the surface of the pavement, lead to the same result as that of economy—viz., that we should have 1½ square inch per 1,000 amperes of current.

I pointed out that if you do not bury your conductors more than about two feet the surface temperature is not affected; only the temperature of the conductor. If you go two feet deeper, you will affect the surface temperature also. I have thought that up to 10° C. is the limit endurable by foot-passengers. In the summer the rising temperature of the pavement is most objectionable. Fortunately this is the time when the current is least used. Moreover, the temperature does not immediately pass through the ground. The daily variations of surface temperature differ as the diurnal change of position of the sun. It does not penetrate very deep down—is very slightly perceptible at two feet depth. If we have 500 amperes flowing for 24 hours, the effect would be almost exactly the same as if 1,000 amperes were flowing for six hours. Another point—instead of laying a sheet one centimetre thick, you might lay cables with the same result, provided the average thickness was one centimetre.

* The Cantor Lecture of Professor George Forbes, delivered on February 2nd, 1885. From the *Journal of the Society of Arts.*

* British Association Report.

Digitized by Google

In speaking of the economical size of conductors, I arrived at the conclusion that I might use 2·7 inches, or say three inches for 1,000 amperes; but, mark you, though 1,000 amperes is the average current, it is not the maximum current to pass through that conductor. The maximum is a very different thing indeed to that. When we have an average of 1,000 amperes, it does not in the least mean that that is the average quantity of current which is flowing through it, because the wasted energy depends upon the square of the current. This leads to a very different law, and a very important one, about which I have a word or two to say. Suppose n_1 is the number of hours during which a quarter of the lamps are burning, n_2 one-half, n_3 three-quarters, and n_4 the number of hours during which all the lamps are burning, then the ratio of average current to maximum current is—

$$\sqrt{\frac{(\frac{1}{4})^2 n_1 + (\frac{1}{2})^2 n_2 + (\frac{3}{4})^2 n_3 + n_4}{n_1 + n_2 + n_3 + n_4}} = a.$$

The table in the next page gives a for different values of n_1, n_2, n_3, and n_4.

Thus the average quantity can be got from the maximum quantity by multiplying by the correct value of a. If half the lamps are burning two-thirds of the time, and the rest of the time all the lamps are burning, we get $a = ·5$. Therefore, instead of having 2·7, we only have 1·35 as the actual area for 1,000 amperes. As a matter of fact, I shall select for the rest of the lectures ·5 as the value for a, and hence 1·5 square inch to the maximum current of 1,000 amperes. It seems to me, for a working hypothesis—which no one need adopt—a good enough value.

The third reason why we cannot reduce the size of the conductors too much is that the potential falls, and the thinner the conductor the greater the fall of potential between the dynamo and the lamps. With a large current there is a great fall of potential (experiment shown), thus showing that in a central lighting station the fall of pressure, and, therefore, the brightening of the lamps in the district, depends upon the number of the lamps in use at the time. This is a serious thing, and the most difficult engineering problem with which we have to deal. We have

TABLE I.

Percentage allowed for interest and depreciation per annum.	5	7½	10	12½	15	20	25

arrived at the consideration that a square inch and a half for 1,000 amperes is the size we must use, which means a fall of potential of 1·6 volt for each conductor in every 100 yards—that is to say, a fall of nearly 3¼ volts, with the double conductor, for a distance of 100 yards; and whether you like it or not you must have it. It may be met by making distant consumers use lamps requiring a different pressure to those nearer. This is the thing which has given the most trouble, and the point will be considered in the next lectures.

RATIO OF $\frac{\text{AVERAGE}}{\text{MAXIMUM}}$ CURRENT.

0	1	0	1	0·790
1	2	2	1	0·744
1	1	1	1	0·685
2	2	1	1	0·604
0	2	0	1	0·500

I had hoped to have gone a little into a description of systems of laying mains which have been already adopted, but time is pressing too much. I will just say a few words about some of the systems I saw at the Philadelphia Exhibition last year. People seemed to have missed altogether the point that is to be aimed at in underground conductors. There was an invention shown, simply consisting of tiles with holes through them, the cables to go through the holes.

EDISON'S CONDUCTORS.

Outside in inches.	Area of one conductor in circular mills.	Maximum current in amperers.
3·5	1,639,880	1,400
3·0	862,976	760
2·25	262,951	370
1·31	107,289	220
1·05	33,000	100

These are laid in bituminous compounds in iron pipes, and seem to work pretty well for low potential work; but every electrical engineer thinks we shall be able to introduce high potentials some time or other, and reduce the cost of these mains.

What is it that makes it so difficult to insulate these mains properly? It is very difficult to say. It may be that there is a faint leak, and a spark passes to the iron pipe in which the conductors are encased, and that gives rise to an increasing leak. It may be that where there is the faintest leakage there is a partial decomposition of the water that comes into contact with it, and that brings electrolytic action into contact with the insulating material, which we know it generally destroys, and so the leak becomes worse, and very bad indeed. Through the kindness of the Brush Company, I have here a specimen of a fault in one of their underground City conductors showing where it is eaten into. In Philadelphia, there were some systems shown in which there was a very wide trough and glass plates introduced here and there, in which was a large number of holes. Glass is a very bad substance to use; it gets moisture upon it, and, besides, there is a tremendous wasting of space for small wire. In another, copper rods were carried through pipes made as water-tight as possible, supported on rings of glazed porcelain, so that there is a very small surface of leakage possible. With the rings here and there, of course, dampness was a serious obstacle; and in this system it was proposed to blow dry air through the pipes so as to keep the moisture continually out of them. I can only say of this that it is only a proposition; the thing has never been done.

I had hoped to speak to you of what has been done in underground conductors, but really there is very little to tell you, and that can be said in very few words. In Philadelphia, there was a system of underground conductors put down by the Excelsior Company, and they worked pretty well. They used large troughs, and where there are large troughs there is no difficulty about it. But these large troughs had very serious inconveniences that one hardly expected from electricity. Three times during the time I was at Philadelphia the troughs in Chesnut-terrace blew up, a most unexpected result from an electric conductor; but it was a positive fact, and the secret was they were too near the gas mains, which leaked and positively filled the troughs, and, consequently, they blew up when a light came near them. However, these were accidents that might have been prevented with care.

I have an illustration here of the installation at Colchester,* which illustrates the way in which very large troughs are laid with conductors cut along them.

The Jablochkoff Company, on the Thames Embankment has had a lengthened experience, extending since 1878, and with a small 7-16 strand wire, covered with gutta percha and tape, and put in troughs underground, where it has given very little trouble. Then, again, in the City, the Brush Company has had these conductors underground since April, 1880, and they have had a great deal of trouble. They tell me that they were put in first very loosely, and covered with sand for some reason or other, and in drawing the cables through the pipes, the sand wore them away, and the consequence was the insulation went.

Among the most successful underground cables which I have seen are those used by the India Rubber Company, at Silvertown. The cables are numerous, and all made of copper coated with india rubber, with a protecting cover of cold-drawn lead. These are laid in troughs underground, with frequent manholes to assist in the insertion of new cables. Parts of these troughs are always full of water; other parts are always dry; elsewhere there are variations of wetness and dryness. An electromotive force up to 550 volts has been constantly used on most of these cables for several years, and although the insulation has varied with the weather, it has not in a single case been permanently injured, and I am informed that no repairs to the underground cables have been in any case necessary, nor have the manholes been opened except to lay down new cables.

With respect to the printed tables included in this paper, the following rules apply to the second one.

RULES FOR FINDING FROM ANY GIVEN DATA THE SIZE OF THE MAINS REQUIRED.

Data required: Annual cost of electrical horse-power and percentage for interest and depreciation per annum, and cost of laying one additional ton of copper, the approximate size having been assumed.

Rule 1.—In Table II*b*. look down the column of cost for additional ton until you reach the given percentage allowed. Take out the number there indicated.

Rule 2.—In Table II*a*. look along the line with the given cost of horse-power until this number is found. The number at the head of that column is the section per 1,000 amperes in inches.

Rule 3.—If this section be largely at variance with the approximate one selected, use now this value for a second calculation.

* For complete illustrations of this installation we would refer our readers to *The Electrician* for June 21 1884.

NOTES.

PERSONAL.—Major Bagnold, of the Royal Engineers, has assumed charge of the British military telephone system in Cairo.

H.M.S. "IMPERIEUSE."—It is proposed to equip this vessel with three engines for driving the Siemens' dynamos to be used in the lighting of the ship.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 16th inst. amounted to £3,424.

OVERHEAD WIRES IN AMERICA.—There is a telegraph pole in Fulton-street, New York, upon which 300 telegraph wires, going in all directions, are said to be strung.

THE ATLANTIC CABLES.—According to the latest intelligence the steamer "Faraday" has picked up one end of the broken Mackay-Bennett cable. It is likely to be restored in a few days.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th October are £1,963, as compared with £1,718 in the corresponding period of 1884.

THE ELECTRIC LIGHT ON RAILWAYS.—The Lancashire and Yorkshire Railway are still experimenting with the electric light for the lighting of their carriages, but will not be able to come to any conclusion on the matter in time for the coming winter.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 16th October, were £2,690, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

APPOINTMENT.—Mr. Henry Stott for three years an electrical engineering student at the Glasgow College of Science and Art has been appointed assistant electrician on board the Anglo-American Telegraph Company's repairing steamer "Minia," now stationed at Halifax.

EARTHQUAKE AT PALERMO.—A telegram from Palermo announces that a shock of earthquake occurred there on the morning of the 15th inst. A house, three stories high, in the Via Santa Rosalia, fell in, and a number of persons were buried in the *débris*. Eight bodies have been recovered.

THE TELEPHONE IN BRESCIA.—The Kinetic Engineering Company inform us that the telephone company of Brescia are now placing the whole of their system of telephone wires underground by means of the Berthoud-Borel cable, and have taken delivery of 106 miles of conductors for that purpose.

"HAYDN'S DICTIONARY OF DATES."—We have received from Messrs. Ward, Lock, and Co. a specimen sheet of this high-class popular record. It is the latest edition, brought down to the summer of the present year, and may with truth be said to be the most universal book of reference of its kind.

THE JOHN PENDER GOLD MEDAL.—This medal has been gained by H. Osbourne Bennie Whitworth, scholar and Royal Exhibitioner. Mr. Pender again offers a similar medal to be competed for by students taking the diploma this session in electrical engineering at the Glasgow College of Science and Arts.

AN AMERICAN CONTRACT OPEN.—Tenders will be received until November 5th by the War Department, Washington, D.C., for furnishing 1,050 galvanised iron telegraph poles (with foot-supports and cross-arms) complete, 2,100 wooden insulator plugs, and 70 miles No. 9 galvanised iron telegraph wire.

L'EXPOSITION DU TRAVAIL, PARIS.—The jury of the electrical section of this Exhibition commenced its labours on the 10th inst. It is composed of MM. Bourdin, of *La Lumière Electrique*, president; Hospitalier, of *l'Electricien*, reporting secretary; Armengaud, Boivin, Gariant, and Mildé, members.

AERIAL NAVIGATION.—In view of the successful experiments in aerial navigation by means of electricity carried out by Captains Krebs and Renard at the Chalais-Meudon Park, the French Minister for War has decided to ask for a special credit for the purpose of continuing the experiments on a larger scale.

OMINOUS.—The Western Union Telegraph Company are said to be importing a number of low salaried operators from the Canadian provinces for service in Eastern offices, and it is supposed by some that this is a note of preparation for the rate competition with rival lines which for some time has been on the *tapis*.

NOTICE OF INTERRUPTION.—The Direct Spanish Telegraph Company, in notifying the interruption of both of their Falmouth-Bilbao cables, inform us that arrangements have been made by which telegrams for Bilbao, Madrid, and other places in Spain can, during the interruption, be promptly forwarded by the Eastern Telegraph Company's route.

BUSINESS NOTICE.—We hear that Messrs. Walter T. Glover and Co., of Manchester, the electrical wire and cable makers, contemplate placing their business on the limited liability company basis, but that only a small amount of additional capital will be available for the personal or business friends of the firm, the concern becoming what is generally termed a private "limited."

THE EDINBURGH EXHIBITION.—Particulars will be found in our advertisement columns of the International Exhibition of Industry, Science, and Art, to be opened in Edinburgh next year. This Exhibition will be open to the products, manufactures, &c., of all countries, and should, if its list of patrons be taken as a criterion, be one of the most perfect things of its kind we have seen.

A PROGRESSIVE PEOPLE.—While at Bergen Mr. Gladstone is said to have been particularly struck by the fact that in a town with a population not exceeding 50,000, there are not fewer than 500 subscribers to the telephone, and that between three and four thousand townspeople have already subscribed to a project for substituting electric lighting for gas in private houses and in the streets.

CHEAP TELEGRAMS AND REGISTERED ADDRESSES.—A correspondent writes as follows to *The Times*:—"In order to facilitate the transmission of telegrams, I would suggest that the authorities should issue periodically a complete alphapetical list of registered names and addresses, giving the corresponding 'indicators.' This would greatly add to the usefulness of the new system."

AN IMPORTANT SALE.—The important sale of the plant belonging to the Hammond Company, now being conducted by Messrs. Wheatley Kirk, Price, and Goulty, is deserving of notice. Full particulars of the auction will be found in our advertisement columns, and we strongly recommend those of our readers whose tastes or business considerations warrant them in doing so to pay the sale a visit.

THE ELECTRIC LIGHT IN CANADA.—The promenade known as the Dufferin-terrace, Quebec, has recently been lighted with electric lights. The power for generating the electricity is supplied by the Falls of Montmorency (some nine miles distant), which give a strength equal to about 1,600 horse-power. The experiments have been satisfactory and successful, and the question of lighting the entire city in a similar manner is now under consideration.

THE FREEMAN INCANDESCENT LAMP.—The incandescent lamp recently invented by Mr. W. P. Freeman, of New York, possesses some novel features. The carbon is a straight thread, which is supported by a thin glass rod bent at the top. This allows the length of the carbons to be regulated so as to be of uniform resistance, and the distribution of light in the plane perpendicular to the lamp is equal in all directions. The cost of the lamp is also claimed to be considerably decreased by this method of construction.

ELECTRIC MACHINERY IN AMERICA.—The applications of electricity to trade purposes are continually increasing in America. Amongst others, the Wiswell Electric Machinery Company has erected a number of pulverising mills at different mines in that country. The work done has been quite satisfactory, and in a number of instances additional mills have been ordered. A number of certificates of the work done have been published by the company, and are of interest to proposing purchasers. This looks rosy enough.

THE EDISON LIGHT IN BELGIUM.—We are informed that the Compagnie Edison de Paris are about to concede to the Société Anonyme du Phœnix, at Ghent, an exclusive right to the exploitation in Belgium of the Edison system for the generation and maintenance of the incandescent light, and the transmission of power. The Société Phœnix have already installed 1,200 lamps in the important manufactory of M. Ferd. Lousbergs, at Ghent, an experiment which, as gas is very cheap in that place, is being watched with great interest.

PUZZLED.—The American papers revel in stories about the English operator. Here is the latest:—"Won't you please rush that," said an American, as he handed a despatch to a telegraph operator in a little town near London. The operator looked up with a blank expression. "Won't you rush that despatch, please?" repeated the gentleman. The look of amazement on the operator's face deepened. "Won't you send that just as quickly as you can?" the American explained. "Oh, yes," exclaimed the relieved operator; "just as soon as you get the stamp on."

ANOTHER CELL.—Prof. Dolbear has discovered that if zinc be immersed in a saturated solution of ammonium chloride in a porous cup, and carbon in a saturated solution of bichromate of potash, mixed with sulphuric acid, the E.M.F. of the combination is 1·1 volt. The internal resistance of such a cell, with a simple zinc rod such as that used in the Leclanché, and the carbon plate 6in. by 2in., is less than 0·5ω. Its constancy is said to be such that if kept on short circuit (through 4ω or 5ω) it does not fall in strength to any appreciable degree. If the bichromate solution be mixed with strong nitric instead of sulphuric acid the E.M.F. rises to 2·3 volts.

HOW IT CAME ABOUT.—According to a letter written to an American contemporary, when Professor Morse was engaged in the slow and tedious process of laying his first telegraph wire underground between Washington and Baltimore, a sudden shower compelled him to seek shelter under a bridge. While waiting there, he remarked to his son Charles, that "when it was first proposed to use glass window panes in England, it was strongly objected to as impracticable on account of the risk of their being smashed. Glass was used," continued the professor, "and from here on I mean to string my wire on poles and take the risk." And henceforth poles were used.

THE ELECTRIC LIGHT IN THE TEMPLE.—The arrangements for illuminating the Inner Temple Library with the electric light are now completed. The testing experiments will shortly be made, and it is anticipated that all will be in readiness for lighting the library by electricity tomorrow, when the regular opening of the library for the Michelmas sittings will be resumed. A new engine house has been erected adjacent to the Inner Temple Lecture Hall, in King's Bench-walk, and a 12 horse-power engine for generating the electric light has been placed therein. The Swan-Edison system is the one adopted, and about 130 small lamps will be employed for illuminating the library.

THE ELECTRIC LIGHT AND THE CHELSEA VESTRY BOARD.—At a recent meeting of this Board the Electric Lighting Committee reported, recommending that the clerk be authorised to reply to the Chelsea Electricity Supply Company that the vestry will view with approbation any proposal to light the district with electricity, and that, provided the terms of the provisional order be satisfactory, the vestry will support it. Also that the South Kensington District and Electricity Lighting Company be informed that as soon as the applicants have obtained the necessary statutory authority to supply the electric light in this parish the vestry will be prepared to entertain the proposal. This was adopted.

THE CITY AND GUILDS OF LONDON INSTITUTE.—At a meeting of the executive committee of this institute, held on Monday, the following letter from the Prince of Wales was read:—"Sir: Believing that the Right Hon. Sir R. N. Fowler, Bart, M.P., Lord Mayor, is able and willing to render efficient service to the City and Guilds of London Institute for the advancement of technical education, I have great pleasure in the exercise of the powers conferred upon the president by the articles of association in nominating him for a period of five years vice-president of the institute.—I am, sir, yours faithfully, ALBERT EDWARD. Philip Magnus, Esq., Director and Secretary of the City and Guilds of London Institute."

A FAILURE PREDICTED.—So far everything has worked well with the installation in the Theatre Royal at Bucharest. On the 10th instant the theatrical season commenced, and according to the terms of their contract with the Société du Gaz de Bucharest, the company whom M. Jehl represents, were to operate the plant to the end of the third representation and then to hand it over to the gas company. This has been done, and the gas people are now responsible for its working, the Société Electrique Edison de Paris having nothing more to do with it. This latter fact seems to require mention in that a new gas director at Bucharest, who has the control of affairs in his own hands, is said to be strongly prejudiced against and inimical to the electric light, and it is felt in well-informed circles that a breakdown is somthing more than probable. It may be added that the gas company have their own electrician in charge of the installation.

ELECTRIC LIGHT FOR WAR SHIPS.—Messrs. Goolden and Trotter have received orders to supply the machinery and fittings for the two latest additions to the navy, viz., the "Mersey" and the sister ship "Severn." The dynamos will be of the sizes known as 40 and 20 units, there being one of

Digitized by Google

each of these in each ship. The Admiralty rules require very low speeds for driving electric machinery, which necessitates very large and heavy machines. Each pair of dynamos will weigh about 3½ tons, and running at their ordinary speed, would light 2,400 electric lamps of 10 candle-power each. Messrs. Goolden and Trotter have been engaged for some weeks in fitting the well-known ironclad "Devastation" with the electric light. This ship presents great difficulties on account of its unusual shape. It is fitted with incandescent lamps with mountings, which have also been made by the same firm, together with two powerful search lights.

SUGAR MADE BY ELECTRICITY.—The synthesis of saccharose having been accomplished by Messrs. Aubert and Giraud, it is anticipated, says a contemporary, that the discovery may prove most important to the sugar industry. Amylaceous matter obtained from the potato, having been converted into glucose in the usual manner, is submitted to the action of an electric current equal to about seventy-five volts. The electrodes were immersed in the solution, and the current reversed from time to time. In about two hours the reaction terminated, as indicated by the liquid no longer giving the characteristic colour with tincture of iodine or a precipitate with alcohol. The liquid was then defecated with lime, which was subsequently removed by carbonic anhydride, and the syrup was decolourised and crystallised. On analysis it yielded 88·38 per cent. of saccharose, but was far from being cane sugar. It is questionable whether the reaction consists in the dehydration of glucose, the union of a molecule of dextrine with one of glucose, or the hydration of dextrine.

THE MAGNETIC UMBRELLA.—With reference to the umbrella of a passenger which recently affected the compass of the steamer "Princess Beatrice," when crossing between Belfast and Stranraer, the captain of the vessel has received a letter from Mr. Bottomley, assistant at Glasgow University to Sir William Thomson, stating that Sir William has examined the umbrella and found it powerfully magnetised. Sir William Thomson thinks it probable that the steel ribs of the umbrella have been magnetised through being brought near to a powerful dynamo when at work. The umbrella was so powerfully magnetised that it would produce a very considerable effect on the compass if brought near it. Sir William desires to add that, in these days, when electric lighting is becoming so common, and when anyone, without knowing it, may get the steel ribs of his umbrella magnetised by going near to dynamo machines, he thinks it of great importance that steps should be taken to prevent passengers on vessels with umbrellas going near the compass in use. Mr. Bottomley also states that he has known the rim of his hat to slightly disturb the compass of a vessel.

TELEPHONING FROM LIGHTSHIPS.—The following letter has been written to *The Times*:—"The Elder Brethren of the Trinity House, observing the notice in *The Times* respecting the progress made in establishing electric communication between the Sunk Lght Vessel and the shore, will be glad if you will enable them to prevent possible misapprehension on the part of the shipping community by stating the following particulars:—The Telegraph Construction Company have undertaken for a certain sum to maintain the communication for twelve months as an experiment. They have met with many difficulties, occasioning interruptions, sometimes of a few hours, at other times a day or two. Communication ceased on the 2nd inst., and has not yet been restored; but the company are still hopeful of complete success. But this corporation have not undertaken, nor authorised the company to undertake, to signal passing ships to Lloyd's or to convey orders to them. The experiment is being made with the consent of the Board of Trade, under conditions which involve, perhaps, considerable expense to the Mercantile Marine Fund, and no individual or association has the privilege of receiving intelligence or giving instructions by this means at the expense of that fund."

SOUTH STAFFORDSHIRE MILL AND FORGE MANAGERS' ASSOCIATION.—A monthly meeting of this institute was held recently in the Geological Museum, Dudley, Mr. R. S. Casson presiding. Mr. Arthur Edgar Cotterell (Birmingham) read a paper on "The Development of Telephony." The reader traced the earliest efforts of inventors in the direction of telephony to the systems of the present day. He paid special attention to Prof. Bell's efforts, and said it was due to him that the telephone had become a permanent industry, and one calculated to change many of the social aspects of the countries in which telephony was adopted. The instrument was clearly described, and then the reader went on to the inventions of Edison, who, by the introduction of an improved microphone, enabled one person to speak to another fifty miles away with no more exertion than was needed for fifty yards. The loud-speaking telephone, used for exhibition but not for business, was also described. Mr. Cotterell then described and worked a Bell-and-Blake combination machine, and said he believed the National Telephone Company was about to start a branch in the town. The reader finally discussed the progress made by the company in the past six years, and the work of a telephonic exchange. A hearty vote of thanks to Mr. Cotterell concluded the proceedings.

INFLUENCE OF STORMS ON SUBTERRANEAN TELEGRAPH LINES.—When the construction of the long subterranean lines in France was commenced some years ago, it was thought that their conductors would be quite free from the effect of storms. Accidents are much rarer than with aërial lines, but that they do occur was evidenced by the violent storm on the 9th March at the middle of the underground line connecting Belfort with Besançon, when sparks appeared at the two extreme stations. This phenomenon, apparently contrary to the theory of static electricity, M. Blavier thinks may be explained either as an effect of electro dynamic induction or as an effect of electrostatic induction. If the cable is buried only to a small depth in a badly-conducting earth, the sheathing takes, under the influence of storm clouds whilst the internal wire remains neutral, a more or less considerable electric charge. At the discharge of the clouds this charge becomes free, and escapes into the earth, following the sheathing in two opposite directions. This will develop in the interior conductor two induced currents of contrary directions, the difference of which will act on the apparatus at the end stations. Or the conductor may charge itself from the earth-plates and lightning-guards under the influence of this sheathing charge.—*Abstracts, Proc. Institution of Civil Engineers.*

DETERMINATION OF DEATH BY MEANS OF ELECTRICITY.—This idea, far from being new, is one of those that were early suggested in the minds of physicians in the application of the electric current for the cure of disease. It would naturally be supposed that the current might serve to indicate the presence of death by some specific difference in the nature or intensity of the muscular contractions. But experiment demonstrated that generally the muscular contraction under the stimulus of electricity was, for three or four hours after death, exactly the same as in life. For this reason electricity was abandoned as a method of proving death. But the question has again been brought forward by some recent experiment by Dr. Buch. This observer has shown (1) that the temperature is

Digitized by Google

sensibly increased during life at the surface of the muscle exposed to the action of the electric current; (2) that this increase of temperature is never produced upon the dead body, even immediately after death, and while the muscular contractibility is still perfect. This should afford an absolutely sure proof of death. Dr. Buch, in his experiments, makes use of an ordinary mercurial thermometer, simply applied to the surface of the skin. He waits until this thermometer shows the temperature of the surrounding medium, and then submits the subjacent muscle to the current of induction. The temperature of the skin increases several degrees under the influence of an energetic contraction. This phenomenon is constant during life, even in cases of complete paralysis of the part. On the other hand, in the dead body, whatever may be the force of the current and the violence of the contraction, the mercury remains stationary in the tube.—*Electrical World.*

Railway Carriage Lighting.—The following letter from "Another Railway Traveller" appeared in *The Times* of the 10th instant, in reply to one written asking for more light in the carriages and adversely criticising the action of the company in giving such a good light at the Paddington station:—"I trust you will allow me to make some remarks in reply to certain injurious observations in a letter under the above heading, which appeared in *The Times* of Friday, regarding the great electric lighting undertaken by the Telegraph Construction and Maintenance Company at Paddington. This is the greatest experiment which has yet been tried in England, and I believe also there is no equally large installation from a single centre even in the American towns, which are so far ahead of us in electric lighting. Your correspondent, as a constant traveller, should know enough of the Great Western management to feel sure that they were only accepting it on proof that it would show a reduction in the very heavy cost of the present gas lighting there, and he is certainly not justified in imputing that the directors are allowing it as an advertisement for the benefit of the Telegraph Construction Company, which is, I hope, too well known and stands too high to require any such advertisement. The company is the only company which have retained their license for lighting up part of London under the provisions of Mr. Chamberlain's Bill. As that quarter of London which is included in their order contains all the chief London clubs, there are few of us who will not benefit by the great success of the experiment. I think, therefore, the severe remarks of your correspondent were hardly justified. Your correspondent is equally in error in stating that the electric lighting of the carriages is out of the question on account of the great expense. It is found to be such an economy that before the end of the year it will, I learn, be largely adopted, to, I hope, our great additional comfort."

The Telegraphists' School of Science.—The tenth annual session of this school, for the operators at the Central Telegraph Office, St. Martin's-le-Grand, commenced recently. Mr. W. Slingo is lecturer, and the school is in connection with the Science and Art Department, South Kensington, and the City and Guilds of London Technical Institute. The accompanying list of prizes and certificates awarded to last session's students will give some idea of the range of study offered to the rising telegraphists. Results of science and art examinations: Mathematics — Certificates: 1st class, Messrs. Brooker and Honeysett; 2nd class, Mr. F. W. Butler; advanced, Mr. Mansbridge. Chemistry—Certificates: 1st class, Messrs. H. S. Beach and Honeysett; 2nd class, Messrs. Bennett, W. G. Franks, Honnor, Pace, Philpott, Senhenn, and Winn. Magnetism and Electricity—Certificates: 1st class, Messrs. Beach, Bell, Connell, Cooper, Honnor, Knight, Mason, and Waller; 2nd class, Messrs. G. Barnett, Miles, Neasmith, Offord, and Twyford. Magnetism and Electricity (advanced stage)—Certificates: 1st class, and Queen's prizes, Messrs. F. W. Butler and Mansbridge; 2nd class, Messrs. Bennett, Crabtree, W. G. Franks, Honeysett, McSweeney, Pace, Philpott, and Strank. Results of City and Guilds Institute Examination:—Telegraphy—Bronze medal, £5 prize, and 1st class honours certificate, Mr. Mansbridge; bronze medal, £3 prize, and 1st class certificate, Mr. Brooker; 1st class certificate, Mr. F. W. Butler; 2nd class certificates, Messrs. G. T. Bennett, Philpott, and Winn; honours certificates, Messrs. W. H. Butler, Beach, Hendri, and Connell. The above were supplemented with what are known as the local prizes, twenty-six in number, the first aggregate, or controller's prize, going to Mr. Mansbridge; the second, or sub-controller's to Mr. F. W. Butler; the third, or committee's prize, to Mr. H. S. Beach; the fourth, or engineering superintendent's prize, to Mr. Brooker.

Cornell University.—For the last two years the greater part of the additions to the physical apparatus at the Cornell University for the study of electrical science and electrical engineering have been instruments for study and investigation in electrical science or its applications. An instrument has been constructed during the last year, for the absolute measurement of electric currents of all values from a milliampere to 250 amperes. It is believed to be larger, and to have a wider range than any other standard instrument in existence. It has been constructed with the utmost care, and is capable of giving results of the highest precision. The building in which it is placed contains also several other instruments for the measurement of currents, potentials, magnetic intensity, &c., and the physical laboratory with which it is connected contains five dynamos from which currents may be obtained up to 50 amperes at 100 volts, or up to 20 amperes at 1,000 volts. A resistance of about seven miles of No. 16 German silver wire in about 100 sections, capable of combinations to give resistances from less than half an ohm to 2,200 ohms serves for controlling dynamo currents. A steam engine of about 30 horse-power, having a governor of the most perfect type, will soon be in place for driving dynamos. Dynamometers, &c., are provided for measuring power, and, in fact, all the instruments are at hand that can be required for the measurement of any quantity connected with the use of electric currents for electric lighting. With the arrangements provided, currents of great uniformity and of any strength desired are available for purposes of experiment and investigation. These instruments are not only seen, but are in constant use by students, who, when they are sufficiently advanced, are encouraged to undertake some investigation of scientific or practical value. It is the aim of the course in electrical engineering as here taught to give to the student a thorough mathematical training and a full knowledge of the theory of electricity as a basis of the practical work that is to follow. Drawing and the theory and construction of machines and motors are taught as essential to the success of any electrical engineer. The course requires four years for its completion, and is very comprehensive.

The Telephone in Carlisle.—The National Telephone Company recently inaugurated the practical working of the wires which they have erected in this city and district. The mayor, several members of the corporation, the corporation officials, and a number of other gentlemen interested in the undertaking, attended at the central office of the company in Devonshire-street. The wires between Carlisle and Dalston were then joined up, and commenced to work.—The Mayor

Digitized by Google

then declared the Telephone Exchange open, and in a few complimentary remarks wished the undertaking success.—Mr. A. R. Bennett, general manager, gave some explanations as to what the company were doing and intended to do in Carlisle and the neighbourhood. The subscribers already numbered 26. The corporation had 10 connections between their various departments. The company had opened three call offices, which were places where subscribers who happened to be passing could go into and use the telephone for the purpose of speaking to any other subscriber. One of these was at the chief bookstall at the railway station. The benefits of the call offices were not confined to subscribers. Any member of the public having occasion to communicate with a subscriber would be allowed to do so by going to a call office and paying threepence for each three minutes' conversation in telephone stamps, which were on sale at all the call offices. He called attention to the great facilities offered by the Exchange for conveying alarms of fire. Some towns had gone so far as to connect the police office with the house of each individual fireman, and to place loud-sounding bells over each man's bed. Something of the same kind would, no doubt, be ultimately adopted in Carlisle, but in the meantime the new connections for the fire and escape stations were far in advance of the old system. The company had opened during the present year exchanges in Maryport, Workington, Whitehaven, Cleator Moor, and Frizington, and joined all these towns together, and as support was forthcoming they would work north from Maryport and south from Carlisle until the two systems were connected. In Yorkshire the company had connected Bradford, Leeds, Sheffield, and many other towns together; in Scotland their system was continuous from Greenock to Edinburgh, a distance of seventy miles; and from Perth to Dundee, Forfar, and Arbroath. Everywhere the lines were extending, and the day was close at hand when the different sections, at present isolated, would meet, and the telephonic system would be co-extensive with that of the telegraph.

THE LIGHTING OF THE CITY.—In an interesting article upon the electric light the *City Press* says :—" There are some mysteries in the proceedings of the Commissioners of Sewers that seem quite incomprehensible. The handsome Holborn Viaduct was lighted with electricity for some time, with great satisfaction to everybody; it was suddenly changed back to the old dismal gas, nobody knows why. Many of the shops on each side of the way are still lighted with electricity, so the only possible reason for the change in regard to the public lamps must be the question of expense. This is, of course, a matter of importance, but it all depends on the question of degree. We were informed last week, on such authority as we cannot doubt, that this same Holborn Viaduct could be relighted with electricity, giving double the present amount of light, at an extra expense of some £400 per annum. Surely this amount cannot be considered prohibitory. We have heard the calculation made that the whole City might be lighted with electricity, producing double the amount of light now, not enjoyed, but endured, at an additional expense of less than one halfpenny in the pound in the consolidated rate. When we remember that the cost of the new street at Billingsgate, which can only possibly be of advantage to the immediate neighbourhood, if really of advantage there, represents, we are told, an addition to the rates of not less than twopence in the pound for at least twenty years, or four times the price estimated for doubling the present lighting of the City, we can but wonder at the ignorance displayed by some public men in the science of proportion. The great mistake seems to be in waiting for some plan to be discovered that will enable the Commissioners to simultaneously light the whole City without the possibility of any temporary failure. But this is really something like putting off any advantage from this wonderful discovery for an absolutely indefinite period. What is wanted is a series of experiments on a sufficiently large scale to be a fair test of efficiency; and if this be done under the able superintendence of any of those men who have made electricity their study, and have demonstrated what brilliant results can be obtained from its use, we have but little doubt that in a very short time such an improvement will be witnessed in our street lighting as will not only gratify all who have to use our streets after dark, but will also afford to our excellent police that increased facility in carrying out their arduous and important duties that we are told, and thoroughly believe, can be obtained by no other means."

CONTINENTAL NOTES.—The development of the electric lighting industry in France has been, in comparison with other Continental countries, but slow and uncertain. In Germany, on the other hand, such rapid strides have been made that it has been found necessary to formulate statistics for the information of the people. In Berlin at present there are in all 41 arc and 31 incandescent lamp installations, of which 25 are actuated by gas and 46 by steam engines. The number of lamps is not indicated, but it is believed not to exceed 5,000. Two central stations, each capable of alimenting 7,500 incandescents, are, however, in course of construction. At Munich there are 34 installations, comprising 140 arc and 4,045 incandescent lamps. The principal theatres and the Central Railway Station are the establishments which up to now have adopted the new illuminant. Hamburg has not more than 25 installations, with a total of about 80 arcs and 1,400 incandescents. Five of these installations, with 25 arcs and 200 incandescents, are worked by gas engines, whilst the more important or larger ones employ steam power. At Hanover the station entrance is lighted by 12 arc lamps, the Jardin des Palmièrs by 8 arc lamps, and 10 others of the same kind are installed in two of the streets. Hanover does not as yet possess a single incandescent lamp. Bremen possesses but two arc installations, *i.e.*, at the public baths and the Bureau de la Caisse d'epargne. In the first of these the dynamo is driven by steam, and in the second by gas power. At Cologne there are 8 arcs and about 400 incandescents. At Leipsig three cafés dansant, three manufactories, and one electric store are lighted by electricity. Dresden has 14 installations, comprising together 62 arcs and 446 incandescents. Of these ten are in manufactories possessing steam power, and four are driven by gas engines. At Breslau the electric light has not made much progress. A few restaurants and shops only are so lit. Amongst the industrial villages, however, the new illuminant has found more extensive application, principally, of course, in the manufactories. Chemnitz has seventeen installations distributed among various establishments, and including 117 arc and 470 incandescent lamps, actuated in the majority of cases by existing steam plant. Crefeld has 69 arcs and 1,203 incandescents, about half of them being driven from steam and the other half from gas engines. At Barmen there are fourteen installations, having 81 arcs and 630 incandescents in the different factories. Elberfeld possesses seven installations, with nine arcs and 126 incandescents. Gladbach has 15 arcs and 230 incandescents, driven as in former instances by the steam engines used in the establishments for business purposes. In other towns in Germany there are isolated installations. Dr. Schilling estimates the actual number of installations in German towns at about 400, comprising approximately 1,500 arc and not less than 20,000 incandescent lamps.

THE DETERMINATION OF CURRENTS AND RESISTANCE IN A NETWORK OF CONDUCTORS.

In the larger "Treatise on Electricity and Magnetism," by Professor Clerk Maxwell, we find given a solution of the general problem of determining the distribution of currents in any system of conductors, containing any sources of electromotive force, whatever may be the form of the network. Maxwell does not, however, give any *general* method whereby we may determine the *resistance* between any two points upon such a network, when the resistance of each separate branch is known. This latter problem has recently been investigated by Dr. Fleming, and in a paper read before the Physical Society he has shown that by means of a development of Maxwell's method we may calculate, not merely the final distribution of current and the steady resistance between any two points of a network, but we may also take account of the time variation when there is self or mutual induction between the two branches, or when the current arises from a condenser discharge. It will thus be seen that Dr. Fleming's paper is one of very considerable interest and value, and it will well repay careful study.

We propose at this time to give the substance of that portion of the paper relating to the determination of currents and resistances, which is of the more immediate and general importance. We shall confine ourselves principally to a statement of the results which are arrived at, leaving those who wish for the demonstration of the methods to consult the original paper.

We will take first Professor Clerk Maxwell's solution of the problem of determining the distribution of current in a network of conductors. The process employed will, perhaps, be most easily explained if we work out a case in illustration.

Let Fig. 1 represent a network of conductors (the form being of course indifferent); let the resistances of the separate conductors A, B, C, D, E, F, G be known; let there be sources of electromotive force e_1 and e_2 acting in the branches B and G respectively, and let these E.M.F.'s be directed as indicated in the figure. It is required to determine the distribution and direction of the currents throughout the system.

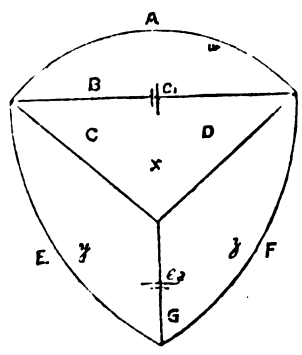

FIG. 1.

First, suppose that around each mesh or cell of the network an imaginary current circulates, always in the positive direction; that is, in the direction opposite to that of the hands of a watch. Let w, x, y, z denote these imaginary currents. Then it is easy to see that any conductor which forms a boundary between any two adjacent meshes is necessarily traversed in *opposite* directions by the imaginary currents belonging to the meshes upon either side of it. Then the *real* currents in the conductors will be found by taking the differences of the imaginary currents which we attribute to the meshes which they bound. For instance, in Fig. 1, going around the boundaries of mesh x we shall have the following values for the actual currents:—The current in branch B will be denoted by $(w-x)$, that in branch C by $(y-x)$, and that in branch D by $(y-x)$. The x, y, z, &c., are called the cyclic symbols of the areas in which they are placed; the cyclic symbol of external space being taken as zero. Now, as the real currents must all be of positive sign, it will be seen that when we know the values of the cyclic symbols we can immediately state the *direction* of the current in any branch.

To obtain these values we have now to form an equation for each cycle or mesh. For the case represented in Fig. 1 we shall have the following set of equations, beginning with the mesh at the top:—

$$\begin{aligned} e_1 &= w\overline{A+B} - xB - yO - zO \\ -e_1 &= x\overline{B+C+D} - yC - zD - wB \\ e_2 &= y\overline{C+E+G} - zG - wO - xC \\ -e_2 &= z\overline{D+F+G} - wO - xD - yG \end{aligned}$$

These equations may each be formed according to the following rule:—Write as the coefficient of the cyclic symbol the sum of all the resistances which bound that cycle, and subtract the cyclic symbol of each adjacent cycle, multiplied respectively by the common bounding resistance as coefficient, and equate this to the effective electromotive force acting in the cycle, written as positive or negative according as it acts with or against the imaginary current in the cycle. If there is no electromotive force acting in any conductor bounding the cycle, the expression is equated to zero. For a reason which will presently appear, the cyclic symbols of non-adjacent meshes are written down in order with zero coefficients.

In this way we can form as many independent equations as there are cyles, and by the solution of these we may determine each of the independent variables, x, y, z, &c. And, finally, we obtain the magnitude and direction of the real currents in any of the conductors by taking the difference of the values of the cyclic symbols for the meshes adjacent to it. In order to save labour whenever the current in one branch only is required, Maxwell writes the cyclic symbol upon one side of the branch equal to $(x+y)$ and upon the other side equal to y, and then the real current in the branch will be $x+y-y=x$. In this way, by a simple re-arrangement of the network equations, we have only to complete the solution for one variable. Dr. Fleming points out that the solution of the set of simultaneous equations thus obtained is much facilitated by employing the method of determinants. It can easily be shown that if there are n linear equations of the type

$$\begin{aligned} a_1x_1 + a_2x_2 + \ldots\ldots a_nx_n &= p_1 \\ b_1x_1 + b_2x_2 + \ldots\ldots b_nx_n &= p_2 \\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ k_1x_1 + k_2x_2 + \ldots\ldots k_nx_n &= p_n \end{aligned}$$

The solution for any variable x_1 is the quotient of the determinants.

$$x_1 = \frac{\begin{vmatrix} p_1 & a_2 & \ldots & a_n \\ p_2 & b_2 & \ldots & b_n \\ \ldots & \ldots & \ldots & \ldots \\ p_n & k_2 & \ldots & k_n \end{vmatrix}}{\begin{vmatrix} a_1 & a_2 & \ldots & a_n \\ b_1 & b_2 & \ldots & b_n \\ \ldots & \ldots & \ldots & \ldots \\ k_1 & k_2 & \ldots & k_n \end{vmatrix}}$$

The rule by which these two determinants are formed will be obvious on inspection, the denominator being constant for each variable. When the numerical values of the terms are known the evolution of a determinant of any order reduces itself to the successive application of the elementary rules of arithmetic.

As a simple case of the use of this method let us employ it to investigate the conditions which are required to obtain a balance in the Wheatstone bridge as ordinarily employed to measure a resistance.

We have six conductors connected together so as to produce three cells or meshes. Writing $\overline{x+y}$, y and z for the three cyclic symbols, E for the E.M.F. of the battery, and taking the

Digitized by Google

resistances as lettered in the figure, we obtain for the cyclic equation

$$E = z(\rho + c + d) - yd - \overline{x+y}\,c$$
$$0 = y(d + b + g) - zd - \overline{x+y}\,g$$
$$0 = \overline{x+y}(a + c + g) - zc - yg$$

Rearranging we obtain

$$E = -xc - y(c+d) + z(\rho + c + d)$$
$$0 = -xg + y(b+d) - zd$$
$$0 = x(a+c+g) + y(a+c) - zc$$

Solving for x we get the determinant equation

$$x = \frac{\begin{vmatrix} E. & \overline{c+d} & \overline{\rho+c+d} \\ 0 & \overline{b+d} & -d \\ 0 & \overline{a+c} & -c \end{vmatrix}}{\Delta}$$

where Δ stands for the determinant forming the denominator,

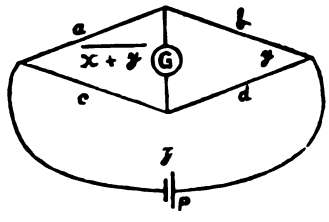

Fig. 2.

whose specific value we shall not require. This expression reduces at once to a second order determinant

$$x\Delta = E \begin{vmatrix} b & -d \\ a & -c \end{vmatrix}$$

or $x\Delta = E(ad - bc)$.

In this expression if we put x equal to zero we obtain the known relation

$$a : b :: c : d$$

Whenever the branch for which we have to find the current forms a part of the external boundary of the figure, we shall evidently have $(x - 0)$ for the real current; so that some additional trouble is saved by taking care to arrange the figure in this way whenever it is possible to do so.

As a further illustration, consider Poggendorff's method of comparing the electromotive force of cells. The required connections may be drawn as in Fig. 3.

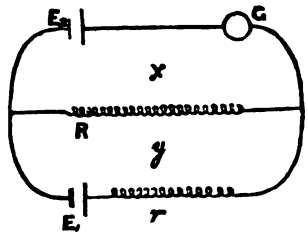

Fig. 3.

E_1 represents the E.M.F. of the standard, and E_2 that of the trial battery, R and r are the adjustable resistances. To determine the conditions which establish equilibrium in the galvanometer, that branch being a part of the external boundary, we write x (only) for its adjacent cyclic symbol, and y for the symbol belonging to the other mesh. The cylic equations are

$$-E_2 = x\overline{G+r} - yR$$
$$E_1 = -xR + y\overline{R+r}$$

from which

$$x\Delta = \begin{vmatrix} -E_2 & -R \\ E_1 & \overline{R+r} \end{vmatrix}$$
$$= E_1 R - E_2(R + r)$$

which, when x is made equal to zero, gives for the required condition

$$E_1 : E_2 :: R + r : r.$$

We proceed now to Dr. Fleming's method for obtaining the resistance of a network between any two given points. It is shown in the original paper that in any network of conductors the resistance between any two points can be expressed by the quotient of two determinants, of which the denominator is formed directly from the numerator by taking the first minor of its leading elements. This may be symbolically expressed by writing

$$R = \frac{\Delta_n}{\Delta_{n-1}},$$

where n is the number indicating the *order* to which the first determinant belongs. As before, we will explain the method of procedure by means of an illustration.

Let there be a network in the form of a square, 1, 2, 3, 4 (Fig. 4); let it be crossed by a diagonal from 1 to 4; and let

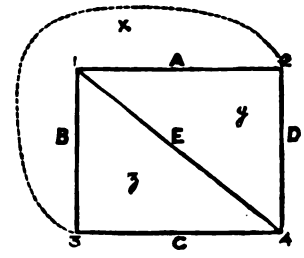

Fig. 4.

it be required to determine the resistance between the points 2 and 3. Let the resistances of the five conductors be A, B, C, D, E respectively. We proceed thus:—Join the points 2 and 3 by a line representing a conductor whose resistance is supposed equal to zero, and let this imaginary conductor have acting in it an imaginary electromotive force, e. We thus form a new mesh which we call *the added mesh*. Place symbols for the cyclic currents in each mesh, and write down the current equations for each cycle according to Maxwell's rule. In this case we shall obtain

$$e = x(A+B) - yA - zB$$
$$0 = -xA + y(A+D+E) - zE$$
$$0 = -xB - yE + z(B+C+E)$$

Then in the expression for R just given we have for Δ_n the determinant formed of the coefficients of the set of cycle equations taken in proper order, and Δ_{n-1} is the first minor of its leading elements. So that in this case we shall have

$$R = \frac{\begin{vmatrix} \overline{A+B} & -A & -B \\ -A & \overline{A+D+E} & -E \\ -B & -E & \overline{B+C+E} \end{vmatrix}}{\begin{vmatrix} \overline{A+D+E} & -E \\ -E & \overline{B+C+E} \end{vmatrix}}$$

It is easy in the present case to test the correctness of the result thus obtained. In Fig. 4, if we make A = D and B = C, it will be obvious that the resistance between the points 2 and 3 becomes equal to $\frac{1}{2}(A+B)$. And in the above expression for R, by making these substitutions for D and C and developing the determinants we shall obtain the same result.

After we have put in the conductor of zero resistance connecting the points between which the resistance is to be found we need not trouble to write the cycle equation, but may proceed at once to form the determinant according to the following rule:—Write down for the elements of the dexter diagonal the sum of the resistances which bound each mesh, *beginning with the added mesh* (proceeding afterwards in any order). Complete each row by writing in the resistance which separates the meshes whose resistance appears in the same row from the mesh whose resistance appears in the same column, prefixing the minus sign in each case, and writing zero for those elements which correspond to non-adjacent meshes.

Digitized by Google

This rule will probably become intelligible on examining the formation of the determinant written above. It will be found that the determinant so found is always symmetrical, one half being, as it were, the reflection of the other half in the diagonal considered as a mirror.

As a second illustration we may take the somewhat interesting case of a circular wire A P B Q, with a diametrical wire, P Q, across it.*

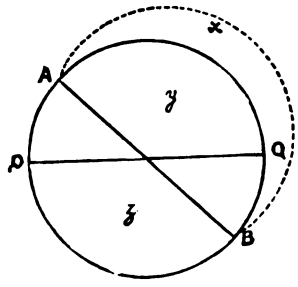

FIG. 5.

Take any two points A, B, at the extremities of a diameter not coinciding with P Q, but separated by an angular distance, θ, from it, and let us obtain the resistance of the circular wire so crossed between the points A and B. Join the points A, B by a dotted line of zero resistance. Call the three meshes so formed x, y, and z; let r be the radius of the circle, and let ρ be the resistance of the wire per unit of length. Then the

Resistance of branch P Q $= 2\rho r$,
" " A P $= \rho r\theta$,
" " A Q $= \rho r(\pi - \theta)$,
" " B Q is the same as that of A P,
" " P B " " " A Q.

Then the network determinant d_n is

$$\begin{vmatrix} \rho r\pi, & -\rho r(\pi-\theta), & -\rho r\theta \\ -\rho r(\pi-\theta), & \rho r(\pi+2), & -2\rho r \\ -\rho r\theta, & -2\rho r, & \rho r(\pi+2) \end{vmatrix}$$

which becomes

$$\pi\rho^3 r^3 \begin{vmatrix} 0 & \theta & \pi \\ -1 & 1 & 2 \\ -\theta & -2 & \pi \end{vmatrix},$$

and finally,

$$\therefore d_n = 2\pi\rho^3 r^3(\pi + \pi\theta - \theta^2).$$

The value of the minor of the leading element of the network, viz., d_{n-1}, is

$$\rho^2 r^2 \pi(\pi + 4).$$

Hence the resistance of the network between A and B = R is

$$\frac{d_n}{d_{n-1}} = R = 2\rho r\frac{\pi + \pi\theta - \theta^2}{\pi + 4}.$$

This result can easily be tested in the extreme cases.

It will thus be seen that Dr. Fleming's method is easily applied in all cases, whether the network is symmetrical or unsymmetrical, and is capable of furnishing an immediate solution in cases where other methods of calculating the resistance would be extremely laborious, if not altogether impossible of application.

* The treatment of this case is entirely due to Dr. Fleming, but he is not responsible for the illustrations previously given.

(To be continued.)

THE ELECTRIC LIGHT FOR THE POST OFFICE SAVINGS BANK.—We understand that the Maxim Weston Electric Company have just completed their contract with the Government for lighting the Post Office Savings Bank in Queen Victoria-street. The lamp to be used is the Weston wavy filament. Gas engines supplied by Messrs. Crossley Bros. will be used for the installation, this eminent firm having devised means whereby the disagreeable pulsation of the incandescent lamps has been overcome.

ON THE USE OF ALTERNATE CURRENTS FOR THE MEASUREMENT OF LIQUID RESISTANCES.*

BY MM. BOUTY AND FOUSSEREAU.

Two methods have been indicated by which the measurement of liquid resistances may be carried out with great exactitude. The one based upon the employment of the electrometer, and which we have adopted exclusively in our earlier investigations, is an admirable method, in that it eliminates thoroughly and absolutely the influence of the polarisation of the electrodes; the other consists of decreasing this polarisation until it is rendered a negligable quantity, by increasing as much as possible the active surface of the electrodes, and in having recourse to rapidly alternating currents. Desirous of obtaining an accurate comparison of the results given by the two methods and their relative precision, we have endeavoured to obtain the conditions indicated by M. Kohlrausch, so far as the resources at our command would permit. We procured two platinised platinum electrodes, each having $0^{mq}\cdot01$ surface, and made use of alternate currents furnished by a small Marcel-Deprez motor, revolving at a mean velocity of 100 revolutions per second.† These currents passed through a Wheatstone bridge in which a galvanometer was replaced by the Ader telephone.

From our preliminary experiments we found it necessary to obtain perfect insulation of the electro-motor and the resistances, but despite the care and attention we devoted to this purpose we failed, under the ordinary conditions of the test, to reduce the telephone to silence. Finally, however, we eliminated the inductive influences of the metallic resistances, and succeeded in obtaining absolute silence in the telephone. In order to effect this we dispensed with metallic resistances in the bridge, and employed a new liquid rheostat.

In the first experiment the four arms or branches of the bridge were formed of standard metallic resistances. We employed (1) a bridge by Elliott Brothers, of London, having three resistances of 10,000ω; and (2) four boxes of 1ω to 10,000ω, and two boxes of 10,000ω to 100,000ω, by Breguet. A series of careful determinations of the relative values of these resistances gave an invariable error somewhat below $\frac{1}{2000}$.

When the four resistances were small it was possible by regulation to arrive at a *minimum* of sound in the telephone, which, although far from being an extinction of sound, could almost be neglected. According, however, as the resistance was increased this minimum of sound became less and less perceptible, and at the same time the sound minimum became stronger as the resistance fell from a high value. The most important fact which should be stated is that *the bridge regulated for the minimum of sound was found to be absolutely incorrect in regard to the value of the resistances it contained*, and the error increased in magnitude with resistance. For instance, two arms of the bridge, A and B, were equal to 10,000ω, and the third branch, C, also to 10,000 ω. When regulation was made for the minimum of sound the fourth arm, D, was found to be 9,300ω instead of 10,000ω. The error, therefore, in the measurement of this resistance, supposing D to have been an unknown quantity, would have been 7 per cent. When C was made = 100,000ω, the value of D became 80,000ω, the error in this case amounting to no less than 20 per cent.

These results defy interpretation, unless it be admitted that the resistance boxes, such as are placed upon the market by the best makers, are not free from induction. The coefficient of self-induction of each coil is variable, and there cannot be any relation between the coefficient and the resistance proper. It can easily be seen, therefore, that the equilibrium of the bridge cannot be realised, when alternate currents are employed, by any combination of resistance coils contained in a box.

In replacing successively the first, second, and third arms

* Translated for *The Electrician* from the *Journal de Physique* for September, 1885.

† The motor, which was constructed by M. Carpentier, had a coil of about $0^m\cdot15$ in length and $0^m\cdot03$ in diameter, revolving between the arms of a magnet, formed of three plates of charcoal iron, each $0.^m\cdot01$ in thickness.

Digitized by Google

of the bridge by liquid resistance free from polarisation much greater clearness is obtained, but not an actual *extinction* of sound. The effect of the induction in the coils continues to exist, and the measurements in consequence are illusory. The results are the more incorrect as the reversals are more rapidly made, and the most careful series of experiments, carried out with the same apparatus, give no guarantee of their exactitude. We have here a systematic and grave cause of error which does not appear to have sufficiently occupied the attention of scientific men who have made use of the method of alternating currents.

In the second experiment we constructed fixed liquid resistances, free from polarisation, by means of two vases of large capacity, such as, for instance, two battery jars, each containing amalgamated zinc plunged in a solution of a concentrated sulphate of same metal. The two vases were connected

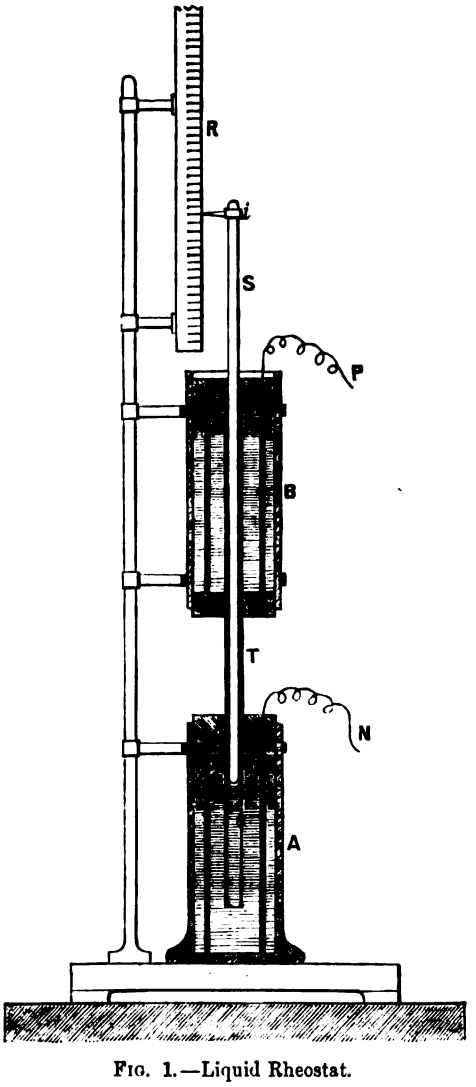

FIG. 1.—Liquid Rheostat.

by glass siphons, the number and diameter of which were arranged in accordance with the value it was wished to give to the resistance of the system. We then constructed a bridge of three resistances of this kind, and a liquid rheostat formed of a bitubular vessel full of sulphate of copper; a copper wire entered by one of the tubes, and constituted one of the electrodes, and a vertical capillary tube placed in the central main tube received the second electrode. This latter was also a copper wire, arranged so as to be raised or lowered at will, in order to vary that portion of the tube containing the liquid resistance. Under these conditions it was yet impossible to obtain absolute silence. The polarisation of the small copper electrodes played here the same part as the resistance boxes, and disturbed the equilibrium of the bridge. For the liquid rheostat, therefore, electrodes of large surface were found to be indispensable.

Liquid Rheostat.—Our rheostat (Fig. 1) is composed of two vessels, A and B, superposed upon each other, and each containing a cylindrical electrode of copper of a surface of several square decimetres. These vessels are connected by means of a vertical glass tube, T, open at both ends, in which is placed a plain glass rod, S, of almost equal section. The two vessels are then filled with a solution of sulphate of copper, and by raising or lowering the rod S in the tube the resistance can be varied at will. An index point, *i*, moving to the divisions of a scale, serves to indicate the position of the rod, and by an electrometric measurement of the increase of resistance represented by each division of the scale mentioned some useful data can be obtained. For absolute measurements it is, of course, necessary to make careful observation of the temperature of the liquid at the time of the test, for the reason that its resistance varies for each degree centigrade to the extent of $\frac{1}{30}$th of its value at zero. For relative measurements which require to be taken rapidly this correction may be dispensed with. One of our rheostats, of which we have made frequent usage, had a resistance ranging between 1,200ω and 5,000ω; it thus permitted of the comparison of two resistances in which ratio did not exceed 4 as a multiple. By varying the ratio of the arms of the bridge, however, with supplementary siphons, a range of from 24ω to 62,000ω was obtained for the smaller of the two resistances. We have not had occasion to exceed this limit.

The resistance which it was required to measure consisted of two glass vases, each containing an electrode of platinised platinum as before, connected by a narrow siphon, full of the same liquid as the vases. This resistance constituted the fourth arm of a Wheatstone bridge, in which the first two arms were liquid resistances, free from polarisation, and the third arm the liquid rheostat. We have operated upon chloride of potassium, chloride of magnesium, and sulphuric acid in various stages of dilution.

In every case we had the satisfaction of obtaining *absolute extinction of sound in the telephone.* With solutions which had but a small resistance, the extinction was got with great exactness, but with liquids of lesser density, the extinction, although apparently achieved, was yet shown upon an appreciable portion of the scale of the rheostat, and the relative error in the measurements became also appreciable in consequence. *This error is always greater than those observed in the electrometrical measurements made of the same liquids and under the same conditions.* As an instance of our meaning, we may cite the results given by a solution $\frac{1}{1000}$ of chloride of magnesium* compared with a solution of chloride of potassium of the same strength or concentration:

	Alternate currents.	Electrometer.
Mg Cl	1,609	1,546
K Cl	1,563	1,541
Mean	1,586	1,5435

Two tests repeated under conditions which, as far as possible, were identical, and with alternate currents, differed from each other to the extent of $\frac{1}{10}$th, whereas the difference between the tests taken with the electrometer seldom if ever exceeded $\frac{1}{300}$th. In regard to very weak liquids, the measurements made by the first methods are untrustworthy.

Concerning the exactitude of the alternate current method itself, the results of our experiments, conducted comparatively with the same liquids and at the same temperature, go to show that the mean of the measurements so taken bears about the same relation to the mean of the electrometrical tests that individual tests of the telephone may be expected to bear to themselves. The alternate current method yields good results when concentrated or moderately concentrated liquids are used in conjunction with large platinum electrodes such as those recommended by M. Kohlrausch, and, above all, when *non-rectilinear metallic resistances are carefully excluded from the four arms of the bridge.* Even with these precautions it is by no means certain that the best results will be obtained if it is attempted to apply the method to very weak solutions.

* $\frac{1}{1000}$ of Mg Cl + 6 HO.

THE NEW YORK OVERHEAD WIRES.

It will be in the recollection of our readers that for some considerable time past the overhead wires of New York and its Brooklyn suburb have been under notice to quit, the Legislature having peremptorily enacted that either the said wires must get themselves buried within a given period or have their funeral undertaken by the local authorities without leave or ceremony. That period has now passed by; and, needless to say, the wires are still above ground as lively as ever, the owners not showing any disposition to incur the expense of interment, and the municipality being wholly unprepared with a suitable grave. The case is another illustration of the fact that it is one thing to pass a law and quite another thing to get it obeyed. It illustrates also one thing more which we on this side the Atlantic may do well to note, namely, that when we have tacitly winked at the growth of an abuse we cannot shirk all responsibility when the consequences have become intolerable. The critical stage has been reached in New York sooner than in London, because the process, or "progress" as some may call it, has been more rapid there than here. But we are travelling in the same direction, and the warnings we have repeatedly uttered on the unchecked multiplication of overhead wires in this metropolis are now fully justified by what has happened in New York.

In view of an evident determination on the part of the Telephone and Telegraph Companies not to remove the nuisance at the bidding of the Legislature, a Commission of Inquiry was instituted, apparently to devise means to enforce the law when the time of grace had expired. After devoting two months to the subject the Commissioners have issued a preliminary report. Their present conclusions are as sensible as one could expect under the circumstances, being, in fact, the recommendation of a system which in all essentials is identical with that of the British Post Office Telegraphs. It consists of underground conduits, either of timber or lead, along the main thoroughfares, with manholes and terminal posts at suitable intervals. The system, we need hardly say, is simple, more permanent, and in every way more easily maintained than any other; and where there are no subways already in existence, it is the least expensive. Though the first cost is not nearly so great as has been represented, and is repaid in time by cheaper maintenance, it is certainly greater than for overhead wires; and of course, when a large outlay has been already incurred for one system, the cost of superseding it becomes a very serious matter. This is the consideration which has paralysed all local effort hitherto, the evil having gone too far to be worth checking if it could not be wholly removed. On this point the Commission is silent; and we can only inferentially assume that its members desire to throw the expense upon the Companies.

For their part the Companies are evidently of a different mind. We are told that they mean to dispute the "constitutionality" of the law before they succumb, and if it be true, as is asserted, that they "had authority to string the wires through the streets," it does seem an arbitrary and unjust act not merely to rescind the authority, which the Legislature has a clear right to do, but to saddle the Companies with the cost of undoing their own work. In this country the Companies have neither sought nor obtained such authority; and although the absence of prohibition is a tacit consent which it would be very unfair to ignore altogether, still they have been fairly warned that they are running a great risk, greater it would appear than their friends in America. That the proprietors of overhead wires in New York are throwing every obstacle in the way of the enactment is natural, and is evident in every paragraph of the Commissioners' report. An American contemporary complains that there was not a single competent electrician upon the Commission. This is ungrateful. If there had been, the report would have been much shorter, more emphatic, and far less beclouded with nonsensical difficulties propounded in the interests of the Companies. The major portion of the document is taken up with discussing propositions made with no conceivable purpose except to demonstrate the impossibility of putting the wires underground. A vast system of subways is gravely discussed, only to be dismissed as ruinously expensive. "Solid conduits" are considered, and rejected on the less adequate grounds that if one wire fails the whole mass is worthless, and repair impossible, except at an expense "greater than the original" outlay. It was even discovered that gutta percha is no adequate protection to the conducting wires. Quite providentially a "curious disease" broke out in the gutta percha covering of the wires belonging to one of the Companies interested just while the Commission was sitting. Diseases equally curious and opportune are known to attack the human Britisher when he is summoned to serve on a jury, or to vote in Parliament when his Party wishes to be beaten. What is more to the point, we have known submarine cables, covered not merely with gutta percha but with solid iron of great thickness and strength, to be suddenly smitten—bitten through and through—with some fatal malady just when an opposition cable is being completed. These, however, are curious coincidences which a "competent electrician," had there been one on the Commission, might have at least partially explained to the Commissioners' satisfaction, if not exactly to the Companies'.

Digitized by Google

It is gratifying to notice that the framers of this report, while loyally bent upon carrying out the edict of the Legislature, are warmly in favour of the telephone as a medium of social and commercial intercourse. They grow almost eloquent over the "last invented agencies of civilisation," which has established easy communication between Brooklyn and New York, "promoting its territorial extension," and increasing "residence in its beautiful outlying wards." If handsome dwellings are "no longer confined to the Heights," the circumstance is due, amongst other things, to the "growing telephone system," which not only benefits the subscribers, but "enhances the value of house property"—and, indeed, "of vacant lots where no houses stand." We do not presume to interpret this language; but it can hardly be other than friendly towards the telephone. Yet the conclusion arrived at is that the wires of this civilising agent must be put underground—perhaps, amongst other reasons, because the beauties of "outlying wards" and "vacant lots" are being wholly obliterated, and residence on "the Heights" becoming a terror and a burden. As to ways and means, the Commissioners are almost persuaded that the Companies, if left to choose, will adopt the best system themselves; and that, subject to the approval of the Local Board, they may be allowed to do the job in their own way so long as they do it effectually and without conflict with the municipal authorities who have charge of the pavements. As to time, nothing is specified; but we infer that the change is to be a gradual one, and that there will be no summary cutting down of wires such as was at first threatened. Probably, however, the Companies have not said their last about who is to pay the bill; on this point we have to wait later developments.

CORRESPONDENCE.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not know that I can fully clear up the points mentioned by Mr. Williams, p. 433, because, though I have often observed the facts and formed some general idea of the cause, I have not gone into them seriously. The change of "according to," instead of "amounting to," in my letter, p. 413, is a correction of a printer's error, and it will be perceived that my interpretation comes to the same result as Mr. Williams's, p. 396, that "completing the secondary circuit relieved the primary coil." It causes a greater current to be generated in the secondary, and lessens that of the primary. The actual effect will be variable with every coil, as it depends on two elements of construction, the number of turns in the two coils and their arrangement, or in effect (1) on the E.M.F. which is developed in the several wires, and (2) the repetitions of the generated current and consequent reaction on the core.

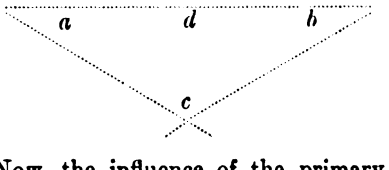
During the ordinary action of the coil, both circuits have an air space included at the moment of "break," but that of the primary is very small, while also its E.M.F. is much smaller than that of the secondary. But the division of the energy between the two coils, and the consequent currents generated, will vary with every alteration of the resistance of the secondary circuit. If this be metalically closed, the facilities of its path are so much increased that nearly the whole current will be produced there; but the energy will be mainly employed in producing E.M.F. rather than C, and will be largely expended as heat in the secondary wire. In these circumstances I should say that the resulting "ampere turns" reacting on the core may be less than when a considerable part of the energy results as "extra current" in the primary. If this were so, the rapidity of vibration of the break would increase, the force of its impact on the screw point would be lowered, and the spark at the break would disappear when the secondary circuit is closed. If I remember rightly this is what I have observed.—Yours, &c., JOHN T. SPRAGUE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My letter which you were good enough to publish on the subject of "Current Induction," p. 395, having called forth from your readers some comments by way of conversation, as well as through the medium of your columns, I hope you will allow me to draw attention to some misconceptions in connection with this subject which have come under my notice.

Persons come to me and urge that the outsetting primary current "does work" when it induces a current through the closed secondary circuit, implying that it does not do work when it sets out with the secondary circuit broken. I have little doubt that this class of thinkers (for I feel they number more than one) imagine that an induced current runs the whole rounder, so to speak, like a voltaic circuit. I will state what really happens.

Imagine a primary current from A to B arising, with a secondary circuit, *a b*, under its influence, whose horns are



united at *c*. Now, the influence of the primary current consists in causing a decline of potential in its own direction (viz., A to B). That is to say, a downward slope of potential is created along the line of wire *a d b*, or in other words an E.M.F. is set up between *a* and *b*, *for which there are two channels available*, viz., *a d b* or *a c b*. A current is remarked at *c*, passing in the "inverse" direction *a c b*; meanwhile, in the portion of the secondary circuit which is under the influence of the primary, the stream is going the other way, viz., *a d b*, instead of there being (as some appear to imagine) one continuous stream in the direction *b d a c b*.

Now, whether the secondary circuit be closed or open the work done by the primary consists in setting up the electrotonic state in the neighbouring conductor, or in other words, in creating the slope of potential already mentioned, and the consequent dispersion of electricity from *a* and accumulation of it at *b*. When the secondary circuit is not joined up at *c*, this distribution has to be made entirely through *a d b*, and the only difference is that the electro motion is made under greater resistance.

But there is an easy way of showing that the outsetting primary does its external work none the less with the secondary circuit broken. Set on the primary, and afterwards, while it is flowing, close the secondary; now cut off the primary, and the resulting "direct" induced current is the paying back of our invested energy.—Yours, &c.,

E. ALDRED WILLIAMS.

October 17th, 1885.

[The writer has since asked us to explain that the dogmatic form of the above letter is a mere *ruse*; he is quite aware that the "misconceptions" are the sanctioned view, and the opposed view a suggestion of his own.—ED. *E.*]

THE KAUFFER-GOLDNER BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The letter signed by Desmond G. FitzGerald, which appeared in your issue of 21st August, in regard to the Kauffer-Goldner battery, has escaped my notice until the present moment.

In reply I have to say as follows:—

The test of the Kauffer-Goldner battery was made under my supervision, and it is not my wish, any more than it is that of

Digitized by Google

the inventors, to foist upon the public statements which are not true.

The figures quoted in your issue of 14th August, to which Mr. FitzGerald justly objects, must have been taken from some unauthorised source.

I will briefly state the conditions of the test, and the actual consumption of zinc.

Nine cells of the battery were used, which were hitched in series. In the circuit were placed two 8 candle-power incandescent lamps, which were hitched in multiple arc. A clockwork mechanism closed the circuit for five minutes and thirty-eight seconds, and opened it for six minutes. At the end of 310 hours, considerable talk had been made in the press that I purposely made the intervals of rest very close together because the battery required it. It is easier to answer unintelligent criticism by experiment than by argument, and so to silence certain critics who had become prolix in the information they gave the public on the subject of closed and open circuit batteries, I removed the clockwork and closed the battery on the lamp circuit for thirty consecutive hours; after which runs of eight hours were made at short intervals, followed by a final run of five hours, at which time the lamps began to burn low. The lamps had been lit to full incandescence for 202 hours during a period of 408 hours. The battery was not entirely exhausted, although no longer capable of lighting the lamps satisfactorily. Two and a half pounds of zinc had been consumed in each cell. The depolarising solution had not been renewed nor tampered with in any way.

The utmost precaution was taken to make it a fair test in every way.

The cells were placed upon the floor and covered with a large cotton cloth, fastened to the floor with sealing wax bearing the impress of my seal and those of the gentlemen for whom I was making the test. All the joints in the conductors were soldered and were also sealed with wax. These conductors went up through the floor of the room overhead, where the lamps were placed. This room was always open, and the lamps were watched by many people. The room where the battery was placed was locked and a wax seal was placed over the keyhole by the gentlemen for whom I was making the test.

There were no accurate photometric observations made, but the test was considered at an end when the lamps burned lower than competent judges believed they ought to burn in practical house lighting.

The above briefly states the conditions of the tests and the results obtained.

I might here add that since the test above described the battery has been rendered still more efficient by using the ingredients of the solutions in proportions corresponding more nearly to their chemical quantivalence, and by slightly altering the shape and dimensions of the electrodes.—Yours, &c.,

ALLAN V. GARRATT.

Boston, Massachusetts, U.S.A.

INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see by a note in your journal that Prof. Hughes is investigating by means of the induction balance the superior transmissive power of copper to iron conductors, as pointed out by Mr. Preece.

Having employed copper aerial lines for many years past, I am of opinion that the cause of this difference is the lower electrostatic retardation of the copper, consequent upon its superior conductibility and smaller surface.

Some of our apparatus, which require the correct transmission of 6,000 currents per minute to control their movements, are perceptibly affected by the enlargement of the inductive surface of the wires by the moistening of their coverings during rain.—Yours, &c.,

F. HIGGINS.

The Exchange Telegraph Company,
21st October, 1885.

NON-MAGNETIC STEEL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As the subject of non-magnetic manganese steel has been attracting some attention lately, having been examined by Dr. J. Hopkinson and my brother, Mr. J. T. Bottomley, perhaps the following extract may be of interest to your readers. It is taken from a patent of Mr. F. A. Paget, No. 843, 1868:—

"A mixture of from 20 to 30 per cent. of manganese destroys the capability for getting polarised of cast iron, and a mixture with antimony has a similar effect on wrought iron."—Yours, &c.,

W. BOTTOMLEY, JUN.

Glasgow, Oct. 19, 1885.

BICHROMATE BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following description of a useful battery may be interesting to some of your readers:—

Six half-gallon stoneware jars, with holes for tap or plug. In each jar a round porous pot 9in. by 3in., surrounded by carbon plates and broken carbon. In the porous pot a zinc rod 8½in. long, weighing 1½lb. Solution of common salt and water. Solution for the six carbon cells:—

		s.	d.
Water	14lb.	—	
Potash bich.	1¾lb., at 6d. per lb. ...	0	10½
Sulphuric acid,	6lb., at 1½d. per lb. ...	0	9
		1	7½

I have four 2½ candle-power 4·8 volt lamps in places where the light is only wanted for a few minutes at a time. One is used as a night-light, to be turned on when wanted. Besides this the current is used through resistances for bells, gas, &c.; for this I use four cells in series. A third wire runs from the batteries to my room with six cells in series for a 10-volt lamp (5 candle-power) or other purposes. I am sure I understate the fact when I say the current is used only fifteen minutes a night, and for a second time this combination has lasted me over ten weeks. To equalise the wear of the solution, I empty all the cells together about the fifth week, and refill with the mixed solution. The loss of zinc is about 2lb., at 4d. per lb. equals 8d., added to cost of solution equals 2s. 3½d., or between ½d. and ⅓d. per night. A night-light alone costs ½d.

The carbon of the cells has just been overhauled after six months' continued use. There are not enough crystals of chrome alum to cover a sixpence; but in each cell is about 2oz. of a pale bottle green crystal, very brittle, and (unlike chrome alum) easily detached from the carbon.

I have never heard of the use of iron in these batteries in the place of zinc, and shall feel greatly obliged if any of your readers can give me any information on these subjects. I have tried a short experiment with the following result:—

7 cells, in each 1 iron plate, immersed surface 4in. × 1½
2 carbon „ „ 4in. × 2

and equally divided among the seven cells a solution of

Water, 6lbs.,
Potash bichromate, 12oz.,
Sulphuric acid, 41½oz.

This kept a 2½ candle-power 4·8 volt lamp at a useful light for 3½ consecutive hours.—Yours, &c.,

W. N.

THE ELECTRIC LIGHT AT MORECAMBE.—At a recent meeting of the Morecambe Board of Health, Messrs. Paterson and Cooper's tender for lighting the promenade by means of the electric light was received, and the question of its consideration was postponed. Messrs. Paterson and Cooper's tender amounts, we believe, to the sum of £1,700.

THE OPENING OF THE FIRST TELPHER LINE.

Saturday the 17th October may prove historical in the annals of electrical science. The late Prof. Fleeming Jenkin, as is well known to our readers, designed a system whereby he hoped electricity might be utilised for the transmission of goods.

The development of this system received the name of "telpherage." Seeing that certain parts of Profs. Ayrton and Perry's patents relating to electrical railways contained the solution of the problem of sending, *without attendants or control*, a stream of electric trains, Prof. Jenkin invited these gentlemen to become his colleagues in working out the telpherage system. Experiments upon a practical scale showed that the thing would work, and the question now to be solved is, will it pay? The Sussex Portland Cement Company has been sufficiently interested in the system to adopt it for the carrying of 150 tons of clay used per week in their works over a distance of about a mile. The plans for this line were almost completed before the lamented death of Prof. Jenkin, and, with the necessary modifications always required, have been carried out under the supervision of Prof. J. Perry, who succeeded Prof. Jenkin as engineer to the Telpher Company.

Saturday the 17th October was the day set apart for the opening ceremony. A large party—some three hundred—of visitors was conveyed by special trains from Victoria to Glynde, where the line is erected upon the property of Lord Hampden. Among those present we noticed Sir F. Abel, Major Armstrong, Prof. Ayrton, the Hon. A. Brand, Major Cardew, Mr. Crampton, Mr. Latimer Clark, Mr. E. Cowper, Prof. Carey Foster, Mr. Graves, Prof. Hughes, Major Hutchinson, Admiral Sir E. Inglefield, Mr. Massey, Prof. Perry, Mr. W. H. Preece, Mr. C. E. Spagnoletti, Mr. Swan, Mr. H. Taylor, Major-General Webber, Mr. Willans, Mr. T. Wood, Mr. Woodhouse, and many others interested in applications of electricity.

On the arrival of the visitors at Glynde they were conducted to the engine house, and Lady Hampden upon lifting a valuable jewel, resting in its case, caused contact to be made, when the "skeps," already loaded with clay, started upon their journey to Glynde Station, which they reached in due course without a hitch, and the clay was turned into the railway trucks waiting to receive it, the skeps going back for another load. The whole of the arrangements were satisfactory, the "telpher train" went backwards and forwards, and although only one train was worked, it was sufficient to prove the practicability of the system. The question in the minds of those present, however, was not so much a scientific one as a commercial one. All knew the system would work, but they wanted to know if it would pay—what were its advantages as compared with a wire-rope system, or a light tramway. Those who support telpherage maintain that it can be used in places where neither wire-rope nor tramways are practicable. Its opponents deny this. Nothing but an attempt to utilise the system practically will prove the correctness or not of the views expressed.

The advantages claimed for telpherage are—first, that the trains will go round sharp curves without loss of power, whereas with the overhead wire rope haulage system there is a great waste of power, and considerable wear and tear of the mooring rope at every curve on the line; secondly, there are no wheels all along the line that require to be regularly oiled; thirdly, the employment of electricity enables water power to be utilised even when it is at some distance from the telpher line; and, lastly, the electric power can be tapped at any point on the line, and, without the trains being stopped or delayed on their journey, used to work stationary machinery, a turn up cutter at the face of one of the posts illustrating, on Saturday, this last advantage. As compared with any form of tramway or railway on the ground, the land need not be purchased, way-leave to erect the telpher posts being all that has to be obtained. That the system is applicable for many purposes is undoubted; whether it is superior to a wire rope system in these places is questionable. The solution of the problem commenced with the opening of the Glynde Telpher line; the complete solution will, however, be a work of time. If energy, confidence, and ability will command success, then the telpher system can hardly fail, for Mr. Pryor (the chairman of the company), Prof. Perry (the engineer of the company), and the staff are thoroughly convinced that telpherage will eventually prove almost as great a success as railways, not, however, as a substitute for railways, but as a cheap means of bringing the goods to the railway. The work to be now done is to convince the sceptical business man.

ELECTRIC CONDUCTIVITY OF METALS AND THEIR ALLOYS.

BY M. LAZARE WEILER.

(Concluded from page 437.)

Variation of Conductivity with Change of Temperature.—The influence of temperature on electric conductivity is well known. Heat expands bodies, and thus separates their molecules by spaces of greater or less width. It would seem to follow, therefore, that heat should modify the conducting power in a manner depending upon whether the molecule or the intervening space is the better conductor. In the case of metals, elevation of temperature diminishes the conductivity. Silver sulphide, on the other hand, according to Faraday, gains in conducting power as its temperature is raised. Non-metallic elements are unlike the elements in this respect. A familiar example is afforded by the incandescent lamps. The conductivity of the filament is notably greatest at the time of incandescence that when it is cold. Becquerel made researches upon this subject in 1846. Without considering the details of his method, we will limit ourselves to mentioning the fact and to giving some of his results. The coefficient of increase of resistance is given in the following table for each degree rise in temperature. The coefficient is the value of k in the formula $R = r(1 + kt)$, in which r is the resistance at 0° and R that at $t°$.

Mercury	0·001040	Copper	0·004097
Platinum	0·001861	Lead	0·004349
Gold	0·003397	Iron	0·004726
Zinc	0·003675	Tin, possibly containing lead	0·005042
Silver	0·004022	Tin, pure	0·006188
Cadmium	0·004040		

The change of volume due to the expansion has in reality no effect. The augmentation of conductivity, when this is the consequence, is nearly balanced by the diminution resulting from the increase in length, which is a part of this same expansion. The relative conductivity of several metals (the bodies of most interest in this relation) are given in the following table, which should be compared with that by the same physicist, previously given, for the mean temperature of 12·75° :—

	Conductivity. at 0°	at 100°.
Silver, pure, annealed	100	71·316
Copper, ,, ,,	91·517	64·919
Gold, ,, ,,	64·960	48·489
Cadmium	24·579	17·506
Zinc	24·063	17·596
Tin	14·014	8·657
Iron, annealed	12·350	8·387
Lead	8·277	5·761
Platinum, annealed	7·933	6·688
Mercury, distilled	1·7387	1·5749

We have at present no similar experiments of our own with which to compare these. We may therefore accept these results for the present, with the reservation before expressed, relating to the purity of the metals and the precision of the methods. We shall have occasion to refer to this subject in the next communication.

Electric Compared with Thermic Conductivity.—The prevalent notions regarding the identity of divers physical phenomena have led physicists to seek to determine the relation between heat, light, and electricity. Without repeating the theories bearing upon this subject, I may recall the opinions expressed in relation to the analogy between electric and thermic propagation, by giving the figures previously referred to, and specify the experiments, the results of which will form the subject of

Digitized by Google

a later communication. The analogy referred to has been supposed to exist since it was known that some metals appeared in the same order when classified either by their electric or their thermic properties. Also metals are good conductors of heat and electricity, while dielectrics are generally poor conductors of heat. Furthermore, the coefficients of conduction for heat and electricity are for many metals nearly the same. The researches of Wiedemann and Franz yielded the following results :—

	Conductivity.	
	Thermic.	Electric.
Silver	100	100
Copper	74	73
Gold	53	59
Brass	24	22
Tin	15	23
Iron	12	13
Lead	9	11
Platinum	8	10
German silver	6	6
Bismuth	2	2

These results are certainly very interesting, and at first view tend to mislead those experimenters who seek to simplify the explanations of physical phenomena, and who are always seeking to unify the theoretical conceptions of elementary laws. Meanwhile, we do not find it possible to accept unreservedly these results, nor the conclusions which it is desired should be drawn from them. We know that the table of electric conductivities needs revision. Copper, for example, appears in the table of Wiedemann and Franz with a coefficient of 73 for electric conductivity, whereas it is well known to be entitled to rank with silver at the top of the scale. We find, also, some remarkable divergences in the following list :

	Conductivity.	
	Thermic.	Electric.
Copper	73·6	100
Gold	53·2	78
Zinc	19·1	29·9
Aluminium	19·6	54·2
Silicious bronze	68	98
Antimony	21 5	3·88
Tin with sodium	13·34	46·9

The whole question clearly deserves to be re-studied without the embarrassments of preconceived theories. We have undertaken this new study, and we will limit ourselves here to describing our preliminary experiments. These researches have been carried on with the valuable assistance of M. Jannetaz, Maitre de Conferences of the Sorbonne, who has willingly brought to our aid his profound knowledge of the subject, and the apparatus with which he prosecuted his previous labours in determining the conduction of heat in minerals. The process which he employed and which we have adopted is as follows :—The apparatus as devised by M. Jannetaz consists essentially of a plate upon which is placed the mineral whose conducting power is to be tested. This body has been previously prepared by coating a plane face of it with a thin layer of wax or grease. In contact with this is a small bead of platinum about the size of the head of a pin, which has been welded to the apex of a triangle of platinum wire. A current being sent through the wire heats it, the bead fusing the wax over a circular or elliptical space, whose dimensions, taking into account the temperature of the wire and the time of contact, afford data for determining the conducting power of the specimen. To complete the description it is only necessary to add that the wire is brought through a copper casing which is supplied with a current of cold water, and that the wire is also supported by a carrier, which facilities making contact with or withdrawal from the specimen. It is with this apparatus that we have begun our researches. Unfortunately, it has not been possible in the time available to prepare thin plates of the metals and alloys. We have been obliged to content ourselves with half-cylinder sections, cut from the little bars employed in the previously mentioned experiments. Under these circumstances, the external conditions may have modified the results, and we prefer at present not to exhibit numerical results which may require correction.

It is sufficient now to say that some of the results appear to invalidate the law of identity above referred to, and others lead to the interesting conclusion that there may be a difference of conductivity in the same metal depending upon the method of preparation, whether it was cast, drawn, or rolled. You will notice upon the specimens submitted to you, which bear traces of these experiments, that the elliptical form of the curved spaces takes a direction corresponding to the lamination of the specimen. We have completed the observations which we set out to present to you, and which, as you see, form a programme of researches to be made quite as much as of results accomplished. We wish especially before closing to call your attention to the double interest attaching to the subject which has enlisted your attention. From the practical point of view alone the subject is of the highest importance, as has been shown by the results obtained, bearing as they do upon the vast problem of transmission of electric energy. But we do not insist upon this point. The estimate of this subject from the scientific standpoint is no less great, involving as it does the nature of electricity itself.

Among the facts which we have noted, we will refer again to the strange anomaly exhibited by the alloys as conductors of electricity when we consider them as compound substances. This might serve as an occasion to review the theories promulgated by certain eminent physicists, Clerk-Maxwell among others. But these theories are yet such mere hypotheses, and their interpretation appears to me so abstract, that I fear to venture upon this ground. But there is no rashness in affirming that, in the resistance offered by a body to the electric current, the magnetic orientation of the molecules of each body plays an important part. Each of them, influenced by the passage of the current to a degree probably depending upon its constitution, modifies the resistance. The question may be asked whether the compound molecules of the alloys do not behave as other elementary electric couples, having a special electromotive force that determines the passage of the current, and which produces in the total mass a series of currents analogous to the so-called Foucault currents, the effect of which is contrary to that of the primary current. We are tempted to believe that in the alloys the chains of molecules of the same kind are not able to act like a cable made of wires of different metals. As the alloy of equal parts of gold and silver has already been referred to, let us determine the resistances under the different conditions. If the current be transmitted through two wires each a kilometre long and a millimetre in diameter, one being of gold and one of silver, the formula for derived currents enables us to determine the total resistance. The formula is :—

$$x = \frac{R_1 R_2}{R_1 + R_2}.$$

The resistance of the silver being 19 ohms, and of the gold 24·36 ohms, the total is by the above formula, 13·38 ohms. But a wire made of the alloy in these proportions, having the same length and a double cross-section, offers a resistance of 58·50 ohms. This result shows that the law governing derived currents does not apply in the case of conduction through alloys. Some other cause intervenes ; possibly such a one as is mentioned above ; perhaps an unknown cause which essentially modifies the flow of electricity.

We may be permitted to recommend this investigation to physicists, and we are ready to devote our efforts to the same end. If this task, to the accomplishment of which we wish to dedicate ourselves, is crowned with success, we shall be sufficiently recompensed by the satisfaction which labour affords to those who seek thereby to advance science.

ALUMINUM BY ELECTROLYSIS.—According to *La Lumière Elictrique*, Mr. L. Senet has invented a new process that permits of the manufacture of aluminum, as well as copper, silver, &c., by electrolysis. A current of from 6 to 7 volts and 4 amperes is made to act upon a saturated solution of sulphate of aluminum in the presence of a solution of chloride of sodium, the two solutions being separated by a porous vessel. A double chloride of aluminum and sodium is formed, which is decomposed, and the aluminum that is set free deposits upon the negative electrode.

IRON SHIPS AND COMPASSES.

The Philadelphia *Times* gives an account of adjusting the compasses of iron ships :—

The business is monopolised by three persons in the United States—two in New York and one in Philadelphia. An iron ship, said one of these professionals, is a great magnet. The magnetism of such a ship is technically known as "permanent" from having received the same from some other magnet itself styled permanent. The position the vessel occupies in the shipyard while in course of building is the principal feature in the shaping of her magnetic influence. A vessel lying due north and south on the stocks will be highly charged with magnetism. Every blow struck upon the iron plates of the sides, upon the rivets, or even by the caulker, has a pronounced effect upon the ship's magnetism. In shipbuilding it is impossible to reverse the manner of striking the metal, and the result is that the magnetic currents are not equalised. If a vessel that was built north and south in the yard travels generally north and south she loses a great portion of her magnetism, and a corresponding change is noticeable in her compass. The lines of magnetism always run in a contrary direction to the position the ship occupied in building. Occasionally it happens that a variation of but one point will be noticed when the ship is headed north-east, but when headed south-east five or six points of variation exist. The magnets used to neutralise the ship's magnetism consist of large bars of iron, spheres, spheroids, coils and, in fact, iron of almost every shape. These are placed in different portions of the vessel and exert a great permanent influence the further away they are placed. If the engines are changed during the trip, if new boilers are shipped, iron taken aboard or "patches" put on the sides, the magnetism of the ship is proportionally disturbed, and a readjustment is necessary.

THE BEST FORM OF DYNAMO.

In a recent interesting paper on "The Best Form of Dynamo," read before the National Electric Light Association of America, Mr. A. E. Sperry, of Chicago, the author, said :—

"The best dynamo is that which with economy operates continuously with the least expense ; one that does not require the constant attention of an expert (by no means, however, underrating efficiency in an attendant); one which has no delicate parts liable to derangement, one in which all the parts are accessible for cleaning and proper attention. Large journals, heavy framework, and substantial construction throughout are not to be overlooked in dynamo machinery any more than in a locomotive. A tendency, which I am pleased to see is becoming less prevalent, has been toward developing the greatest possible current with a given size or weight of machine. The construction in this case is generally too delicate, and all parts are overworked to such a degree that they are constantly giving way. The effect of this upon the commercial operator and public generally has been disastrous, establishing the impression that all electrical appliances are inherently unreliable. The latter constructions are more durable, less delicate as to details, and generally more satisfactory; although it is true they may occupy a slightly increased floor space." After dealing at length with the subject, Mr. Sperry concludes :—"The matters going to determine the best form of dynamo are so numerous, and the various forms of dynamos being best adapted each for its peculiar sphere, that a general formula, prescribing that form which is best in all cases would be impossible. The art, however, has brought dynamo machinery, the construction of which at first was attended by so many difficulties of a high scientific nature, down to a sufficiently practical basis, so that good judgment with regard to ordinary mechanisms of a higher order are relevant to the more salient features, and may be depended on largely in guiding those interested in investigating this class of apparatus."

THE DISTRIBUTION OF ELECTRICITY.*

BY PROF. GEORGE FORBES.

(Continued from page 442.)

LECTURE II.

In my last lecture, I introduced to your attention the elementary principles which must guide the engineer in the selection of the right size of mains to use. These principles maintain whether it be a private installation of the electric light or a large supply from a central station. But, in the future, I shall confine my remarks chiefly to the latter class. In whatever manner the mains be laid down, the mass of copper contained in them is very large, and their establishment constitutes a large portion of the prime cost of laying down a system of central station lighting. For 100,000 Edison lamps we require over a ton of copper per yard run, and everyone knows how rapidly the number of miles of mains mounts up, even in a small district, owing to the large number of side streets.

Now, when a bridge like the Forth or the Tay Bridge, or the Brooklyn Bridge at New York, is designed, the engineer spares neither time, labour, nor expense in his preliminary calculations of the weight of metal required in the several parts to combine strength with economy. In such bridges the mass of metal is enormous, and the reduction of cost in this item is very important, independently of the fact that, within a certain limit, the less metal there is in it the more efficient is the bridge. Consequently, the proportions of the different parts must be most carefully calculated by the ablest mathematicians.

Now I maintain that exactly the same care should be taken in the estimation of the proportions of different parts of our electric mains. It is a point which has been sadly overlooked in the past, even by some of the most advanced and far-seeing of electricians. But when we consider the enormous amount of capital which must be sunk in mains I hope that engineers will see how intensely important it is to spare neither trouble nor expense in preliminary calculation in order to ensure the best result.

Now, in the present state of electric lighting economy is of primary importance. Judging by the experience of the New York central station for electric lighting, we should be prepared to deny the possibility of economically furnishing the electric light to the British public. I, however, do not hold this view. I see several defects in that example of electrical distribution. The dynamos are of an expensive kind, and the outlay in this matter has been excessive. Moreover, the mains are laid on unsound principles, and are both expensive and, I believe, unsatisfactory. The general scheme for an installation is not to be written down casually on a few sheets of paper ; it requires weeks, or even months, to prepare the estimates, and to calculate the requirement of any such central station. I have no doubt the effects that I have alluded to are due largely to the early period at which that station was designed. But even in later estimates, and in our own country, I have seen the want of that detailed calculation which can alone lead to economy.

In any system, at the present time, economy is the main thing to be considered in designing a system of distribution. Other difficulties, such as equalisation of potential, must be looked upon as difficulties to be faced and conquered by the engineer.

In my previous lecture I have given you three reasons why we must not try to economise too much by laying very thin conductors.

1st. It is not economy, on account of the wasted energy in heating the conductors.

2nd. The conductors may become so hot as to injure insulation, increase the resistance excessively, and even be uncomfortable to the foot passenger.

3rd. The fall of potential over a district, and the variation of the potential at each point of a district, are both increased by thinning the wires.

I showed that, by due selection of the method of laying mains, the second can be reconciled with the first, which thus becomes paramount, leaving the third to be overcome by the engineer as best he can.

I showed you the general principles which must guide us in the economical selection of the size of mains, and I gave you some tables which, I trust, will be found of great value to the engineer. Nothing is there chosen for him. He may put his own price on the cost of an electrical horse-power and on the cost of laying mains. In any special case, and in all parts of the scheme he is designing, these tables give him, almost at a glance, the economical size of main he must employ. He can then, by the aid of my formulæ, determine approximately the rise of temperature under different systems of laying, and he will see whether these mains may be laid in a single conductor of circular section, a flat sheet of definite thickness, or a series of cables side by side.

Then comes the question of equalisation of potentials, which we shall have to deal with very fully in this and the following lecture.

I shall now, by way of introduction to what follows, lay before you the principal diverse systems which have been proposed, and shall afterwards examine each in detail. These are five in number, varying either in the way the lamps are connected with the main, or in the introduction of some special appliance. They are as follow :—

1. Multiple arc.
2. Series.
3. Multiple series.
4. Accumulators.
5. Secondary generators.

* The Cantor Lecture of Professor George Forbes, delivered on February 9th, 1885. From the *Journal of the Society of Arts.*

Digitized by Google

Some of these have a large number of sub-heads. I shall confine myself to-day to the first class, as being at present the most important. It will be convenient to subdivide this system into several classes, which I venture to name as follows:—1. Parallel line. 2. Reserved parallel line. 3. Network mains. 4. Tree mains. 5. Multiple tree mains. 6. Independent wire mains.

Lamps in Series.—The oldest propositions for electric lighting had no reference to multiple arc. It was proposed to put all the lamps in series. This method economises largely in the cost of mains, but the number of lamps which can be supplied is very limited. The pressure required for lamps in series is greater than for lamps in quantity or multiple arc, in proportion to their number. The hydraulic analogy to electricity is always instructive. Now a lamp is represented by a water-engine or turbine giving off a certain amount of energy; a certain difference of pressure between the inlet and outlet of the water-engines is required to give off this energy. If, now, the outflow goes into a second water main, which again feeds a second water-engine, these engines are in series, and the pressure which must be supplied is exactly proportional to the number of engines placed in series. If the water-engines were all put upon the same main, the pressure required would be the same as for one, but the volume of water required would be greater than for one, exactly in proportion to the number of water-engines. Moreover, the size of pipe must be increased to allow this larger volume to pass without too much resistance from friction of the pipes.

These hydraulic facts, so simple and self-evident, are the exact analogues to facts in electric lighting. If lamps are in series, the electric pressure must be increased in proportion to their number. The electric mains supplying many lamps in multiple arc require the same pressure as for one lamp, but the size of the mains must be increased to prevent waste of energy by their resistance to the electric current.

Thus, if we have ten lamps in series, the current is one-tenth of what is required for ten lamps in multiple arc, and hence, on the economical considerations, the copper mains may be about one-tenth of the sectional area.

But the number of lamps which can so be put in series is limited. The highest potential which has been used hitherto, so far as I am aware, is 5,000 volts, and some people will say that even this is dangerous. I do not hold this view at all. If, as in America, a line be properly insulated, and if it be tested once or twice a day at the dynamo house, there is no real danger to consumers; and if, as in America, the workmen at the dynamos wear india-rubber gloves or the homely golosh, there is no danger for them.

I have no hesitation in asserting that the dangers from high potential electricity are far less than those from gas. Hardly a week passes but we read of dreadful explosions of gas. Suffocation is not uncommon, and in the first days of gas, when ignorant people often blew out their light, it was a dreadfully common occurrence.

If, now, we have 5,000 volts, and consume 100 volts in each lamp, we can only put 50 lamps in series. But, on the other hand, if such a system were to be adopted, it would be desirable to use lamps of much lower potential. When talking of the multiple arc system, I said it was desirable to use lamps of as high a potential as possible to economise the mains; so here I say, in a series system, we must use lamps of as low a potential as possible, so as to economise pressure. If we could have 20-candle lamps of 2 volts, we could work 2,500 lamps off a single wire with 5,000 volts (neglecting the resistance of leads). Assuming 3 watts per candle-power, this would mean a current of 30 amperes. In many cases this would be a highly economical system of distribution. There are, however, two objections to this plan which I look upon as fatal.

If one lamp is put out of circuit, it puts out all the other lamps. Consequently, the switch for a lamp must be one which will short circuit it, just as the plugs of a resistance box cut out resistances by short circuiting them. Then, the engine-driver must regulate his dynamos so that the current is constant. Automatic adjustments have been made for this purpose with arc lamps, and their action is excellent. These are to be found in all American arc systems, and are a great point in their favour.

If, however, the filament of a lamp breaks, all the other lamps in the series go out also. It would be necessary to have an automatic arrangement to short-circuit a lamp when its filament broke. This is no easy matter, and could hardly be done without a local battery, or a second wire from the dynamo. In any case, the introduction of any such apparatus into each lamp would add to the cost and liability to get out of order.

It may be said, however, that with the thick flow-resistance lamps of 2 volts ($\frac{1}{5}$ ohm), they would not break, but would be changed long before they got thin enough to break. In this case, however, the second objection is fatal.

The second objection is that with such thick filaments for lamps it would be impossible to get anything like a candle for three watts. I I think it was in 1874, when the Russian Logodine showed his incandescent lamps of thick carbon, that I tried some experiments at Anderson's College, Glasgow, where I was then Professor of Natural Philosophy. These experiments convinced me that incandescent lamps of that kind could never be economical. The heat carried away by the terminals was so great as to waste a large part of the energy put into the lamp. This is the objection which I have to the Bernstein lamp. I shall never forget the astonishment with which I first saw one of Mr. Swan's lamps with a thin filament. My astonishment was at seeing the filament glowing white up to the terminal. This can only be done to perfection by a lamp of very high resistance.

I remember seeing an able man of science showing some of the small fairy lamps to a scientific audience, and he asserted that its efficiency was doubtless the same as the 20-candle lamps. "because it is made of the same material." This was a serious misstatement.

I think enough has been said to convince you that, although in some cases this system may be worthy of consideration, it is not generally applicable. If the lamps are of low resistance they are not economical. If of high resistance we have few in series, and require a special device to short circuit a lamp when the filament breaks.

It would not be well, however, to leave this system without pointing out to inventors that it has one more advantage as compared with the multiple arc system.

Our present lamps (designed for multiple arc) have a serious drawback compared with gas. You cannot lower them to give less light. Even if there were a means of reducing the current through them you would not get economy because of the lowered temperature. Now with the series arrangement it is conceivable that the filament might by some means be lengthened and shortened, and since the current is constant, the brightness would depend on the length, and all lengths would be equally economical except for the absorption of heat at the terminals. I do not wish to invent, so I will say no more.

In America, arc lights are seen in series, sometimes to the number of 100. One cannot help feeling pleasure either in seeing the dozens of dynamos at work in the central station, or in admiring the graceful curves of overhead wires, well insulated, and supported on well-shaped steel poles, as in Philadelphia, and in seeing the bright light which they are spreading over seventy miles of street, and with which they are gladdening the hearts of thousands In some systems, with ten amperes flowing, an arc lamp is replaced by ten incandescent lamps in parallel, each using an ampere, and with switches to substitute resistances for lamps.

Mains with Lamps in Multiple Arc.—I think it may be fairly assumed that a 16 or 20 candle-power lamp is what is most likely to be generally adopted. It is found that we can get one candle-power for an expenditure of three watts of work. Now this three watts is the product of the current and the pressure, and may be made up in a variety of ways. We may increase the amperes of current and diminish the volts of pressure, or *vice versâ*. So far, however, as economy of mains is concerned, there is no doubt what is the best course to follow. The smaller the current the smaller are the mains. Hence it is clearly desirable to use lamps of a high potential—100 volts is at present about the limit that is used—but I am informed by Mr. Swan that equally good lamps could be made of 400 volts if there were a demand for them. There is at present an absurd regulation of the Board of Trade limiting the pressure in houses to 200 volts; but I think we may take it for granted that more enlightened views will ultimately prevail. If such lamps were used the cost of mains would be reduced to about one quarter, which is, of course, a very great step.

Here, then, is a step which, according to the information before us, can be taken at once. Why it is not taken I am at a loss to understand. If lamps of 20 candle-power can be made with a long life, using 400 volts and ·15 ampere, the question of central station lighting on economical principles is advanced enormously. The inventors and manufacturers are alone to blame if, by delaying to take this step, they hinder the adoption of this system of lighting.

These remarks apply, more or less, to nearly all the systems of distribution, but especially to the multiple arc system, where the mass of copper in the mains is so great.

Now let us look at the simplest distribution, where we lead mains along a single street, and take off the current at various points, using each such point as a source of supply to a house, or it may be to a whole district.

The diagrams below show different systems of laying the mains. In the single parallel line it will be noticed that the potential falls off as we go farther from the station. If the size of conductor is proportioned to the current with 1½ square inch per 1,000 amperes of maximum current, the fall of potential is regular, and amounts to 3·22 volts per 100 yards of double conductor when the maximum number of lamps are in use.

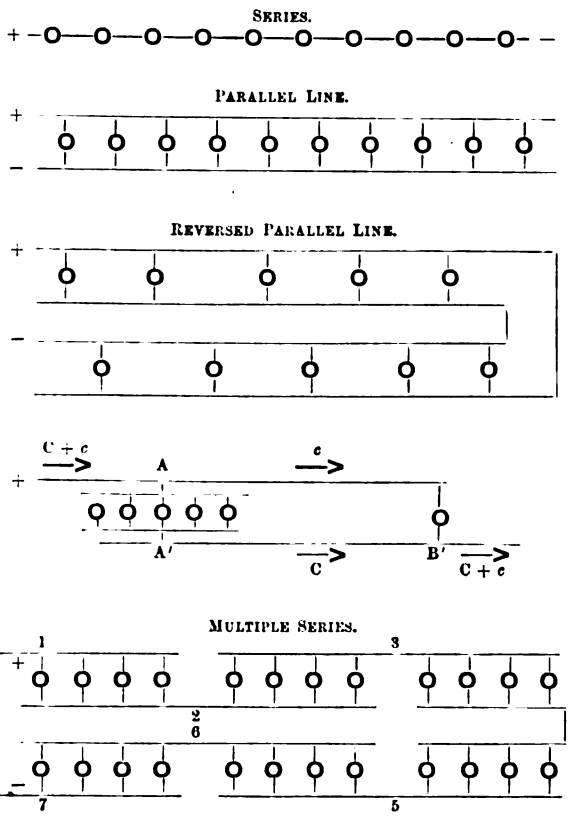
This is a good opportunity to draw attention to a point which meets us in studying nearly every system of distribution. Since the size of conductors is proportioned to the current, they are abruptly diminished in section at each point of consumption. It follows that, so far as weight of copper is concerned, this system is equivalent to one in which separate wires all of the same size go from the central station to each point of consumption.

The difference between these two plans—(1) the massive main system and (2) the independent wire system—consists in this, that while their action is identical in reducing the pressure when all the lamps are lighted, their action is different when some lamps are extinguished. With the independent wire system, the conductors leading to points of consumption not in use lie idle. In the massive main system the equivalent mass of metal is used, under the same conditions, to diminish the resistance of conductors to the points of consumption which are in use. This would seem at first sight to be all in favour of the massive main system; this, however, is by no means sure. If only the nearest and most distant points of consumption were in use, and R be the resistance of mains between these points, V the pressure at the near point, and r the resistance of lamps at the far end, the energy used up by the distant lamps and the mains to them is $\frac{V^2}{R+r}$. The current is $\frac{V}{R+r}$. R is greater for the independent wire system than for the massive system. Hence the current and energy used are less with the former than the latter system. Moreover, since the current is less, r is greater. Hence, *à fortiori*, the energy used with an independent wire system is less. In fact, with the massive mains, the distant lamps will be far too bright. If, however, the fall of potential with the maximum current is only a few volts, this would not be important.

The system of independent wires takes away from the inconvenience of varying pressure at definite points of consumption. It seems at first sight to be ridiculous to think of having a separate wire to each

Digitized by Google

lamp from the central station. But it is by no manner of means ridiculous. In fact, it is well worthy of serious consideration.



In a previous part of the lecture I have shown what loss of energy we must allow in the leads and other conductors. Now this loss of energy shows itself by a fall of potential. If δV be the difference of potential between two points of a main, R the resistance between these points, and C the current, then $\delta V = C R$.

Now, I have resolved to assume in these lectures a section of 1½ square inch per 1,000 amperes. The resistance of 100 yards of a copper conductor of this section is ·00161 ohm, and $\delta V = 1{,}000 \times {\cdot}00161 = 1{\cdot}61$ volt. That is, we have, with such a conductor, a fall of 1·61 volt in every 100 yards of a single conductor, and a fall of 3·22 volt per 100 yards of double conductor. This takes place when the maximum current is being used. With a smaller current the loss is less. With 500 amperes to the 1½in. conductor, it is only 1·61 volt, and with 100 amperes or less it is nearly inappreciable. Now, while it is very satisfactory to the engineer to find that with small currents there is so little waste of energy, still there is a counterbalancing disadvantage of serious importance, I may say the most serious importance, in considering the question of laying mains. [In the following remarks I will assume that the engine is perfectly governed.] Suppose there is a distance of 500 yards between the engine house and the farthest lamps, and that lamps are being supplied all the way along, and that the conductor is properly proportioned to the current, on economical considerations, at every point. Then while the maximum number of lamps are in use those nearest to the engine house have an electrical pressure 16·1 volts higher than those farthest from the engine. Well, this might be counteracted by causing the consumers at a distance to use lamps of 16·1 volts higher than those farthest from the engine. Well, this might be counteracted by causing the consumers at a distance to use lamps of 16·1 volts lower potential. That is all very well while the maximum current is flowing. But when the number of lamps is reduced one-tenth, the difference of pressure to the two consumers is only 1·64 volt. Thus, if the nearest consumer has a constant pressure the distant one has his pressure varying by 14·49 volts. It is true that in this case we might vary the pressure at the engine house, so that the near consumer was 7·25 volts below, and the distant one 7·25 volts above his normal pressure; but even these variations are very serious. A variation of 7·25 volts in the potential of lamps is a most serious matter, even if we look at this variation as being only 3·62 volts above and below the pressure for which the lamp is constructed. To illustrate this I will give you three curves on a diagram. The first shows how the candle-power is affected by the pressure, the second how the life is affected by the candle-power, and the third how the life is affected by the pressure. The first is Mr. Edison's table of 1883; the second is from the experiments of Mr. J. Zacharias; and the third I have deduced from the tests of Woodhouse and Rawson lamps at the Vienna Exhibition. Generally, in 100 volt 16-candle lamps, a volt makes a difference of a candle.

I will now show you, experimentally, the fall of potential along a main. I have three lamps of equal brightness; when I connect the two at opposite ends of my main, the distant one is much feebler than the near one. If I insert a third half way, the distant one falls still more, because the main has to take more current. [Experiment.] This is one of the most serious problems which have to be considered in engineering the mains of a central station, and a large portion of this course of lectures will be devoted to the devices which have been proposed for getting over the difficulty. I have next to describe to you the different systems of connecting the lamps of consumers with the engine house. In the remarks which have gone before, I have confined my illustrations mainly to a multiple arc system; but there are several others, each of which has certain advantages. With the massive main system it has sometimes been proposed to equalise the pressure for lamps over a district by putting in proportionate resistances at the points of consumption. It has also been proposed to prevent variation of pressure when the consumption varies, by making these resistances adjustable automatically. This, however, must not for a moment be thought of. I pass over the fact that automatic adjustable resistances have generally been a failure, because the designers are alone to blame for this; but I do insist that an economical system of working is incompatible with the free use of resistances in the working circuit, which use up a large quantity of energy. It is better to use lamps of different qualities in different parts of a district than to introduce such resistances, and the engineer must find some other means of dealing with the variations of pressure with varying consumption.

The remarks I have made about the independent wire system must be looked upon as parenthetical. We shall recur to the subject. We have now examined the single parallel line, and have seen that, so far as weight of copper is concerned, it is equivalent to a separate wire to each lamp. We have also seen how the pressure falls off as we go from the station.

The reversed parallel line (Fig. p. 1,042) was devised to prevent this fall of pressure. Two wires run side by side; one end of one wire is attached to the + pole, and the other end of the other wire is attached to the − pole. Thus the current supplying each lamp goes around the whole circuit, and so there is a tendency to equalise the pressure for all lamps. In the diagram the wires are shown of taper form, but they have been generally taken to be of uniform thickness. It has been shown by Prof. Ayrton that, in this case, the pressures are not equalised if a larger current is taken off at one point than another. Suppose at point A a large number of lamps is supplied, and at B a small number, so that a current C passes through the lamps at A, and a current c through those at B. Let R be the resistance of A B or A′ B′. The fall of potenlial from A to B is c R, and from A′ to B′ it is C R. Hence the pressure at B is greater than at A by the quantity $(C - c)$ R; *e.g.*, with 500 lamps at A and 10 lamps B, and 0·75 ampere per lamp, and with A B = 200 yards, and resistance = ·0032, the fall of pressure is 1·17 volt.

Mr Kapp (*Electrician*, May, 1883) has gone further, and shown that with lamps equally distributed over the whole line, the middle ones have less pressure than those at the two ends. But it must be noticed that if at each point the section of conductors is made proportional to the current, then the quantity $C R' = cR$, and the fall of potential to both terminals of a lamp is the same, where R R′ are the resistances of A B and A′ B′ respectively. If the size of conductors be properly proportioned, the pressure is constant at all points of the line. Now what does it mean to make the section of conductor proportional to the current? It means that, so far as weight of copper is concerned, it is equivalent to having a separate wire for each lamp going round the whole circuit. Here is the weak point of the whole system. Equalisation of pressure is attained by putting in useless resistance. The wire might go up to the lamp, and then back to the dynamo, without making the whole circuit, and equalisation of pressure attained by putting in a resistance at the lamp equivalent to the copper wire which has been cut out. Such a resistance could be made of much cheaper material than copper. Thus the reversed parallel system, beautiful at the first glance, is the same in efficiency as, and inferior in economy to, the direct parallel system, with resistances in the lamps to equalise pressure.

It seems to me that this consideration is absolutely condemnatory of the reversed parallel system for application to mains. It is worse than the direct parallel system with resistances introduced, and we have already condemned the latter. It becomes, then, hardly necessary to speak of it further, but a somewhat similar arrangement may be used with multiple series systems. I cannot refrain from pointing out to you a device by means of which the equalisation of pressures might be maintained, even when the maximum number of lamps is not in action. In this case the proportion of the + and − conductors should be altered in some parts. Suppose the conductors to be made up of a number of insulated wires in sections, and that at each end of a section each wire is attached to the + bundle, or the − bundle of wires. It would be easy to design an arrangement by which these terminals could be changed from the + to the − bundle, or *vice versâ*. It would be also easy to design an automatic switch by which, when the size of the + and − mains was not proportioned to the currents in them, the two terminals of one or more wires should be so transferred from the bundle which is too great to the one which is too small.

We have now reached the most important and difficult part of the problem. Leaving behind the case of a single street, we come to a district. In the choice of districts to light, care should be taken in the selection of those which will give the best return for outlay of money and cost of maintenance. It is needless to say that a district with many theatres and restaurants is favourable, and that many storied houses have a larger consumption for a given area than a district of low houses. The first thing to be done is to estimate as well as possible (and it is not possible to be exact) the number of lights to be supplied in each part of the district. The only alternative to this method would be to lay mains large enough to supplant gas entirely. This would involve a great outlay in mains which for years would generally be lying useless, or at most diminishing in a feeble degree the cost of wasted energy. It is quite right that the engineer should calculate the cost of mains on these lines, but in general it could not be recommended to spend so much money on laying

Digitized by Google

them. It is generally better to trust to laying additional mains as required.

Tree Main.—First, let us suppose that we have all the mains connected in parallel with all the dynamos. This is a case which I find has been well discussed by Mr. Kapp in *The Electrician*, August 4. 1883, but it is a system which we shall soon find reason to condemn. The reason why I object to this system is that the size of mains is not made dependent on considerations of economy, but on that of variations of pressure allowed by the Board of Trade. This must be the case with the above mode of working, if the district is large. The difference of potential between the near and distant lamps is insensible when there are few lamps burning. The difference when the maximum number of lamps are burning is considerable. Hence, if the near lamps are kept at constant pressure, the far lamps will vary at different times by the amount of the difference between the near and far lamps, when all are on. Now, the Board of Trade forbid a greater variation than 10 per cent. (5 per cent. up and down). Hence the maximum difference of pressure between near and far lamps must not exceed 10 per cent. Here I may say that 10 per cent. is a far greater variation than is permissible. Two or three per cent. up and down is quite as much as can be allowed. Now, Mr. Kapp assumes the size of conductors to be limited by these considerations. He assumes the maximum difference of pressure between the nearest and the farthest lamp to be the maximum which can be allowed. On this view notice the following facts:—

1. If we have two similar areas, with equal number of lamps to light, one larger than the other, the mains in the former must be so increased as to make the fall of pressure to the most distant lamps the same in both. Hence the section of mains is proportional to R, the maximum distance, other things being equal, and their length varies as R, so the cost varies as R^2. 2. The section of mains varies as n, the number of lamps. 3. The section of mains depends in two ways on the pressure required for a lamp; (α) the current and section of mains are less in proportion to the pressure; (β) the variation in pressure allowable (being a percentage) is proportional to the pressure. Hence, on the whole, the section is inversed, as the square of E, the electric pressure of a lamp. 4. The section of mains varies inversely as p, the percentage variation of pressure allowed. On the whole, the section of mains and the cost of mains (assumed proportional) vary as follows:—

$$\text{Section varies as } \frac{n\,R}{p\,E^2}$$

$$\text{Cost varies as } \frac{n\,R^2}{p\,E^2}$$

Mr. Kapp has deduced a coefficient from actual estimates and finds:—

$$\text{Cost in pounds} = 0{\cdot}9 \times \frac{n\,R^2}{p\,E^2} \text{ or } 1{\cdot}2\,\frac{n\,R^2}{p\,E^2}$$

where R is given in 100 yards, and E in 100 volts, according as the most favourable or the least favourable of likely distributions is adopted. [The coefficient 1·2 is used for equal distribution of lamps, and 0·9 when the number of lamps at distance r varies as $\frac{1}{r}$.] To take an example where $n = 60{,}000$ lamps $R = 7$ (hundred yards), $E = \frac{1{\cdot}00}{1{\cdot}40}$ (hundred volts), $p = \frac{4}{10}$ ($\frac{2}{5}$ per cent. up and down). ∴ Cost is between $\frac{£661{,}500}{£135{,}000}$ and $\frac{£882{,}000.}{£180{,}000.}$ If we used lamps of 420 volts, the cost would lie between £15,000 and £20,000, instead of the lower pair of figures. But these figures are of no value; first, because 10 per cent. is too great a variation of pressure; and, secondly, because the economical size of mains is the primary consideration, and we must find a way out of the difficulty of variations of pressure.

We must now consider to what distance we may use the method of connecting all the mains, and charging them all with the same dynamos. I think we may say that 2 per cent. variation of pressure up and down is permissible. This gives a variation of four candles in an Edison 16-candle lamp. Now, by attention to the dynamos, this allows a range of 4 per cent., all lamps in the district requiring the same pressure. If telegraph wires came from the most distant and nearest lamps to the engine house to indicate on voltmeters the pressure at those points, the engineer would have his instructions to keep the near lamps as much above the normal pressure as the distant ones are below. Suppose that 100 volts is the normal pressure. When very few lamps are on, both near and distant mains would indicate 100 volts. This is the case where metal is laid for a large number of lamps, even at the distant points, and in any actual installation it may be taken to be approximately accurate. When the maximum number of lamps are on, there will be 4 per cent. difference. The engineer keeps the near lamps at 102 volts, and the distant ones at 98 volts, and we have only a 2 per cent. variation. If, however, the near lamps be supplied with 102-volt lamps, and the far ones with 98-volt lamps, it will be seen that we can double the distance, with of course double the fall of pressure, giving 8 per cent. variation, with only 2 per cent. variation up or down in any lamp. For when few lamps are on, the near and far lamps have the same pressure. The engineer makes this 100 volts, which is − 2 per cent for near lamps, and + 2 per cent. for far lamps. When all the lamps are on, the engineer makes the near lamps 104 volts, or + 2 per cent., and the far lamps 96 volts or − 2 per cent., giving a difference of 8 per cent., and doubling the distance which can be supplied. This method has the advantage of not always using the near lamps above, and the far lamps below, their normal pressure; but I must confess I do not like the idea of supplying different consumers with lamps of different pressure, if it can be avoided without loss of economy.

We have now to consider at what distance from the central station we may supply lamps, so that the fall of potential does not exceed 4 per cent. or 8 per cent. This depends on the pressure required for lamps, and on the size of conductors chosen per 1,000 amperes. Every engineer in designing mains must fix on these points for himself, but in order to fix our ideas, I will take the case of 100 volt lamps, and 1½ square inch per 1,000 amperes. With that size of conductor the loss of pressure with the maximum number of lamps is 3·22 volts per 100 yards of double conductor; 4 per cent. is lost in a distance of 124 yards, and 8 per cent. in a distance of 248 yards; so that this is the greatest distance of a lamp from the central station (according as we supply lamps of the same or different normal pressures to different districts) which is consistent at the same time with economical size of conductors, and with a maximum variation of 2 per cent., up and down, in the pressure supplied to any lamp. From what has been said, it will be seen that in this way of working, the pressure at the station must be constantly regulated, either by the speed of the engines, or by introducing resistance into the field magnet coils. I prefer the latter method, unless the newly invented electrical governors (such as Willans') prove a success.

The above considerations apply to what I call the tree system of laying mains. The trunk of the tree starts from the engine house, and throws off branches, from which twigs spring, and leaf stalks from these, and the lamps are represented by leaves. The above considerations do not apply to cases where feeder mains go from different dynamos, or generally where the pressure in different mains at the station is different. It appears, then, that the tree system is of limited application under the conditions which I assumed, the maximum distance being 248 yards. If, however, we had lamps of 400 volts, the maximum distance (measured, of course, along the line of leads) would be 992 yards. In the tree system we must lead our conductors along the shortest route from each lamp to the central station, and then count the number of lamps supplied, and so determine the section of copper required by each point of the mains. If we connect the ends of the positive twigs and the ends of the negative twigs, we do not alter the flow of current when the maximum number of lamps are on, if the size of mains is chosen for this maximum distribution; but when the consumption is limited, we consume a little more energy in proportion, and the distant lamps are a little brighter. But, considering the uncertainity of estimating the relative consumption in different parts of a district, the distant lamps will probably be better served if the + twigs are joined together, and so with the − twigs. I wish to repeat the statement that, in the tree system, the amount of copper in all parts of the mains is the same as if a separate wire came from every lamp to the station. As a consequence, the engineer must notice that if a plant has been laid down for a certain number of lamps, and it be afterwards desired to extend the boundary of the district, the conductors already laid down are of no use in leading current to the beginning of the extended district. The conductors must be enlarged, or else new mains must be led to supply the newly-added district. The engineer must also use his influence strongly to prevent the natural tendency to take a larger number of lamps in a district of supply than that for which the conductors have been calculated.

It must be acknowledged that the simple tree system, where all the dynamos are connected in parallel with the mains, presents a very serious obstacle in the rapid fall of potential, the maximum distance of a lamp from the station along the line of conductors, consistent with the economical considerations, being 124 yards, if the pressure required for all lamps is the same. In the year 1880 Mr. Edison took out a patent in England (No. 3,880), besides outher countries, in which he gets over the difficulty by using what he calls feeder mains. It is a result which would certainly have been arrived at by any one who thoroughly and intelligently worked out the problem. But, so far as I can discover, he was the first, by a long time, to hit upon this cure for the evil; and I must say that it is interesting to find how thoroughly he had gone into the problem at that early stage of electric lighting, although, in a patent of slightly earlier date, he describes the tree system as being all that is required for electric lighting, and does not notice the fact of fall of potentials as affecting the problem. In the patent cited above, Mr. Edison gives, among other irrelevant matter, two solutions of the theory which I may call the multiple tree system and the network system of laying conductors. I will not follow him in his method of using these systems in practice, because he does not use them to the best advantage. In this case, as heretofore, I will advance with you, by common-sense arguments, to the more perfect types.

(To be continued.)

NOTES ON THE SEAT OF THE ELECTROMOTIVE FORCES IN A VOLTAIC CELL.*

BY J. HOPKINSON, M.A., D.SC., F.R.S.

The following is an expansion of some short remarks I made when Dr. Lodge's paper was read at the Society of Telegraph Engineers:—

I. *The controversy between those who hold that the difference of potential between zinc and copper in contact is what is deduced by electrostatic methods, and those who hold that it is measured by the Peltier effect, is one of the relative simplicity of certain hypotheses and definitions used to represent admitted facts.*

Taking thermoelectric phenomena alone, we are not imperatively driven to the conclusion that the difference of potential between zinc and copper is the small quantity which the Peltier effect would indicate; but by assuming with Sir W. Thomson that there is an electric property which

* Communicated by the author to the *Phil. Mag.* for October.

Digitized by Google

may be expressed as an electric convection of heat, or that electricity has specific heat, we may make the potential difference as great as we please without contradiction of any dynamical principle or known physical fact. Let us start with the physical facts, and introduce hypothesis as it is wanted. These are, as far as we want them :—(1) If a circuit consist of one metal only, the electromotive force around the circuit is nil however the temperature may vary in different parts; this, of course, neglecting the thermoelectric effects of stress and magnetism discovered by Sir W. Thomson. (2) If the circuit consist of two metals with the junctions at different temperatures t_1, t_2, then the electromotive force round the circuit is the difference of a function of t_2 and of the same function of t_1. According to Prof. Tait the function is $b(t_2-t_1)\left(T-\frac{t_2+t_1}{2}\right)$, or, as we may write it, $A+Bt_2-C\frac{t_2^2}{2}-\left\{A+Bt_1-C\frac{t_1^2}{2}\right\}$; the series may perhaps extend further, but, according to Tait's experiments, the first three terms are all that are needed.

Now, but for the second law of thermodynamis, we should naturally assume that $A+Bt_2-\frac{Ct_2^2}{2}$ was the difference of potentials at the junction of temperature t_2, and $A+Bt_1-\frac{Ct_1^2}{2}$ at the junctions of temperature t_1; we should further assume that what the unit of electricity did was to take energy $A+Bt_2-\frac{Ct_2^2}{2}$ out of the region immediately around the hot junction with disappearance of that amount of heat, and to take energy $A+Bt_1-\frac{Ct_1^2}{2}$ into the region immediately surrounding the cold junction, with liberation of that amount of heat. Now apply the second law of thermodynamics in the form $\Sigma\frac{q}{t}=0$, and we have

$$A\left(\frac{1}{t_2}-\frac{1}{t_1}\right)-C\frac{t_2-t_1}{2}=0,$$

whence it follows that $A=0$, which may be, and that $C=0$, which is contrary to experiment. The current then must do something else than has been supposed, and the hypotheses differ in expression at least as to what that something else is. The fact to be expressed is simply this: When a current passes in an unequally heated metal, there is a reversible transference of heat from one part of the metal to another, whereby heat is withdrawn from or given to an element of the substance when a current passes through it between points differing in temperature, and is given to or withdrawn from that element if the current be reversed. Sir W. Thomson proved that this follows from the fact of thermo-electric inversions and the second law of thermodynamics, and verified the inference by experiment, his reasoning being quite independent of any hypothesis.

Suppose wires of metals X and Y are joined at their extremities, and the junctions are kept at temperatures t_2, t_1. The observed electromotive force around the circuit is $f(t_2)-f(t_1)$, or within limits, according to Tait, $B(t_2-t_1)-\frac{1}{2}C(t_2^2-t_1^2)$. The work done or dissipated by the current when unit of electricity has passed is $f(t_2)-f(t_1)$, and this is obtained by abstraction of heat from certain parts of the circuit and liberation of heat at other parts by a perfectly reversible process. Let $F(t_2)$ be the amount of heat which disappears from the region surrounding the junction t_2 when unit of electricity has passed from X to Y. Let an element of the wire X have its ends at temperatures t and $t+dt$, and let the quantity of heat abstracted from this element when unit of electricity passes from t to $t+dt$ be represented by $\phi(t)dt$, and let the same for Y be represented by $\psi(t)dt$. By the first law of thermodynamics we have

$$F(t_2)+\int_{t_3}^{t_1}\psi(t)\,dt-F(t_1)+\int_{t_1}^{t_2}\phi(t)\,dt=f(t_2)-f(t_1),$$

and by the second law, since the transference of heat from part to part is reversible,

$$F(t_2)/t_2-F(t_1)/t_1+\int_{t_1}^{t_2}\phi(t)/t\,.\,dt-\int_{t_1}^{t_2}\psi(t)/t\,.\,dt=0.$$

Differentiating we have

$$\left\{\begin{array}{l}F'(t)+\phi(t)-\phi(t)=f'(t),\\ F'(t)/t-F(t)/t^2+\phi(t)/t-\psi(t)/t=0;\end{array}\right.$$

whence

$$\left\{\begin{array}{l}F(t)=tf'(t)=Bt-Ct^2,\\ \phi(t)-\psi(t)=tf''(t)=Ct.\end{array}\right.$$

This really contains the whole of thermo-electric theory without any reference to local differences of potential, but only to electromotive force round a complete circuit. But when we come to the question of difference of potential within the substance at different parts of the circuit, we find that according as we treat it in one or the other of the following ways we may leave the difference of potential at the junctions indeterminate and free to be settled in accordance with hypotheses, which may be found convenient in electrostatics, or we find it determined for us, and must make our electrostatic hypotheses accord therewith.

The first way is that of Thomson, as I understand it. Assume that there is no thermoelectric difference of potential between parts of the same metal at different temperatures, at all events till electrostatic experiments shall show that there is. It follows that we must assume that the passage of electricity between two points of different temperatures must cause a conveyance of energy to or from the region between those points by some other means than by passage from one potential to another. Such conveyance of energy may be very properly likened to the convection of heat by fluid in a tube, for, although convection is in general dissipative, it is not necessarily so, *e.g.*, a theoretically perfect regenerator. Suppose, then, that in metal X unit of electricity carries with it $\int\phi(t)\,dt$ of heat, and in metal Y, $\int\psi(t)\,dt$, this will account for the proved transference of heat in the two metals. When a unit of electricity passes across a junction at temperature t from X to Y, it must liberate at that junction a quantity of heat $\int\phi(t)\,dt-\int\psi(t)\,dt$; but the actual effect at this junction is that heat $F(t)$ disappears; hence the excess of potential at the junction of Y over X must be

$$F(t)+\int\phi(t)\,dt-\int\psi(t)\,dt,\text{ or }A+Bt-\tfrac{1}{2}Ct^2,$$

A being a constant introduced in integration. If, then, we assume a "specific heat of electricity," the actual difference of potential at a junction may contain a constant term of any value that electrostatic experiments indicate.

But the facts may be expressed without assuming that electricity conveys energy in any other way than by passing from a point of one potential to a point of different potential. This method must be adopted by those who maintain that the Peltier effect measures the difference of potential between two metals in contact. *Define* that if unit-electricity in passing from A to B points in a conductor homogeneous or heterogeneous does work, whether in heating the conductor, chemical changes, or otherwise, the excess of potential of A over B shall be measured by the work done by the electricity. This is no more than defining what we mean by the potential within a conductor, a thing we do not need to do in electrostatics. This definition accepted, all the rest follows. Between two points differing in temperature dt the rise of potential is $\phi(t)\,dt$ in X, $\psi(t)\,dt$ in Y; at the junction the excess of potential of Y over X is $F(t)=Bt-Ct^2$.

The second method of arranging one's ideas on this subject has the advantage that it dispenses with assuming a new property of that hypothetical something, electricity; but there is nothing confusing in the first method.

II. The thermodynamics of the voltaic circuit may be dealt with on either method of treatment; in the equations already used, instead of speaking only of the heat disappearing from any region, we have to consider the heat disappearing when the unit electricity passes *plus* the energy liberated by the chemical changes which occur. Consider a thermo-electric combination in which there is chemical action at the junctions when a current passes.

If Gt be the function of the temperature which represents the energy of the chemical reaction which occurs when unit of electricity passes from X to Y across the junction, we have

$$F(t_2)+G(t_2)-F(t_1)-G(t_1)+\int_{t_2}^{t_1}\psi(t)\,dt+\int_{t_1}^{t_2}\phi(t)\,dt=f(t_2)-f(t_1),$$

$$F'(t)+G'(t)+\phi(t)-\psi(t)=f'(t),$$

$$F'(t)/t-F(t)/t^2+\phi(t)/t-\psi(t)/t=0;$$

whence

$$\left.\begin{array}{l}F(t)=)f(t)-tG'(t),\\ \phi(t)-\psi(t)=t\{f''(t)-G''(t)\}\end{array}\right\}$$

If now we proceed on the hypothesis of specific heat of electricity, we are able to make the differences of potentials at the junctions accord with the indications of electrostatic experiments. We are, then, by no means bound in a voltaic cell to suppose that there is a great difference of potential between the electrolyte and the metal because there is a reaction there, for we may suppose the energy then liberated is taken up by the change that occurs in the specific heat of electricity.

III. Adopting the second method of expressing the facts, we may consider further the location of the difference of potential in a voltaic cell. In the case of a Daniell's cell consisting of Cu | $CuSO_4$ | $ZnSO_4$ | Zn, at which junction is the great difference of potential? Dr. Lodge places it at the junctions of the metals and the electrolytes. For this there is really some experimental reason, but without such reason it is not apparent why there may not be a great difference of potential between $CuSO_4$ and $ZnSO_4$. In that case, in an electrolytic cell with zinc or copper electrodes and $ZnSO_4$ or $CuSO_4$ as electrolyte there would exist a small difference of potential between the metal and the electrolyte. Take the latter case, an electrolytic cell of $CuSO_4$, and let us leave out of account the irreversible phenomena of electrical resistance and diffusion. First, let us assume, as is not the fact, that the only change in the state of the electrolytic cell when a current has passed is addition of copper to one plate, loss of copper from the other plate; what could be inferred? Imagine a region enclosing the anode, when a current has passed, what changes have occurred within the region? An equivalent of copper has disappeared from the anode, and that same quantity of copper has departed and gone outside the region. But by our supposition, nothing else has happened barring increase of volume for liquid by diminished volume of metallic copper; there is no more and no less $CuSO_4$ in the region, the same quantity therefore of SO_4. All the work done in the region is to tear off a little copper from the surface of the anode and to remove it elsewhere. If the fact were as assumed it would follow that the passage of the current did little work in the

Digitized by Google

passage from copper to sulphate of copper, and consequently that the difference of potential between the two is small. But the fact is other things happen in the cell than increase of the cathode and diminution of the anode. In contact with the anode there is an increase of $CuSO_4$, in contact with the cathode $CuSO_4$ disappears; this is a familiar observation to every one. Reconsider the region round the anode. Assume as another extreme hypothesis that after a current has passed we have in this region the same quantity as before of copper, but more $CuSO_4$; SO_4 has entered the region and has combined with the copper. A large amount of energy is therefore brought into the region, which can only be accounted for by supposing that the electricity has passed from a lower potential in the copper to a higher potential in the electrolyte. The legitimate conclusion is, then, that there is between Cu and $CuSO_4$ a difference of potential corresponding to the energy of combination; and the basis of the conclusion is the simple observation that the copper is dissolved off one plate but remains in its neighbourhood, whilst it is precipitated on the other plate, impoverishing the solution. In other words, it is the SO_4 that travels, not the Cu. Now consider the ordinary Daniell's cell. Is there a substantantial difference of potential at the junction of $CuSO_4$ and $ZnSO_4$? Is there, in fact, a difference apart from the Peltier difference? Imagine a region enclosing the junction in question; it might have been that the effect of a current passing was to increase the zinc and diminish the copper by an equivalent of the electricity which passed, from which we should have inferred that the seat of the electromotive force in a Daniell's cell was at the junction of the two solutions. But it is more nearly the fact that no change whatever occurs in the region in question when a current passes, and that all that happens is that a certain quantity of SO_4 enters the region and an equal quantity departs from it, from which it follows that there is no potential difference, other that a Peltier difference, at this junction.

Neither of the extreme suppositions we have made as to concentration or impoverishment of the solution is in fact true, but they serve to show that the position of the steps in potential depends entirely on the travelling of the ions. The fact is that in general both ions travel in proportions dependent on the condition of the electrolytes; it is probable that the travelling of the SO_4 depends on some acidity of the solution. Given the proportion in which the ions travel and the energy of the *reversible* chemical reaction which occurs, and we can calculate the differences of potential at the junctions.

In the preceding reasoning an assumption has been made, but not stated. It has been assumed that the passage of a current in an electrolyte is accompanied by a movement of ions only, and not by a movement of molecules of the salt; that is, when unit of electricity passes through a solution of $CuSO_4$, xCu travels in one direction and $(1-x)SO_4$ in the opposite direction, but that $CuSO_4$ does not travel without exchanges of Cu and of SO_4 between the molecules of $CuSO_4$. In the supposed case when there is no concentration around the anode, my assumption is that Cu is dissolved off the anode, and that an equal quantity of Cu leaves the region around the anode *as Cu* by exchanges between the molecules of $CuSO_4$. But it is competent to some one else to assume that in this case SO_4 *as* SO_4 enters the region by exchanges between the molecules of $CuSO_4$, and that at the same time a molecule of $CuSO_4$ leaves the region without undergoing any change. Such a one would truly say that there was no inconsistency in his assumption; and that if it be admitted, it follows that the difference of potential at the junction $CuSO_4 \mid Cu$ is that represented by the energy of the reaction. I prefer the asssumption I have made, because it adds nothing to the ordinary chemical theory of electrolysis; but it is easy to imagine that facts may be discovered more easily expressed by supposing that an electric current causes a migration of molecules of the salt, as well as a migration of the components of the salt.

COMPANIES' REPORTS.

Brazilian Submarine Telegraph Company (Limited).

Report and accounts of the Directors for the half year ended 30th June last, to be submitted to the twenty-fourth ordinary general meeting, to be held at the Cannon-street Hotel, on the 29th inst., at two o'clock:—

The revenue for this period amounted to £81,419. 10s., and the working expenses to £19,774. 0s. 11d. (including £7,830. 7s. 3d. for repairs of cable). After providing £9,680 for debenture interest and sinking fund, and £927. 9s. 4d. for income tax, there remains a balance of £51,037 19s. 9d.; to this is added £2,792. 16s. 6d., brought forward from 31st December last, making a total of £53,830. 16s. 3d. A quarterly interim dividend amounting to £19,500 has been paid, and £12,000 transferred to the reserve fund, leaving a balance of £22,330. 16s. 3d. The directors now recommend the declaration of a final dividend of 3s. per share, making a total payment of 6 per cent. for the year ended 30th June, 1885, and that the balance £2,830. 16s. 3d. be carried forward to the next account. The various sections of the Company's line are in good working order, with the exception of the Madeira-St. Vincent 1874 cable, in which a fault appeared on the 12th September. This, however, does not interfere with the regular transmission of traffic by that cable. The Directors regret to announce the recent death of Senor Santos Silva, the Company's representative director in Lisbon. They have, under the powers given them by the Articles of Association, elected the Duke de Loulé to fill the vacancy thereby occasioned. Two of the directors, the Duke de Loulé and the Right Hon. Viscount Monck, retire by rotation at this meeting, and being eligible for re-election, offer themselves accordingly. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

Direct Spanish Telegraph Company (Limited).

Report of the Directors for the half year ended 30th June last, to be presented at the general meeting of the shareholders, on Friday, October 30th, 1885:—

The accounts for the half year ended 30th June, 1885, show, after providing for debenture interest, a balance to the credit of profit and loss of £3,469. 12s. 10d. The traffic receipts show a falling off of £1,384. 6s., as compared with the corresponding half year of 1884, and a decrease of £823. 17s. 3d. as compared to last half year. This unsatisfactory result is due to the stagnation of trade with Spain during the period for which the accounts are presented. The Directors having been unable to obtain a suitable steamer at a moderate cost during the summer months, the overhaul of the original Bilbao cable has been postponed. The new Bilbao cable and the Marseilles-Barcelona cable worked perfectly during the half year. Unfortunately, on 11th inst., an interruption of the new Bilbao cable occurred in deep water, about 70 miles from Bilbao. Arrangements have been made for a cable ship to proceed to the spot and effect the repairs. The Directors would remind the shareholders that the joint purse arrangement with the Eastern Telegraph Company secures to this Company during the interruption a revenue nearly equal to that earned when the Bilbao cable route is open. As the circumstances mentioned by the Directors in their circular of the 14th January last, embodied in the Directors' report adopted at the last general meeting, still exist, they must continue to withhold the payment of dividend on the preference shares, and they therefore propose to put £3,400 to the reserve fund, which will then amount to £8,400, and to carry £69. 12s. 10d. to the next account. At the International Telegraph Conference recently held at Berlin, all European telegraph administrations and private cable companies had to submit to certain reductions in their tariffs. In the case of this Company it is anticipated that the effects of these will be counterbalanced by a development of the traffic and by the reduction in the inland rates at both ends. The new regulations of Berlin come into force on 1st July, 1886.

NOTES.

THE ANTWERP EXHIBITION.—This Exhibition will be closed on the 1st prox.

THE TELEGRAPH IN SIAM.—Information has been received that the Siamese Government have completed the telegraph line from Bangkok to Rahung.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 23rd inst. amounted to £3,137.

ELECTROLYSIS.—Dr. D. Tommasi has recently made public some very interesting notes upon the phenomena attending the electrolysis of hydrate of chloral.

A NEW GALVANOMETER.—We are informed that M. Félix de Lalande is about to lay before the members of the Académie des Sciences a galvanometer upon an entirely new principle.

STRUCK OFF THE REGISTER.—From Tuesday's *London Gazette* we notice that the Electric Engine Company (Limited) has been struck off the register of Joint Stock Companies, and is thereby dissolved.

UNDERGROUND WIRES IN DETROIT, U.S.A.—The work necessary for putting telegraph, telephone, and electric light wires underground in Detroit, Mich., began 29th September. The Dorsett conduit is being used.

A GOOD CUSTOMER.—From *Australian Information for British Journalists* we notice that during the past year no less than 17,512 packages of telegraphic materials were sent to New South Wales from this country.

EARLY!—According to the *Bulletin International des Téléphones* French scientists are rather more given to early rising than their English brethren. On the 26th and 29th inst. two conferences were held in the Exposition du Travail at half-past nine a.m.

CARRIAGE LIGHTING BY ELECTRICITY.—The Lancashire and Yorkshire Railway Company are still experimenting with the electric light for the lighting of their carriages, but will not be able to come to any conclusion on the matter in time for the coming winter.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 23rd October, were £2,424, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE TELEPHONE IN FRANCE.—The telephone system at Saint Etienne, due to the enterprise of the Société Générale des Téléphones, was opened for traffic on the 15th inst., with a list of 26 subscribers. In this system overhead insulated wires have been used.

ELECTRICITY V. GAS AT BRUSSELS.—The two illuminants are in active dispute at Brussels, the bone of contention being the lighting of the Grand Place. The Municipal Council of Brussels are sorely perplexed, but gas will, in all probability, have to take second place.

ELECTRO-THERAPEUTICS IN FRANCE.—An important instal lation, devoted to the service of electro-therapeutics, has been put down in the Salpêtrière Hospital at Paris by the Maison Breguet. This consists of two Carré electrostatic machines, actuated by a Gramme dynamo placed some two hundred yards distant.

QUITE RUSSIAN.—An Electrical Exhibition is to be held in St. Peterburg from the coming month until February, 1886. Foreign exhibits are not to be permitted. The show will probably, therefore, be restricted to the wonderful motor we have heard so much about, and the still more wonderful Stépanoff battery.

A COURSE OF SCIENCE LECTURES.—An important series of science lectures was commenced on the 16th inst. at the Memorial Hall, London-street (near Bethnal Green Junction), and will be continued every Thursday. Yesterday the lecturer was Prof. Guthrie, F.R.S., and the subject "Electricity." The price of admission is a mere trifle.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the directors of this company, held on the 28th inst., it was resolved to place £6,000 to reserve, and to recommend to the shareholders at the approaching meeting that a dividend of 9s. per share be declared on account of arrears of dividend on the first preference shares.

CABLES FOR ITALY.—We are informed that a contract for a submarine telegraph cable to be laid from Naples to Palermo has been concluded between the Italian Government and the firm of Pirelli and Co., of Milan. The maintenance of this line is estimated at about 80,000 lire per annum. It is said that all the islands on the coast are to be similarly connected.

PERSONAL.—Mr. E. W. Parsone (the manager of the West African Telegraph Company) left England in the R.M.S. "Tamar," on Saturday last, to assume his duties at Praia St. Thiago, Cape de Verde Islands. He is accompanied by Mr. Reginald Webb (the assistant accountant), and Mr. A. Kitching (the superintendent of one of the company's stations).

THE EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—This company notify that the coupon on their 5 per cent. Manila Debentures (June, 1880), due on the 1st November proximo, will be payable on and after that date on presentation of the same at the Consolidated Bank, 52, Threadneedle-street, E.C. Coupons should be left three clear days for examination.

TELEPHONIC COMMUNICATION IN BOURNEMOUTH AND POOLE.—The Western Counties and South Wales Telephone Company are progressing with their arrangements for supplying telephone communication for domestic and commercial purposes in Poole and Bournemouth. It is proposed to connect the police station and the dispensary at Bournemouth with the central office, free of charge. The fire stations will also be connected.

THE TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.—This company notify that the 21st distribution on the certificates of the second bonus trust, issued under the trust deed of the 12th March, 1875, will be made on and after the 2nd November, 1885. The distribution will be at the rate of 1s. 1d. per £5 certificate, payable two clear days after presentation of coupon No. 21, at Messrs. Barclay Bevan and Co.'s Bank, 54, Lombard-street.

THE STEPANOFF PRIMARY BATTERY.—Glowing accounts are being given of the Russian modification of the Daniell, called the Stépanoff cell. For electric lighting purposes the battery is said to consist of 55 elements, comprised within a space of 55 cubic decimètres. These are said to be sufficient to supply 10 45-volt Jablochkoff lamps for a period of 120 hours. The cost is estimated at 10 per cent. less than that of gas at St. Petersburg. Hum!

H.M.S. "DEVASTATION."—The "Devastation," Captain Luxmoore, left Portsmouth Harbour, and anchored at Spithead

Digitized by Google

on the morning of the 27th inst., preliminary to superseding the "Lord Warden" as coastguard ship at Queensferry. Since her return from the cruise of the Evolutionary Squadron she has had her bunkers ventilated upon a new principle, and has been fitted with dished torpedo ports—for the purpose of keeping out the water—and also with the electric light.

LIGHTING OF REGENT-STREET.—At a recent meeting of the St. James's Vestry, Westminster, Mr. A. Keevil called attention to the wretched system of lighting which existed in Regent-street. He said several of the lamps had been there for considerably over half a century. They were in a wretched state of dilapidation, and a disgrace to the parish. Mr. R. W. Burgess explained that the Lighting Committee were in communication with the West London Electric Lighting Company as to lighting the street by electricity.

THE ELECTRIC LIGHT IN THE TEMPLE.—The Inner Temple Library was lighted by the electric light for the first time on the evening of the 26th inst. About 140 small lamps are employed, the system in operation being the Swan-Edison. The engine house is situated near the Inner Temple lecture hall in King's Bench-walk, and the engine for generating the light is a twelve horse-power one. As oil lamps only have hitherto been in use in the library, the change effected by the substitution of the electric light is peculiarly striking.

BOOKS RECEIVED.—"High School Science Series. Lectures on Heat, Sound, and Light," an elementary text-book for students. By Richard Wormell, D.Sc., M.A. London: Thomas Murby.—"Etudes Electriques et Mécaniques sur les Corps Solides. Conférences by Lazare Weiller." Paris: J. Michelet.—"Die Internationalen Absoluten Maasse, insbesondere die Electrischen Maasse; für Studirende der Electrotechnik." By Dr. A. von Waltenhofen, Professor of the Technical High School, Vienna. Braunschweig: Frederich Vieweg and Son.

THE ELECTRIC LIGHT IN SWEDEN.—Owing to the great height of water lately in Ljusne river, floating has temporarily been suspended in the lower river, and picking out the logs to be drawn on land for winter sawing at Ljusne saw mill could not, in consequence, be proceeded with, for which reason now, to make up for lost time, having first tried torches to get sufficient light at the timber booms, the electric light has been carried from the saw mill, and been found especially suitable, as it not only considerably lightens the labour, but also enables it to be done with greater safety.

PERSIAN GULF CABLE.—The cable steamer "Dacia," with Colonel Champain and Sir Henry Mance on board, arrived at Port Said on the 23rd inst., and the "International" arrived there on the 27th inst., all well. These vessels proceeded to Yask (Persian Gulf), where they are expected to arrive about the 21st November. Immediately on their arrival the laying of the new Persian Gulf cable will be commenced, under the personal superintendence of Colonel Champain, R.E. We understand that a slight collision occurred between the "Dacia" and another vessel in the Canal.

SHAM LEATHER.—An electrical process for the imitation of leather surfaces has recently been described. The leather which it is desired to imitate is first well cleaned and coated with graphite, as in electro-plating a smaller article. It is then placed in a copper bath, the tank of which is large enough to receive easily a skin of any size. A dynamo generating a powerful current furnishes the electricity. The copper is deposited upon the coated surface of the hide to a thickness of one-sixteenth to one-eighth of an inch. The plate thus formed reproduces, but reversed, every mark and minute vein of the leather, so that a print can be easily taken from it.

THE TELEPHONE AT GREENOCK.—In connection with a series of lectures which are being delivered in Greenock under the auspices of the Philosophical Society of that town, Mr. W. Lant Carpenter, B.A., F.C.S., manager of the School of Electrical Engineering, London, delivered the third of the course, "The Telephone," in the Town Hall, which was crowded to its utmost capacity, about 3,000 persons being present. In the course of his lecture Mr. Carpenter opened communication with the *Glasgow Herald* office, where a party of ladies sat listening to the lecture through the telephone, every word of which was heard with the greatest distinctness. In the Glasgow National Telephone Exchange the lecture was also well heard.

THE ELDORADO THEATRE, PARIS.—The Eldorado is at the present moment the only theatre in Paris entirely lighted by electricity, and this is rendered more remarkable in that Cance arc lamps are alone used. It is the only instance, with which we are acquainted, of a theatre possessing an installation excluding both the incandescent lamp and gas. The mechanical section of the plant comprises an Olry and Grandmange 40 horse-power steam engine and a powerful boiler. The dynamos, a series of small machines, are of the Gramme type, manufactured by the firm of Ducommun. Each of these gives a current of from 35 to 40 amperes, with a difference of potential at the terminals of from 55 to 70 volts, which is distributed between five lamps in multiple arc; 35 Cance arcs are included in the system.

TELEGRAPH POSTS AT BOURNEMOUTH.—At a recent meeting of the Bournemouth Improvement Commissioners, some discussion took place on the subject of a letter from the Telegraph Department of the General Post Office as to the substitution of underground pipes for the present wooden posts in the Bournemouth district. The letter stated that the department were preparing for the laying of pipes between the two railway stations, but a member of the commission moved that the clerk should be instructed to inquire whether the authorities would be disposed to continue the underground pipes throughout the whole of the commissioners' district, especially calling attention to the necessity of the scheme being carried along the Poole road, where at present the poles interfered with the foot traffic. The proposal was agreed to.

THE TELEPHONE SUITS.—The Orange, N. J., *Chronicle* says:—Prof. J. R. Paddock, of the Stevens Institute, has been engaged the past summer in important investigations as expert for the Overland Telephone Companies of New Jersey and Pennsylvania, in the suits pending in the United States courts for infringement of Bell's patents. The defence rests in part upon the inventions of Philipp Reis. Prof. Paddock received some time since the *original instruments of Philipp Reis* from Frankfort, Germany, and has been engaged with E. W. Smith, of New York, in testing their efficiency as regards this much disputed point. They have proved, we are informed, that the *identical telephone used by Reis at his lecture in* 1861 will transmit speech without any alteration. They stated that they had used it in Prof. Paddock's laboratory on a line from the house to the stable, 350ft, and had succeeded in sending many words and short sentences and the words and music of various songs.

ZINC MANGANESE BATTERY.—In some experiments with Leclanché batteries, Dr. Emil Boettcher used for the negative

Digitized by Google

element plates consisting of 40 per cent. of retort carbon. 55 per cent. of manganese, and 5 per cent. of binding medium, the whole being combined under a hydraulic pressure of 200 atmospheres. The dimensions of the plates were 12 centimetres long, 4·2 centimetres wide, and 2 centimetres thick. The electromotive force of a cell composed of such a plate, and an amalgamated zinc rod in a solution of sal ammoniac was 1·56 volt. From a calculation of the quantity of heat generated and absorbed by chemical action in a battery of this kind, Dr. Boettcher concluded that sulphuric acid would give a better result than the solution of ammonic chloride, provided a counter electromotive force was not set up in consequence of the formation of manganous sulphate and liberation of oxygen; but no such opposing force was manifested, although manganous oxide was dissolved. The electromotive force was 2·2 volts, or almost 50 per cent. higher than that of a Leclanché battery, in which a solution of sal ammoniac forms the exciting liquid. After remaining on short circuit for six hours, the cell gave 2·1 volts, and at the end of seventy-six hours, the electromotive force was rather more than 1 volt.—Abstracts *Proc.* Inst. C.E.

THE COLCHESTER INSTALLATION.—It is said that the South-Eastern Brush Electric Light and Power Company have resolved to liquidate, and to dispose of their works at Colchester, if possible. This has not yet been done, but there is some reason to believe that unless the subject is promptly taken up by Colchester people, the whole plant will be removed; the City of London, as well as an American city, says an Essex contemporary, being said to be in treaty for the purchase of the undertaking. The district covered by the license comprises High-street, Head-street, and Culver-street, Colchester. The plant already in position comprises the street works and conductors, sufficient for the supply of about at least 2,200 lamps of present character as to consumption of current. A central station in Culver-street is fitted with a steam engine (by Davey, Paxman and Co.), dynamo machines, and all necessary appliances for the generation and distribution; and five storage battery stations situated in Culver-street, Head-street, and High-street, are fully equipped with accumulators, rocking switches, &c., upon the B.T.K. system, and capable of supplying current for about 1,000 lamps. The cost of the plant amounts to about £8,000, but by arrangement with the vendor company it is said that the whole would be transferred to a new company or other purchaser for the sum of £1,500.

SENSITIVE.—Our gas lighting contemporaries cannot find much that is true to say against our favourite illuminant. They, however, display at times a good deal of ingenuity—in fact—twisting—in order to be able to arrive at conclusions which agree with the interests they represent, and which are therefore inimical to those of electric lighting. In view of this, it is refreshing to find that at least one of our contemporaries is sensitive, even to criticism of a much milder type Commenting upon an article recently published upon Dr. Schilling's report upon lighting in Germany, it says that the position of the writer "respecting gas lighting is similar to that of the Ancient Romans to geography, as described by Mark Twain. He declared that the 'knowledge' of the physical world which they 'did not possess was very extensive.' At least it does not lie in the mouth of a writer of this order to find fault with Dr. Schilling, or any other gas engineer, for seeing more of the weaknesses than of the excellences of electric lighting." To admit any one of the excellences of the electric light would certainly be absurd in a gas engineer. With nothing but faults apparent the light is quite formidable enough as a rival. Argument is, however, unnecessary. We only wish to point out that our gas contemporary is in the position of the small boy who, having repeatedly attacked a more powerful one and eventually provoked a return, plaintively remarked "it hurts!"

WEST AFRICAN CABLES.—The cable steamer "Silvertown" arrived at Dakar, Senegal, on the 22nd inst., and landed the Dakar shore end on the 24th inst.; her tender, the "Buccaneer," arrived at Teneriffe, after a voyage of five days, from England, on the 24th inst., and was expected to reach Dakar yesterday, the 29th inst., where she would join the former vessel. Laying of cable will be proceeded with at once, connecting up Dakar with Conakry (French possession near Sierra Leone), St. Louis du Sénégal, Bolama, Bissao, and St. Thiago in the Cape de Verde Islands. So soon as permission to land has been accorded by H.B.M.'s Government, the West African Telegraph Company intend connecting up Bathurst and Sierra Leone, and to give those colonies the benefit of duplicate communication with England, first through the lines of the Brazilian Submarine Telegraph Company and the Eastern Telegraph Company, and secondly through the lines of the Spanish National and Direct Spanish Telegraph Company. The "Buccaneer," on completion of the cable laying to Conakry, or Sierra Leone, will proceed to thoroughly sound and reconnoitre, as far as St. Paul de Loanda, the ground over which the extensions of these lines will be laid. The English Government are sending out the surveying vessel "Sylvia" to the west coast of Africa especially for the determinations of longitudes of various points along this coast, and the West African Telegraph Company have placed the cables already laid and those in process of laying at the disposal of the Hydrographer to the Admiralty. This vessel leaves at the end of the present year.

WHITEHAVEN SCIENTIFIC ASSOCIATION.—At a *conversazione* recently given by this society there was an interesting display of scientific apparatus. The National Telephone Company exhibited a large collection of telephonic instruments, amongst which were samples of the early telephones of Reis, Edison, and Dolbear. The company had also connected the hall to their Whitehaven Telephone Exchange, through which the guests were able to converse during the evening with Frizington, Workington, and Maryport. At the last-named town a violin player was stationed, whose strains were distinctly audible in Whitehaven, notwithstanding that a distance of fourteen miles separated him from his audience. Towards the finish of the evening Mr. Alfred R. Bennett, general manager of the National Telephone Company, gave a historical sketch of the telephone. He referred to traditions of such an instrument having existed long ago amongst the Chinese and Persians, and read a translation of an anonymous letter addressed to Comte du Moncel in the year 1857, the writer of which not only expressed his belief in the possibility of transmitting speech by electricity, but in stating how he thought the feat might be accomplished he actually described in its essential details the telephone which was used to day in West Cumberland and all the chief cities of the earth. Mr. Bennett then described the mechanical telephone, and the inventions of Reis, Varley, Elisha Gray, Paul Lacour, Graham Bell, Hughes, Dolbear, and Edison, as well as the modification of the Hughes-Bell telephone designed by Mr. Gower, whose death he alluded to in feeling terms. The description of each instrument was illustrated with the actual apparatus.

TELEPHONING FROM LIGHTSHIPS.—An experiment of the greatest importance to the commercial world is now being made on the east coast of England by the Telegraph Construction and Maintenance Company. For the last eight months

Digitized by Google

the company has had several of its best operatives located in the neighbourhood of the Naze, off which the most dangerous sands round England are to be found. These gentlemen are hourly in communication by telephone with a lightship which is anchored ten miles out in the vicinity of the Swin passage. An ordinary telegraph cable has been laid from Walton-on-the Naze to the Sunk Lightship, and telephone and telegraphic apparatus have been affixed to both ends. It was considered improbable that the human voice would be conducted 10 miles, especially in rough weather; but this has been now proved to be thoroughly practicable. A conversation was carried on with Mr. Stevenson, one of the Telegraph Maintenance Company's officials (who was on board the Sunk Lightship) by telephone for a considerable time. Mr. Stevenson had been a month upon the boat, and had experienced all kinds of weather, during which time he had kept Mr. Lewis and Mr. Pinkerton, his colleagues on shore, fully informed of the state of the weather, roughness of the sea, and passing craft, adding frequently forecasts of weather, which usually turned out to be correct. A month upon the lightship is a trying ordeal; but Mr. Stevenson was so satisfied with the success that attended the experiment, and knowing, if the advantage of telephonic communication with lightships was understood and generally adopted, what a splendid boon it would be to mariners and merchants, that he spent his time busily in collecting information and watching the working of his electrical machines.

Telephone Rates.—A correspondent of the *Yorkshire Post* writes as follows:—"The rates charged by the National Telephone Company are simply prohibitory for the multitude. I saw an account of a meeting held in Leeds recently, under the auspices of the Leeds Chamber of Commerce, and the chairman of the company explained why rich physicians, lawyers, and prosperous fishmongers, &c., should have a reduction of £5 made in their rates over the charge of £15 made to merchants, ironmongers, &c. I cannot understand the sense of this dual rate. It is utterly beside the question to say that doctors and other professional men do not transact business by 'telephone.' They make appointments, and save time and money. Why, I have heard doctors say that the telephone is indispensable to them, and saves them the cost of a horse's keep. The thing is simply monstrous. Englishmen don't like being unfairly dealt with, and rather than be subjected to an extortionate charge hundreds of business people do without the telephone. If the thing cannot be supplied for a less rent than £15, how is it that professional men have it at £10? It naturally strikes one that the company make money out of the lower rate, or they would not supply the professional gentlemen at the price. If so, why not make all £10, and they would get hundreds of new members? If they cannot afford to do this, make all pay £15. I mix a good deal with people who are interested in the matter, and am sure that until this unfair system of favouring the rich professions is abolished the thing will not prosper. I am afraid that our only hope is that Government will take the telephones, as in Germany, and serve the public in as liberal a spirit as they do the telegraph."

The Creil Experiments.—M. Marcel Deprez has been experimenting with two new dynamos connected through a resistance equal to that of the cable between Paris and Creil. The results are said to be satisfactory. At a sitting of the Académie des Sciences on the 26th inst., M. Marcel Deprez communicated the result of some experiments made between Creil and La Villette over a distance of fifty-eight kilometres for the electrical transmission of power. M. Deprez stated that complete success was obtained, inasmuch as he had effected the transmission of forty horse-power out of eighty over the line without the current heating the wire or the machine. The costs of the experiment were defrayed by M. de Rothschild. M. Marcel Deprez's public experiments, between Creil and Paris, will take place in November. Two dynamos will be set in motion and several arc lamps lit by a current sent from Creil. As it was judged unsafe to have the earth as part of the circuit, there are two copper conductors hung 19ft. above the ground, which, to suit the somewhat exacting requirements of the telegraph office in view of the public safety, are coated with india rubber. The resistance of the line is 120 ohms; its insulation is absolute. In the preliminary experiments which took place the generator and receptor were placed side by side at Creil, and connected by a copper cable going to Paris and back. The generator can develop 6,000 volts and 30 amperes for 150 revolutions per minute. The force is supplied by two old locomotives, the wheels of which are replaced by flywheels. It is a remarkable feature of the dynamos that there are no sparks whatever at the collector, notwithstanding the high electromotive force. M. Alphonse de Rothschild has spent a large sum to enable M. Deprez to apply his theories at Creil, assisted by a select staff of engineers.

Multiple Telegrams.—A correspondent of the *Standard* says:—"I had occasion recently to send off one message to a number of addresses. As four of these lay within the same postal district, I proposed to send them as a 'multiple telegram,' which under the old tariff I could do for threepence per message for each address after the first. I asked the young lady presiding at the telegraph office whether any change had been made, and she, after consulting a book, informed me that the charge had been reduced to twopence per address. Pleased at this unexpected concession, I paid my money and left; but my satisfaction was somewhat dashed next morning when a messenger called at my house to say a mistake had been made, and that they wanted sevenpence more. In return for the extra sevenpence I asked to see the regulations under which I was (by the cheaper tariff) called upon to pay thirteenpence for what, under the old system, would have cost ninepence. I was handed a paper headed 'Multiple Telegrams,' which began, 'To simplify, &c.,' and then followed a full page of instructions and examples, the upshot of which was that 'all the words in all the addresses were to be added to the original message, and charged for, and then an additional charge of twopence per address was to be made for each one after the first.' The working of this arrangement is that registered addresses may pass at the old scale, but all ordinary addresses will cost from 50 to 100 per cent. (according to the number of words in the address) more than formerly. To the official mind it may be the acme of simplicity to substitute for the three words 'threepence per message' a page of instructions, which serve only to bewilder their own clerks, but I doubt whether it is worthy of a large 'Department' to adopt such a roundabout way of mulcting the public of a few extra pence; and to an ordinary intelligence it does look like (as the telegraph clerk expressed it to me) 'charging twice over.'"

Underground Wires.—According to a paper read by Mr. W. W. Jacques, before the Boston Society of Arts, the first telegraph line constructed in America, from Baltimore to Washington, in 1843, was intended to be laid underground, and the first nine miles were so laid. Four copper wires were each wound with cotton soaked in shellac, and the whole drawn into a lead tube. This tube was laid in a trench by the side of the railroad. Hardly was the section completed,

Digitized by Google

however, when water found its way into the joints, destroying the insulation, and the conductors failed. They were accordingly replaced by wires strung on poles, and the rest of the line was constructed in this way. After the introduction of gutta percha in 1846 many systems were tried, and after repeated failures the result is that there now exists a successful and durable system of underground telegraph wires connecting the principal cities of Germany and of France. In Paris not only all the telegraph lines, but also those for electric lights, telephones, and other purposes are carried through the sewers. Between 1847 and 1850 a system of cables was laid under ground between Berlin and other cities of Prussia. Gutta percha covered wires were drawn into lead tubes, which were buried in trenches two feet deep. In 1853 the entire system had been replaced by pole-lines. Somewhat similar cables were laid in Russia, France, Denmark, and England, but all, with the exception of those laid in the sewers of Paris, were unsuccessful. The trouble with all these systems was due to water, which destroyed the insulation. In 1855 the experiment was tried in France of laying bare wires in a trench filled with bituminous compounds, but the system failed. Since 1870 several lines have been built in England, Germany, and France, which have continued to work successfully. In Germany successful underground cables connect all the principal cities of the empire, while in France there is a system, dating from 1880, which connects Paris with all of the more important cities of that country. In the present German system, which dates from 1875, the cable is composed of seven copper wires, each coated with two layers of gutta percha and two of Chatterton's compound, and the whole covered with an armour of galvanized iron wires. This is laid in a trench by the roadside. The present French system was begun in 1880, and consisted of cables of gutta percha covered wires which are drawn into iron pipes three or four inches in diameter, and buried along the side of the road.

THE TELEGRAPH AND TELEPHONE IN COLUMBIA.—The first line of telegraph constructed in this country was that of the Panama Railroad Company. In the year 1865 the first National Telegraph line was constructed by a Mr. Styles, of New York, and up to that date there were five distinct National lines starting from the capital (Bogotá) covering a distance of 3,940 kilometres, and which put in communication 120 towns. One of these lines puts the capital in communication with the cable station at Buena-Ventura on the Pacific coast, another goes down towards the Atlantic coast, but is not yet complete. It would have been done ere this, but during the last twelve months there has been civil war. For most parts where the lines pass it is not very difficult to obtain splendid wood for posts. The class of insulators used are Siemens' iron hooded, and the instruments are Chester and Breguet manufacture, and are of the writing system. The alphabet used is of the American Morse system. With the exception of the State of Antioquia and the Atlantic coast, where the shut-circuit system is employed, all the lines work upon the open-circuit system. One of the lines puts Venezuela in communication with the capital. There are fifteen translating offices, which is a greater number than there is necessity for. The number of batteries in use in each office ranges from 30 to 100, much too great a number, but this in time will be regulated. The class in use is the Leclanché. When the telegraphs were first introduced into the country the priests preached against them, and they were constantly being destroyed, until the Government took strong measures to stop this barbarism. During this war all the lines have been more or less destroyed; but the Columbian Telephone Company have been able, at a tremendous outlay, to get them in order again. Columbia stands fourth in the list for length of line in S. America. There are two telephone companies there. The one in Barranquilla is the American Bell Company, which has about 50 subscribers. This was the first telephone company in the country. The other is in Bogotá, and is a native company, which, though not in existence a year, has over 100 subscribers, and but for the war would have had more than double the number. Both these companies use the Bell telephone, with Blake transmitter system. Besides these two companies the telephone is in use on four railroads, and also in several of the mines. The Inspector-General of Colombian Telegraphs and engineer to the Colombian Telephone Company is Mr. Ernest Danvers.

THE PITMAN AND THE TELEPHONE.—At one of our Northumbrian pits lately, the telephone has been laid into the clerk's office. As a matter of course, the introduction of such a wonderful piece of machinery created a no small amount of gossip in the district, and the powers of the instrument were exaggerated by the good people of the village to an enormous degree. A well-known pitman, noted for his inquisitiveness, made overtures to the office boy to allow him to have a try at the telephone. A Saturday afternoon was fixed (of course when the coast would be clear) for the trial, and Geordy was ushered into the presence of the mysterious box and tubes. "Stand heor," said the boy, pressing the white knob, "an aa'll ring the beggors up at Newcastle. Tyek haad o' these tubes, and taak when ye heor the bell ring." Presently the bell began to tinkle, and Geordy with a tube in each hand seemed to be puzzled over something. The bell kept on ringing. "Gan on, man; taak," said the boy. Geordy put one of the tubes to his mouth, and shouted with all his might, "Stop that bell." "Get oot, ye feuyl," exclaimed the boy, "taak into the box." "Hoo on airth can aa taak into the box when the lid's on't?" excitedly said Geordy. Still the bell rang on ringing. "Oh, dear me," gasped the youth, "what ignorance! Ye hev to had yor mooth ower the box and taak." "Haad the pipes te yor lugs, ye donkey!" shouted the boy, "or hoo'll ye heor?" Geordy did as he was told, and he distinctly heard, "Are you there? How much longer are you going to be?" Geordy, astonished, looked under the box, and then said, "That box is far ower little te haad onybody, or else he mun be a varry little chap that's in't." "There's somebody knockin' at the door," said the boy, "aa'll away doon and see we it is, ye knaa hoo te de noo. Aa'll be back doreckly." Geordy again placed the tubes to his ears and again he heard the words, "Are you there? What r-l-l-r-do-r-l-l-you-r-lr-want?" Geordy was somewhat puzzled at this last question, and more particularly at the rumbling sound he heard; an idea, however, struck him, and the following conversation ensued:—Geordy: "Wheer are ye?" Telephone: "At the Newcastle office, to be sure. Who do you want to be put into communication with?" G.: "What de'ye mean? T.: "Who do you want to speak to?" G.: "Oh, that aad lass o' mine; she's at Newcassel." T.: "Who-llr-r-r-r lr-do-rrrllrr-you-llr'say? What is—l-l-r-r-r-l-l-r-r—the number?" G.: "What are ye gobblin' on that way for? Aa cannot myek oot what ye say. Aa want te speak to ma wife; she's at Newcassel. An' what d'ye mean be axin hor numbor—she's not a pollis, ye fyeul." Then there was a loud crash. The person at the Newcastle office had evidently hit the telephone a sharp rap, producing, of course, to the listener, sounds like an explosion. Geordy dropped the tubes and rushed down the stairs as fast as he could, nearly knocking over the office boy, who was just then returning. "What's the mettor?" shouted the boy, "What's the mettor?" returned the retreating Geordy; "dinamite! dinamite! thor's somethin' borsted!"—*Newcastle Chronicle.*

THE DETERMINATION OF CURRENTS AND RESISTANCE IN A NETWORK OF CONDUCTORS.

(Continued from page 450.)

In following Dr. Fleming's paper we have so far been chiefly concerned with the development of a process of general application for the treatment of network problems. In the remaining portion of the paper this process is applied to the elucidation of some theorems of considerable theoretic interest, in which self and mutual induction in the branches of the network is taken into account.

We have, in the first instance, another proof, obtained in a very interesting manner, of a theorem due to Clerk Maxwell, and which he has put in the following terms :—"In any system of conductors in which there are no internal electromotive forces, the heat generated by currents distributed in accordance with Ohm's law is less than if the currents had been distributed in any other manner consistent with the actual conditions of supply and outflow of the current." When, however, the theorem has once been stated, it is readily perceived that this is but a special case of the results of general laws governing the transformation and degradation of energy.

We have next an investigation of the case of a shunted galvanometer placed in the circuit of a battery, taking into consideration the self-induction of the galvanometer coils. We will follow the steps of this solution somewhat in detail, as it is of a highly instructive character. We shall, however, give it in a somewhat simplified form.

Let G be the resistance of the galvanometer, L its coefficient of self-induction, S the resistance of the shunt, which, as is usual in practice, is supposed to be wound so as to have no self-induction; and let there be no mutual induction between the coils. Let E be the electromotive force of the battery and B its resistance.

Now, in dealing with problems which involve self or mutual induction, we must have recourse to the fundamental equation established by Maxwell for the treatment of the general case of electricity in motion. This equation yields an expression for the current at any given period of time in any circuit in which the kinetic energy, the impressed electromotive force, and the dissipation function are known—the "dissipation function" being an expression for the rate per second at which heat is being generated in the conductors throughout the circuit.

In the two-mesh network of the circuit under consideration, which is indicated in Fig 6, call the current in the galvano-

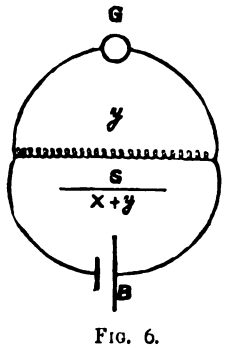

Fig. 6.

meter-and-shunt mesh y, and that in the shunt-and-battery mesh $\overline{x+y}$. Then the current through the galvanometer is y, the current through the shunt is x, and the current through the battery is $\overline{x+y}$. Now, in order to form the cycle equation for the mesh y, in which there is a branch having self-induction, we make use of Maxwell's general equation, which is as follows :—

$$\frac{d}{dt}\frac{dT}{dx} + \tfrac{1}{2}\frac{dH}{dx} = E.$$

Here H is the dissipation function, and is measured by the sum of the squares of the currents in each branch multiplied into the several resistances which they traverse. In this case we have

$$B\overline{x+y}^2 + Sx^2 + Gy^2 = H$$

which may be written

$$\overline{B+S}\,\overline{x+y}^2 + \overline{G+S}\,y^2 - 2S\,\overline{x+y}\,y = H.$$

Now, taking the first partial differential of this expression with respect to y, we obtain, for the second term in Maxwell's equation,

$$\tfrac{1}{2}\frac{dH}{dy} = \overline{G+S}\,y - S\,\overline{x+y}.$$

But this is seen at once to be the identical expression which would be equated to the effective electromotive force in the circuit, in forming the cycle equations according to the ordinary rule, if there were no self-induction in the circuit. It follows that, in order to obtain the complete expression for E, in accordance with the fundamental equation, we have merely to write down the ordinary cycle equation, and then add to it, upon the side opposite to the effective electromotive force, the value of the term

$$\frac{d}{dt}\frac{dT}{dy},$$

and this is a perfectly general rule.

Now, in the above expression T is the kinetic energy of the system, and in the case under consideration, treating as negligible the energy expended in moving the needle of the galvanometer, the kinetic energy of the system at any instant is wholly electro-magnetic, and will be measured by

$$\tfrac{1}{2}Ly^2 = T.$$

Hence $\frac{d}{dt}\frac{dT}{dy} = \frac{d}{dt}Ly$, and the complete equation for the y cycle will be given by

$$\frac{d}{dt}Ly + \overline{G+S}\,y - S\,\overline{x+y} = 0,$$

and for the x cycle we shall have

$$\overline{B+S}\,\overline{x+y} - Sy = E.$$

Rearranging, these become

$$\left(L\frac{d}{dt} + G\right)y - Sx = 0$$

and

$$By + \overline{B+S}\,x = E.$$

The solution of these, for x and y, is

$$y = \frac{\begin{vmatrix} E, & B+S \\ 0, & -S \end{vmatrix}}{\begin{vmatrix} B, & B+S \\ L\frac{d}{dt}+G, & -S \end{vmatrix}} = \text{current through [galvanometer,}$$

$$x = \frac{\begin{vmatrix} B, & E \\ L\frac{d}{dt}+G, & 0 \end{vmatrix}}{\begin{vmatrix} B, & B+S \\ L\frac{d}{dt}+G, & -S \end{vmatrix}} = \left\{\begin{array}{l}\text{current through}\\ \text{shunt.}\end{array}\right.$$

The first of these gives the following differential equation in y:—

$$\frac{dy}{dt} + \frac{BS+BG+SG}{(B+S)L}y = \frac{ES}{(B+S)L},$$

of which the solution is

$$y = \frac{ES}{BG+BS+GS}\left(1 - e^{-\frac{BG+BS+GS}{(B+S)L}t}\right).$$

Which result agrees with that of Helmholtz's equations for the current in circuits having self-induction at the end of any period, t, from the commencement of flow.

When stated in words this expression amounts to saying that after the lapse of t seconds the current in the galvanometer has a value which is less than it would have if there were no self-induction in its coils by a quantity the logarithm of whose reciprocal is inversely proportional to the coefficient of self-induction, and directly proportional to the total resist-

Digitized by Google

ance of the circuit and to the time that has elapsed since the current commenced to flow. It will be seen that when t is zero, y is also zero, and as t increases y increases, but that it is not until t becomes equal to infinity that the factor within the brackets vanishes, and it is only then that y obtains the value given by the formula in ordinary use for the current through a shunted galvanometer.

If we write N for the factor within the brackets in the equation for y, we shall get for x, the current through the shunt,

$$x = \frac{E(BG + BS + BG - BSN)}{(B+S)(BG + BS + SG)},$$

and therefore the value of x diminishes as t increases. It will thus be seen that the self-induction of the galvanometer acts like a spurious resistance which is added to its coils at the moment the current commences, and which gradually dies away.

The combined resistance R of the galvanometer and shunt coils will thus be a function of the time t. From the cycle equations which are written above we may obtain R by means of the method previously considered. We shall have to take the battery-circuit resistance equal to zero, that is put $B = 0$; then, writing down the determinant of the cycle equation, and dividing by its first minor, we have

$$R = -\frac{\begin{vmatrix} S, & -S \\ -S, & G+S+L\frac{d}{dt} \end{vmatrix}}{G+S+L\frac{d}{dt}} = \frac{S\left(G+L\frac{d}{dt}\right)}{S+\left(G+L\frac{d}{dt}\right)}$$

And it may be shown that the expression $\left(G + L\frac{d}{dt}\right)$ is equivalent to

$$\frac{G}{\left(1-e^{-\frac{G}{L}t}\right)},$$

and therefore,

$$R = \frac{SG}{G+S\left(1-e^{-\frac{G}{L}t}\right)}.$$

We have next an examination of the case when a condenser discharge is taken through a shunted galvanometer. This investigation, which is of a more difficult character, is very ably treated by Dr. Fleming. He arrives at the somewhat remarkable result that the *total* quantity of the discharge is divided between the two circuits merely in the inverse ratio of their resistances. So that self-induction does not affect the the ratio of division of a discharge in a divided circuit; provided, however, that no external work is done such as the moving of magnets, or of circuits conveying currents. Hence, if a ballistic galvanometer is shunted and a discharge sent through it, even in the case when the shunt has self-induction, so long as the needle has sufficient moment of inertia and the discharge is sufficiently short, so that the needle has not perceptibly moved from its position before the discharge is over, then the whole quantity of electricity is divided between the galvanometer and the shunt in the inverse ratio of their resistances. The examination of the value of the current flowing through the galvanometer and shunt at any instant leads to the result that, if the self-induction of the galvanometer exceed a certain limit the discharge from the condenser may assume an oscillatory character. For the case in which the shunt has no self-induction, in order to prevent this electrical oscillation in the galvanometer circuit, we must have the relation

$$\frac{G^2 S}{G+S} > \frac{4L_1}{C}$$

where L_1 is the coefficient of self-induction of the galvanometer, and C is the capacity of the condenser.

If the original quantity in the condenser be Q, and if y be the value of the current in the galvanometer circuit at any instant, then after the commencement of discharge it may be shown that for y we shall have

$$y = \frac{Q}{\sqrt{\frac{G+S}{S}CL_1 - \frac{G^2C^2}{4}}} e^{-\frac{G}{2L}t} \sin\left(\sqrt{\frac{G+S}{SL_1C} - \frac{G^2}{4L_1^2}}\right)t.$$

The memoir concludes with two examples which are taken from the course of lectures upon electromagnetism which Prof. Clark Maxwell delivered at Cambridge in the May term, 1879, an occasion which, unhappily, proved to be the last on which Maxwell was able to discharge his professorial duties.

The first of these theorems is on the comparison of the mutual induction between any two pairs of coils. Let α, β, γ, δ be four coils of wire. It is required to compare the mutual induction of α and γ with that of β and δ. The coils are placed in position and joined up as shown in Fig. 7, α and β in series with a galvanometer, γ and δ in multiple arc with a battery.

Let R and S be the resistances of the primaries γ and δ, and let Q be the sum of the resistances of the two secondaries and of the galvanometer, and let the resistance of the battery be

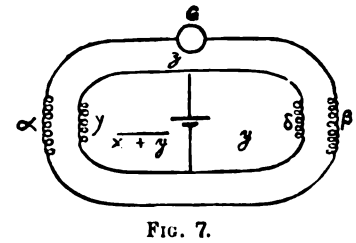

FIG. 7.

neglected. Let the coefficients of self and mutual induction be taken as follows:—

Coefficient of self-induction of coil	α	$= L_1$
" " "	β	$= L_2$
" " "	γ	$= N_1$
" " "	δ	$= N_2$
" " galvanometer		$= \Gamma$
" mutual induction of coils	α and γ	$= M_1$
" " "	δ and β	$= M_2$

Call $\overline{x+y}$ the cycle current of the mesh containing γ, y that of δ, and z that of the secondary circuit. Therefore, the current through the battery will be x. The kinetic energy of the system is given by

$$2T = \overline{x+y}^2 N_1 + 2\overline{x+y}\,z M_1 + z^2(L_1 + L_2 + \Gamma) + y^2 N_2 + 2yz M_2.$$

Hence, writing the cycle equations as before, and adding to each the respective value of

$$\frac{d}{dt}\frac{dT}{dx}$$

obtained from this expression, we shall have

$$\begin{aligned} n\overline{x+y}N_1 + nzM_1 + \overline{x+y}R &= E \\ nyN_2 + nzM_1 + yS &= -E \\ n\overline{x+y}M_1 + nyM_2 + nz(L_1+L_2+\Gamma) + zQ &= 0; \end{aligned}$$

where for convenience n is put for $\frac{d}{dt}$.

From these equations, eliminating y, we may obtain z in the form

$$z = \frac{\{n^2(M_2N_1 - M_1N_2) - n(M_1S - M_2R)\}x}{\text{a denominator which does not concern us}}.$$

If matters are arranged so that $z = 0$, or the galvanometer shows no current,

$$(M_2N_1 - M_1N_2)\frac{dx}{dt} = M_1S - M_2R.$$

Hence if there is no "kick" on the galvanometer on making current, then

$$\frac{M_1}{M_2} = \frac{R}{S}.$$

(To be continued.)

UNDER THE HAMMER.

The quaint conceits of Lamb, or the versatility of Goldsmith, would have endowed the auctioneer's hammer with a charm which modern writers fail to give. The delicate touches of humour which hovered, as it were, around the subject never failed to soothe the reader, and to bring his mind into accord with that of the writer; although it may be that in some cases their natural flow of language and fertility of idea led these authors to clothe their inceptions in a garb of such superabundant beauty that the moral they sought to inculcate was lost in the telling. The moral of the auctioneer's hammer is, however, always plain. It shows the volume is closed—with "failure" written distinctly across the last page. There can be no mistake; the result is clear.

Good may, however, come from failure. Others may be led to inquire into the causes which led to that failure, and, taking care to avoid those causes, to work steadily onward and upward to success. It is to be hoped that this result will accrue to those engaged in electric lighting. The Hammond Company, one of the largest companies floated for electric light work, has passed away. The auctioneer has, during this and the preceding week, been busy disposing of the effects of the company. The lesson to be learnt has been taught in a rough and violent manner, though it is none the less valuable. The large companies floated in the halcyon days of hope were undoubtedly a mistake. The sums of money paid for patents and concessions were far too great, and have proved millstones around the necks of drowning men. There is not a single electric light patent that gives its holder or holders a monopoly. Dynamo machines are made on every hand, and the machines of different makers are so admirably constructed as to make it very difficult to decide which is the best. Good arc lamps are to be obtained from various firms, and at least half a dozen makers of incandescent lamps have their wares before the public. When the history of artificial illumination comes to be written, the chapters devoted to the initial development of electric lighting will have to deal with numerous mistakes. It is easy to point out these mistakes after they have been made. The difficulty is to show that a certain course of action will be a mistake before such action has been commenced. The perils and dangers of the system pursued as regards electric lighting were pointed out in the initial stages of the industry, but the alarmist view was poohpoohed as being simply the opinion of a very small minority. Experience has since shown those views to have been correct; though such experience comes too late to save investors from the effects of the system adopted. Illumination by gas did not supersede illumination by oil in a year; nor did the network of railways thread the whole country within a similar period. An attempt to run before being able to walk generally ends in disaster, and the course of electric lighting has been no exception to the rule.

It is pleasant to find that the public is beginning to value concessions similar to those imported into electric light speculation at a proper estimate—that is, as having no value whatever. They increase the cost of plant, and are favourable to untrammelled competition, without having any corresponding advantage. The only favourable opinion about these concessions is to be obtained upon the Stock Exchange. A fictitious value is therein given to them in order to induce speculation. The fatal error made by those who promoted the system of concession was to conclude that the special machinery made under the patents they controlled was machinery that could not be approached, much more surpassed in excellence, by any other maker.

We cannot say how it is, because we have not been behind the scenes so far as the company is concerned whose break up gives us our text, but we should imagine that the untoward result is traceable to three causes. In the first place we have the amounts paid for concessions and patents; then we get the apathy of the public to support by its patronage so large a capital; and, lastly, we have the errors of forecasting the cost of work, so that the doing of the work ends in loss instead of gain. The causes, it seems to us, are common to the development of new industries. Ultimate success is generally built upon failure. It is a common saying that those who bear the burden and heat of the day do not reap the reward. The same reasoning that applies to the purchasing instead of the building of a house applies to a new industry. Those who rush to encounter and to overcome early difficulties are generally ruined; those who wait can take advantage of the experience gained and are successful. These facts are not to be gainsayed, though they have been overlooked. Time brings about its revenge, and the history of the electric light will be found to be nothing out of the common.

A few words may not be amiss as to the apathy of the public. This apathy is comparative, and only exists in the imagination of the promoters of companies. Thousands of men would like to have the electric light in their houses, but they have to consider that already a large outlay has been incurred, and that, however cheap and good the new illuminant may be, its introduction will necessitate a considerable initial expense. After all, it is useless to contend or to attempt to persuade a man that he ought to spend two or three hundred pounds at once when he has not got the money. An extra five or ten pounds a year is easily met and paid; when the first

THE INTERNATIONAL INVENTIONS EXHIBITION.

In the East Court Messrs. J. D. F. Andrews and Co. exhibit a selection of apparatus illustrating the details of their electric light manufactures.

As a starting point in his work Mr. Andrews decided that, for a system to be general, the complications involved in arranging fittings for two wires would be out of the question, and he therefore worked out the various appurtenances of his complete system for the one wire principle, whether applied to ships or buildings.

He has arranged all fittings to be entirely independent of the wires that lead the current to them, so that they may be removed from their place of erection without in any way interfering with the wiring, and the various parts of the fittings may be taken to pieces without each part carrying its own connections. Several kinds of these fittings are exhibited, consisting of double-jointed brackets with switch in the fitting and safety fuse in the backblock, electroliers, ship fittings of all kinds, switches with quick break without springs, suitable for sinking in the wall or the floor, as a gas tap now is, and safety fuses to suit, and switches of the same mechanical design arranged to fix on the face of the wall, &c.

There are also a variety of fittings on exhibition for the double wire system for cases of special necessity, besides arc lamps and dynamos.

Mr. Andrew's dynamo is a four-pole Gramme machine

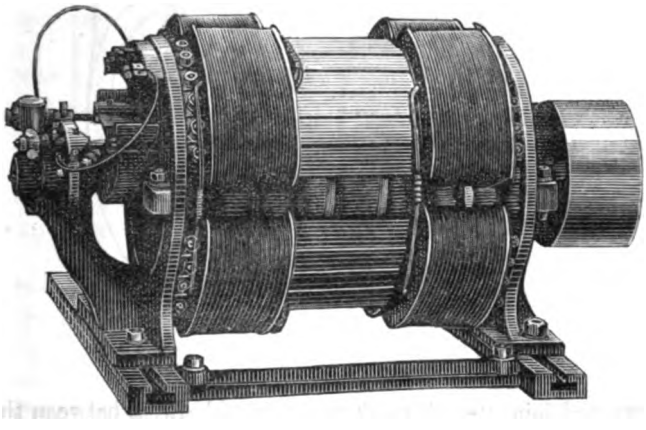

FIG. 1.—Andrews' Dynamo.

arranged in a novel way, as will be seen in Fig. 1. The armature (Fig. 2) rotates within a cylinder, nearly three times

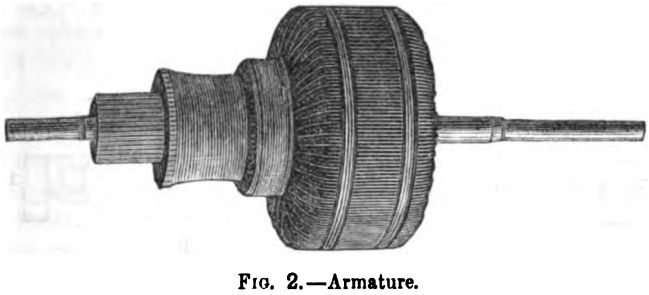

FIG. 2.—Armature.

as long as itself, and formed of wrought-iron bars, arranged like the staves of a cylindrical cask. The cylinder, or cask, to keep to our simile, is not entire all round, some of the staves being omitted so as to create four longitudinal openings ninety degrees apart. These staves form the field magnets, the central portion being the poles, the bobbins being arranged at each end of each group. There are no pole pieces, and consequently there is no break in the magnetic field except at the neutral points, where the framing acts as coupling between the adjacent magnets.

A special feature of the machine is the method of connecting up the coils of the armature to the commutator, which we show in Fig. 3. N N and S S represent the staves forming the poles, and C C C the armature with its coils, and M the commutator. It is necessary, according to this method of connecting, that the number of coils should be uneven. Usually 59 are employed, but only 17 are shown.

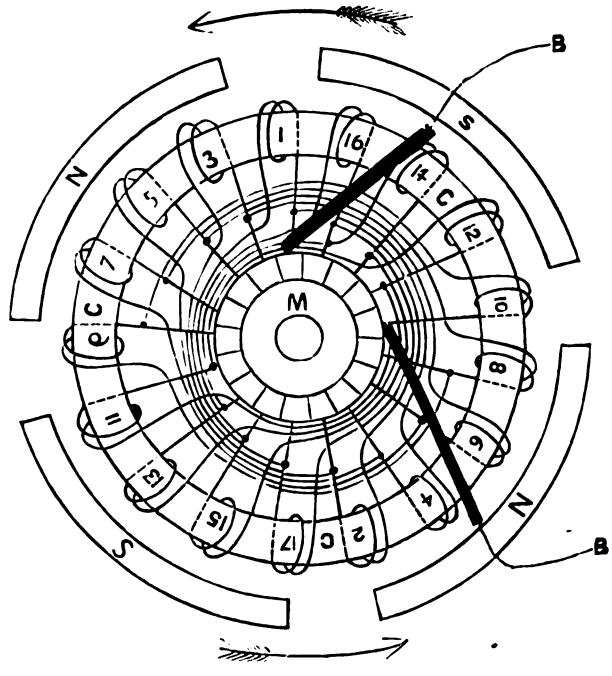

FIG. 3.

The coils are connected in series; not, however, each one to its next-door neighbour, but each to its diametrically opposite neighbours—that is, coil No. 1 is joined between Nos. 17 and 2, and No. 2 between Nos. 1 and 3, and so on. One end of each coil, however, is connected to the commutator plate nearest to it, as will be better seen on the diagram than described.

The collection of the currents from these coils is effected by placing two brushes, B and B, at right angles to each other on the commutator; thus, as coil No. 1 enters field N its other half, or coil No. 2, which is connected to it, enters field N and brush B collects the current. Correspondingly, as coil No. 10 enters field S and its other half No. 11 field S, the brush B is in position to gather the current from both south poles. The adjustment of the brushes on the commutator is another new feature of the dynamos. On an axle (Fig. 4) are held two

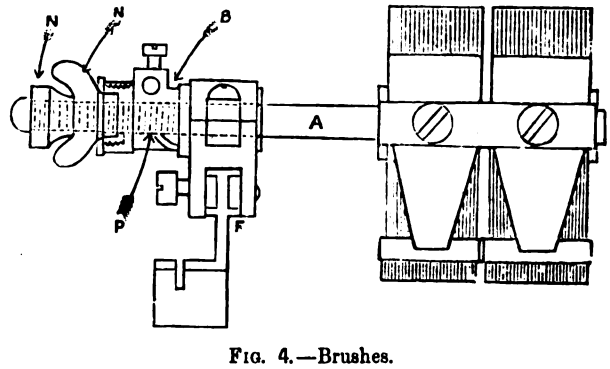

FIG. 4.—Brushes.

brushes in one holder. This axle passes through an insulated brass sleeve or bearing B, and its screwed end fits into the thumb nut and lock nut N N; the thumb nut is turned, the brush axle is drawn through the sleeve, and a pin, P, fixed to the axle, and fitting into a spiral slot in the sleeve causes the axle to turn and press the brushes on to the commutator or lift

Digitized by Google

them entirely off. With this simple arrangement the pressure can be very finely adjusted.

Fig. 5. is an end view, showing the two brush holders fixed to a semi-circular brass frame, F, upon which they can be shifted independently and the angle adjusted, and after this the frame itself carrying both brushes may be oscillated till the point of no sparking and best effect is found on the commutator.

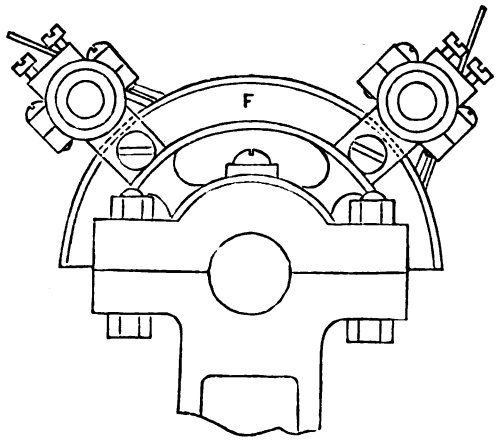

FIG. 5.—End View of Brush Holders.

One of these machines, size B4, is supplying current to 8 25-ampere arc lamps lighting the engine shed. The lamps are connected up in four branch circuits parallel, two lamps and a resistance of six ohms being on each circuit.

Arc lamps are also exhibited on the stand. Those lighting the engine shed are of the simplest type for running in parallel circuits. They regulate with great certainty and steadiness, and consist of a long solenoid of fine wire, connected as a shunt to the arc, in which hangs a core suspended by a ribbon passing over a pulley, which can rotate in one direction only to lift the core. When the core descends, the ribbon slides over the pulley, and acts as a brake, the other end of the ribbon carries a tube to which the upper carbon is attached. This tube is within another that acts as a guide, and a slot is cut through its whole length to allow of a flexible connection being attached to the carbon holder tube. The core carries the bottom or negative carbon, and being heavier than the positive holder, the carbons are apart so long as there is no current passing through the solenoid. The moment the current starts the solenoid has great power, till it lifts the lower carbon against the upper one, and thus short circuits itself, and allows the carbons to part and so form an arc. The strength of the current now passing through the solenoid depends on the difference of potential of the two carbons, and so long as the difference of potential remains constant, no matter what variations take place in the quantity of current through the carbons, the solenoid will regulate the arc to the required light; consequently, the lamp being once adjusted to a fixed electromotive force, the light may be varied from 500 candle-power to 3,000 by increasing the current without any further adjustment.

The solenoid has a greater power over the core, as the latter enters, than when it is within, to its full length; and as it is necessary this power should be uniform to keep a uniform length of arc as the carbons are consumed, a very simple device of a heavy chain, H, passing over a pulley is arranged, as will be better seen in Fig. 6. One end of the chain is attached to the upper end of the positive carbon holder tube, and passing over the pulley; the other end is attached to a lead weight or number of weights, W, which are made removable, so as to regulate the lamp. Thus, when the core is at its lowest in the strongest part of the solenoid, the chain is balancing part of the weight of the positive carbon holder tube, which is itself a counterbalance to the core, and as the core ascends the distribution of the weight of the chain is gradually reversed till the whole weight of the carbon holder tube is balancing part of the core.

This lamp is arranged to work in series by the addition of an automatic shunt, A, placed in the upper portion of the lamp. This will be better understood from the diagram Fig. 7 and plan Fig. 8.

In addition to the shunt it is necessary to wind a thick wire solenoid, B, forming part of the circuit or main wire, over the working fine wire coil. One end of this is connected to the terminal and the other to a contact, D, on which the spring E

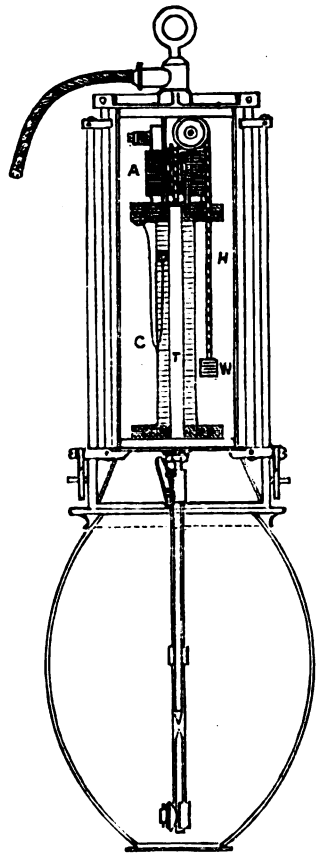

FIG. 6.

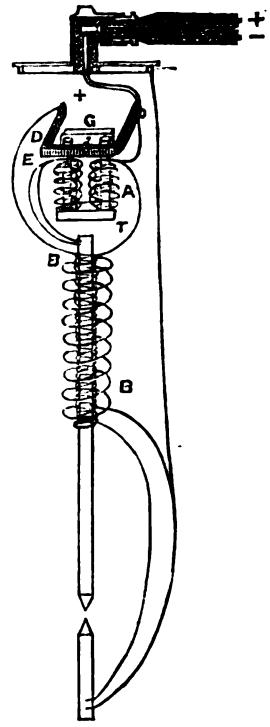

FIG. 7.

rests, and joins up this thick wire solenoid direct between the terminals of the lamp. Supposing now the current to be started its power in the solenoid will bring the carbons into close contact, and the current will now also pass through the thick wire on the magnet F, through the carbons and away. This magnet,

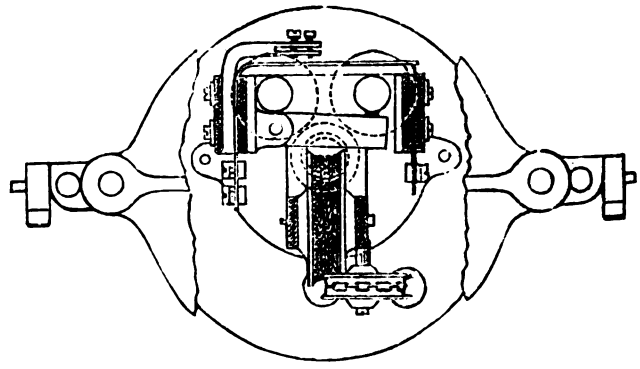

FIG 8.

by means of the armature G, will break the circuit of the thick wire solenoid at D, and allow the carbons to part and form the arc. The lamp now goes on regulating with the fine wire solenoid, the thick wire solenoid being cut out. If the arc should grow extra long or stick through dirt, the magnet F, which is wound also with fine wire, opposing the current through the outer solenoid, forcibly adjusts the carbons.

Digitized by Google

Another arrangement of this lamp is shown in Fig. 9. It is well adapted to burning parallel, and is specially designed to stand rough usage; the lower carbon holder is fixed, and the solenoid is part of the circuit wire. As in the other lamp, the chain compensation is necessary, and the ribbon carrying the coil, after passing over the pulley from the core, is attached to a counter weight, and to this also is attached the chain passing over the sheave, and carrying a smaller weight at the other end.

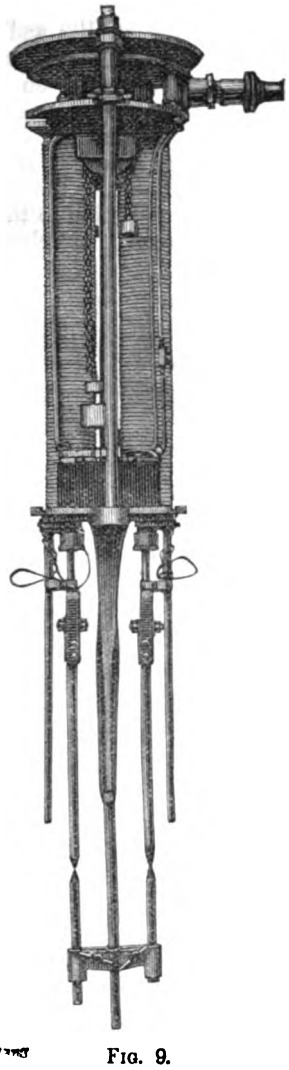

FIG. 9.

Now, let us suppose the lamp to be ready to be lighted. The carbons will be in contact, the greater part of this weight being carried by the ribbon when the circuit is completed; the solenoid will lift its core and establish the arc, and the combined influence of the solenoid, the friction of the ribbon, and the counter weight will hold the parts in position. As the arc lengthens the solenoid will gradually lose its power, and its core will slide down to compensate for the waste. This lamp is always made in duplicate in the one frame, with an automatic shunt to switch in the second, when the first is finished burning, or when the first is being trimmed with fresh carbon.

The armature core is a coil of No. 12 iron wire, measuring 17½in. diameter, 8in. wide by 1⅝in. thick; on this core are wound 185 yards of cable, consisting of 14 strand 16 B.W.G., in two layers and 59 sections. The outside of the core is set at seven-eighths distance from the inside of the magnet poles, and when it rotates at a speed of 2,300ft. per minute an electromotive force of 110 volts, and a current 110 amperes are generated in the cable wound on it, being 1 volt to each 1·85 yard of wire, which, taking the lowness of speed into account, is a very good result.

At Messrs. Paterson and Cooper's stand, in the East Arcade, are exhibited several of their latest types of Phœnix dynamo machines for arc and incandescent lighting and for electro-

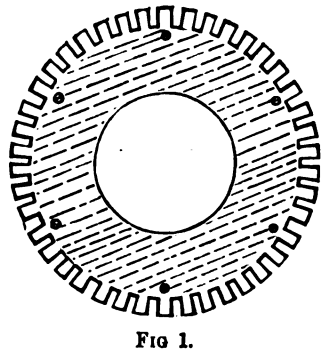

FIG 1.

plating. These machines are made some with wrought iron field magnets and some with cast iron magnets, and are of several different types, according to the purpose for which they are designed. The armature of the machine is constructed of plates of wrought iron of the softest quality, punched out and melted to the shape shown on the diagram (Fig. 1), the wires being wound in the slots, two coils in each. The plates are carefully insulated from each other by sheets of paper, and the whole armature firmly braced together by insulated bolts passing through the armature from end to end. In construction the object has been to obtain a substantial and strong mechanical connection between the armature and the spindle consistent with completely insulating every part where an absence of this precaution would tend to the generation of wasteful Foucault currents, and Messrs. Paterson and Cooper claim to have in the Phœnix machines succeeded in gaining their object. The machines are of strong substantial design, and all built to do heavy work, and with due regard to durability.

In Fig. 2 is illustrated a longitudinal section of the 1,000-light Phœnix machine running nightly in the electric light shed. The magnets of this machine are of wrought iron bars, 9in. square, arched in the centre, and having cast iron yokes at each end which serve as the base of the machine. From these yokes, on each side of the armature, springs a cast iron spandril, which supports, in gunmetal bearings, an armature spindle. This is clearly shown on Fig. 3. The armature is constructed, as above described, of wrought iron plates, and has wound on it 84 coils having a similar number of sections in the collector. The collector has a wearing depth of three inches, and the machine is fitted with double brushes, which are not only capable of adjustment round the collector, but which can be altered in position relatively to each other by adjusting screws actuating sliding blocks. The armature is wound with a conductor formed of 50 small wires laid together and covered with four thicknesses of varnished tapes. Such a conductor is much more easily wound than a conductor formed of a few thick wires in parallel, and it is more suitable for armatures of this form than are simple bars of copper. It appears that in this machine the proportion of copper wire to iron has been reduced to a minimum. Another machine, for 200 lights, of different design, also running in the electric light shed, is also exhibited. The magnet bars in this machine are of square form, as before, but pole-pieces of cast iron are employed. These two dynamos, in conjunction with a smaller machine, light the dining halls and the buffet by Bernstein lamps of 50 candle-power each, the lamps being suspended from the roof in groups of threes, enclosed in effective conical glass shades. In addition to the several different sizes of dynamos, varying from 10 to 200 lights, made by this firm, and employed at different parts of the Exhibition, there are two 12-light arc machines running in the electric light shed to supply current for 24 Phœnix arc lamps employed to light the west burners. The opal glass lanterns which enclose these lamps are of a new design, and look very well. The lamp is of the clutch type, and the feed is effected by a vibrating hammer, which continuously delivers infinitesimally small blows on the free side of the clutch, the hammer being actuated by a differentially wound shunt magnet. At Messrs. Paterson and Cooper's stand are shown, besides the Phœnix lamp above described, the Clark-Bowman, the Pilsen, and J. F. arc lamps, for all of which the firm are agents. The selection of measuring instruments shown here is very complete. Some Wheatstone bridges, resistance boxes, and reflecting galvanometers of first-class workmanship are exhibited, as well as the ordinary line testing instruments employed by workmen. A good assortment of Ayrton and Perry's ammeters and voltmeters is shown; but these instruments are so well known as to call for no special description here. It might just be mentioned *en passant* that all instruments now made by this firm are calibrated direct in amperes and volts, and that the deflections are always proportional to the current flowing. Paterson's electro-magnet ammeter is an instrument which may probably be new to some. In this instrument the permanent magnet is replaced by an electro-magnet which is magnetised by the current which deflects the needles. The voltmeter invented by Capt. Cardew, now that some hundred are in use, can scarcely be considered a novelty, but its action may be here briefly described. The voltmeter consists essentially of a fine platinum silver wire, one end of which is attached rigidly to one of the terminals of the instrument, and the other to a staff or pulley which by its rotation indi-

Digitized by Google

cates the amount of expansion the platinum wire has undergone due to the passage of the current through it. A certain difference of potential at the terminals of the wire gives a certain expansion, and a needle fixed on the staff indicates the difference of potential on a dial calibrated direct in volts. These instruments can be kept on the circuit continuously, as the heating by which in galvanometric voltmeters the efficiency of the instrument is impaired is here employed to produce the indications. Having no coiled wires, the error introduced due to self-induction is not found in these instruments, and they can consequently be employed for alternating as well as continuous currents. A fuse of very fine wire is placed in the instrument to prevent fusion of the working wire, should the difference of potential at the terminals of the instrument exceed the working limit. Several of Paterson's engine room ammeters are shown, and also Paterson-Joel ammeters.

One form of Thompson and Starling's patent universal photometer for measuring the candle-power of incandescent or arc lamps consists of a graduated bar, at the centre of which are fixed back to back two opaque screens attached to one another at a small angle. On one screen falls the light which is to be measured ; on the other falls the light from two standard candles of spermaceti.

By adjusting the relative positions of the candles and of the light whose intensity is to be measured the relative intensities are ascertained, and the scale marked on the bar of the photometer is so graduated as to reduce the calculations to a minimum. When the instrument is employed to measure the candle-power of arc lamps it is set on a tripod, and a mirror is employed to throw the light from the lamp directly on to the screen. In addition to these exhibits the firm have several specimens of their electro-

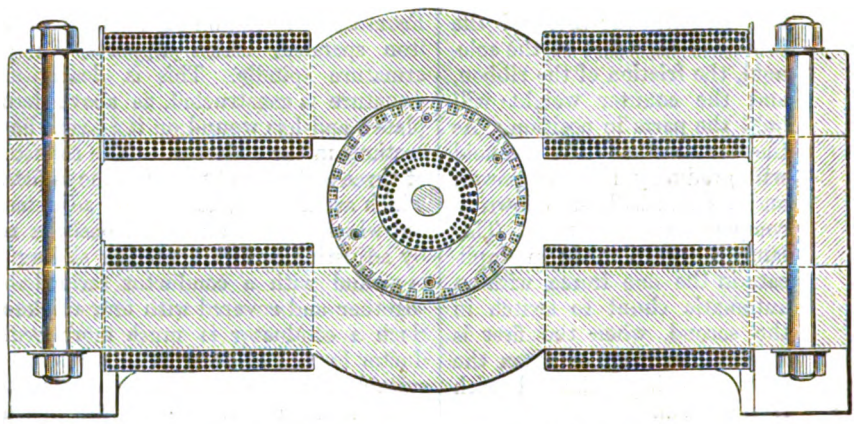

FIG 2.—Phœnix Dynamo. Longitudinal Section.

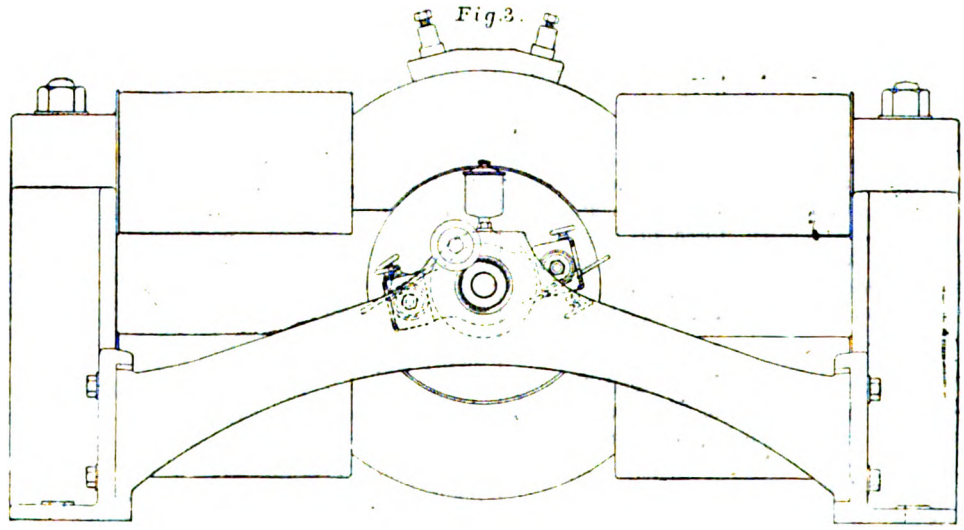


Phœnix Dynamo.

In these instruments the galvanometric coil is replaced by a single strip of copper. A number of ornamental fittings and shades for incandesceut lamps are exhibited along with all the necessary apparatus and accessories required for fitting up installations such as the well-known Eidesforth and Co. and Maynard switches, fuses, fuse holders, lamp holders, &c. A selection of Wallace, Diamond, and other carbons employed for arc lamps can also be seen. A battery of 20 Joel accumulators is shown, and in this accumulator it is claimed that the principal difficulties which have been incidental to the use of accumulators in the past have been overcome. The positive and negative electrodes are firmly braced together in a wooden frame, and are quite independent of the cell or box in which the dilute acid is contained. They can therefore be lifted out and inspected at any time.

deposition of metals, including zinc, brass, copper and tin deposited on iron ; nickel on iron, brass, and copper ; silver on iron, copper, and brass, &c. A small dynamo used for electroplating is shown, which is capable of depositing 5lbs. of nickel per day.

Side by side with this is a machine for copper refining, which is capable of refining 5 cwts. per day. Machines are constructed by the firm capable of depositing one ton of copper per day. Photographs of most of the machines made by the firm are exhibited, which vary in size from machines for ten 20 candle-power lamps to machines for one thousand 20 candle-power lamps. Many of the machines have been made for special purposes, and several are working continuously with the greatest success in different parts of the world.

Digitized by Google

outlay is absolutely unattainable. The earlier exponents of electric lighting acted as if men individually or collectively would wish to pay the initial charge, and gladly write off as lost the amounts already paid for other illuminants. Nothing of the kind has happened. The electric light has been introduced into factories where the proprietors thought directly or indirectly it would pay them to do so. Individuals who can afford luxuries have introduced the light; and in this manner its use is extending, and will as time goes on more rapidly extend. These, and a host of other thoughts rush through the mind as we contemplate the fall of the auctioneer's hammer. Our sympathy goes out to the sufferers, though we cannot wholly refrain from pointing out that no other solution than that which has occurred was possible. A certain, but comparatively small, capital is all that the electric lighting industry will at present support. There was too much capital, and natural laws have acted in its extinction. We trust that in the near future natural laws will act to bring about a different result.

CORRESPONDENCE.

ON LOW RESISTANCE INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The interesting Cantor lecture of Prof. Forbes which you published in last week's *Electrician* induces me to make a few remarks upon low resistance incandescent lamps, in connection with which Prof. Forbes mentioned my name.

Let me first consider the lamp itself, irrespective of its application for the purpose of distributing electric light.

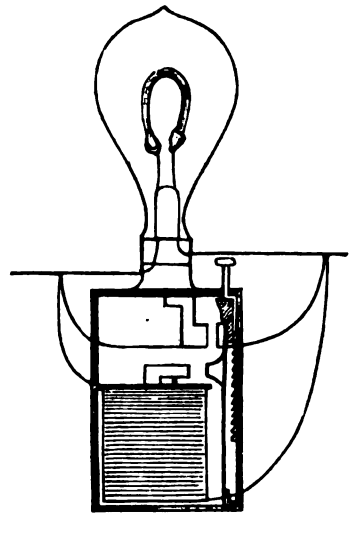
I cannot understand why lamps of low resistance should *à priori* be considered less economical in the production of light than those of high resistance. To my great surprise, I have occasionally heard the expression that high E.M.F. in incandescent lamps favours the generation of light; and I am inclined to think that a faint notion of possible relations between electricity and light is at the bottom of such vague ideas. Now, E.M.F. in itself is merely a tendency to do work, but the actual work is done by the current, which generates the heat in the carbon; and again, it is the temperature of the carbon on which the amount of light radiations depends. Different substances will emit different amounts of visible radiations if heated to the same degree of temperature. I am inclined to think that our knowledge on this very important point for the production of artificial light is more deficient than it ought to be. But in the absence of proofs to the contrary, we may assume that the amount of light radiations emitted by incandescent carbons of the same quality and surface is merely a function of its temperature. Now, it can make no difference whether the heat-generating current is produced by a low E.M.F. working through a low resistance or a high E.M.F. working through a high resistance.

As to the amount of heat which is lost at the terminals, the same is alike in both kinds of lamps, if the dimensions of these terminals are in proportion to the amount of current which is passing.

In order to still more convince Prof. Forbes, whose good opinion on low resistance lamps I should like to win, I may be allowed to mention that, according to the measurements made at the Vienna Exhibition, the Bernstein lamp of low resistance has shown the highest degree of efficiency; and, furthermore, I should like to call attention to the interesting experiments on the relation between light and heat radiations in different incandescent lamps made by Mr. Penkert in Hanover, and published in the *Centralblatt für Elektrotechnik*, No. 22, 1885. Furthermore, it can certainly not be denied that a lamp with a short tube of large diameter is far more agreeable to the eye than one with a very long thin filament.

I now come to the application of low resistance lamps for the practical purposes of lighting. Four years ago I devoted considerable time to the production of large candle-power incandescent lamps, which were intended to take a place between the ordinary arc lamp and the small incandescent lamp then gradually coming into use. It seemed to me that it ought to be laid down as a general principle for economic electric lighting that the size of light to be used should be in proportion to the space to be lighted, and should be as large as the proper distribution of light will allow. It appears a mistake to light large areas, like railway stations, with small incandescent lamps. Now, as the arc lamp has never proved very satisfactory, my desire was at the same time to replace it by suitable incandescent lamps, and I shall quote an example of such replacement later on. For reasons, the explanation of which would lead too far from the subject, I came to the conclusion that a hollow carbon would have those qualities which I considered most desirable in a practical lamp of large candle-power, and after long and tedious experiments in this matter I met with some success. It further occurred to me that it would often be advantageous to place incandescent lamps in series, as the multiple arc system offers many difficulties, which Prof. Forbes has so ably described in his lecture.

The lamp for this purpose had then to be of low E.M.F. and large current. As a matter of course, it was necessary to use a device, in order to prevent the interruption of the circuit, in case a lamp should break accidentally; but this is by no means so difficult as Prof. Forbes seems to imagine. It does neither require a local battery nor a separate wire from the dynamo. As the simple arrangement which has been used in several places in connection with the Bernstein lamp for the last two years has never been described in any electrical paper, although the same was shown in Vienna and in Philadelphia, I may embrace this opportunity of giving a sketch of it.



A small box, which generally serves as a lamp holder at the same time, contains an electro-magnet, which is placed in a shunt round the lamp, and therefore wound so as to represent about a hundred times the resistance of the lamp. If this magnet attracts its armature, which is fastened on a flexible brass strip, contact is made between two pieces above the armature, so as to close a short circuit around the lamp. In order to insure a good contact a wedge is arranged in such a way that it rests on the brass strip, as long as the same is not attracted towards the magnet, but slides down behind the brass plate as soon as this begins to move, and in this position it presses the two contact pieces together. After the broken lamp has been replaced by a new one the wedge is lifted by hand into its former position, when the current will again pass through the lamp.

The action of these cut-outs depends upon the peculiar behaviour of incandescent lamps when several of them are placed in series. In this case the lamp does not give out suddenly but gradually, because an arc is formed and long sustained

Digitized by Google

between the two ends of the broken carbon. The resistance of the lamp then increases many times, and therefore the current in the shunt electro-magnet becomes soon strong enough to act. In fact, I have never known any of these cut-outs to fail.

If two lamps are used in parallel, then the electro-magnet is wound differentially with the line wire, and one cut-out will answer for both lamps. This later arrangement was adopted two years ago in an installation about which I should like to say a few words.

In the Nantasket Hotel, near Boston, Mass., 16 arc lamps had been used for lighting the dining rooms, passages, verandahs, &c., but, on account of the unsteadiness and flickering of the arc lamps, the lighting was not considered satisfactory. I therefore made the following change :—I replaced every one of the arc lamps by four incandescent lamps, each having half the current and half the E.M.F. of the arc lamps. Although the total amount of light produced was of course less than before, this difference did not appear so very large, as the arc lamps could not be used without opal globes. There was a reduction of expense, and the effect was considered far more pleasing than before. To my knowledge the new arrangement has given great satisfaction up to the present time. I mention this case because I believe that the example may be considered worthy of imitation.

Prof. Forbes will be interested to know that the idea of regulating the light of incandescent lamps, when placed in series, by altering the length of the light-giving carbon, is embodied in my English patent No. 6,075, 1885.

I must forbear enlarging further upon this subject, although a great deal may be said on the use of low resistance lamps, especially for street lighting. But, in order not to be misunderstood, I wish to state that I by no means recommend the use of low resistance lamps for all purposes. At the present stage of electric light engineering they are entirely out of the question where large numbers of lamps are to be arranged quite independent of each other.

The special feature of the Bernstein lamp is not the low resistance, as has often been stated by mistake in electric literature ; but it is the use of the tubular carbon, which can be made for small and for large currents, with this distinction, that where large lights are required the hollow carbon alone will answer, as far as my experience goes. But I have of late made 100-volt lamps, which only require ·35 ampere, and represent a cold resistance of 570 ohms. In fact I am at present engaged in experimenting on two kinds of lamps, which may be taken as the extremes—one for the largest possible current, to be used for lighthouse purposes and projectors, and the other with the thinnest practicable tubular filament and the use of high E.M.F. for the distribution of electric light from central stations.

Between these two extremes there are a great many intermediate lamps which will be found useful for practical purposes.

I hope that the great interest which is attached to the subject of this letter will serve as an excuse for the great length of it.—Yours, &c., ALEXANDER BERNSTEIN.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have carefully studied the reply of Mr. Sprague to my further inquiry on this subject, and feel again indebted to him for devoting so much attention to a matter that has perhaps engrossed my own interest more than that of others. I was using a very vague expression when I suggested that "completing the secondary circuit *relieved* the primary coil," and therefore have myself to thank if it has been misunderstood. However, I meant that the primary coil was relieved, not of extra current to be carried, after break, but of an *external load* on the primary current itself—that is to say, of a certain counter E.M.F. coming from the secondary wire. Thus I am unfortunately unable to feel Mr. Sprague's interpretation confirms my own. Moreover, I betrayed (p. 396) that I believe in a stronger primary current when the secondary line is closed as lying at the root of the matter, so that we are not yet altogether in agreement.

I now understand clearly that Mr. Sprague supposes that the prolongation of magnetism in the core after break will be *less* when the secondary is completed than when it is open. Such a view, however, brings me face to face with a strange anomaly, for I reason that the secondary circuit when incomplete is practically *not* a circuit, and might as well not have been wound on ; so that the two cases under consideration are :—(*a*) Primary wire alone upon core, (*b*) primary wire upon core, with additional fine-wire circuit (closed) wound outside ; and in case (*b*) the prolongation of magnetism is to be less. But it is for me a hard saying when I am told that winding on additional wire as a circuit for the core to act upon, be it thick or thin, can have any other effect than that of increased prolongation of magnetism owing to its reaction. I also find some contradiction in supposing that the increased facilities of the metalically closed secondary should be favoured with "nearly the whole current," unless this circuit offers less resistance than the primary ; but, in that case, why should the energy appear there as "E.M.F. rather than C ?"—Yours, &c., E ALDRED WILLIAMS.

26th October, 1885.

SHIP LIGHTING AND COMPASSES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with interest your note in issue of 16th October on Commander Hudson's article in the *Nautical Magazine*.

To my mind, the fact that so many of our steamers are running fitted with electric lamps, without any complaints of misbehaviour of compasses being heard, is sufficient of itself to refute Commander Hudson's theory.

With regard to the intrinsic merits of the two systems—single and double—of wiring iron ships, I have had considerable experience in both systems, and am of opinion that the design and workmanship being equal in both cases, the single wire system is the better and safer of the two. I should always use it when free to do so. One of the first things to be considered in ship lighting is that the conductors shall be laid in such a way as to be free from all danger of short circuit. The best way to do this is obviously to keep the two conductors a considerable distance apart. With double wires this is very inconvenient and is seldom done, the usual method of laying them being to run the pair of wires in a double grooved wood casing, the casing frequently having to be cut away at joints and crossings until there is nothing left between the two wires but the insulation. With the single wire system, on the other hand, with a little management it is generally a matter of no difficulty to keep the wires at a respectable distance from the iron of the ship.

When purposely fitted with fuzes on the main and branch wires a single wire system on board ship gives absolute immunity from fire risk, and has the additional advantages of being so simple that it can at once be comprehended by the meanest intellect, and manipulated by the rawest of electricians.

It would be interesting to know what the experience of some of your other subscribers may be in these matters.—Yours, &c.,

October 23, 1885. REGINALD A. SMITH.

[The attention of electricians on board the numerous cable ships might be directed to the question of the action of electric light wires on the compasses, with good results.—ED. *E.*]

BICHROMATE BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see in this week's *Electrician* that "W. N." advises the zinc rod being immersed in a solution of common salt. This is a step in the right direction in the case of batteries for electric lighting. The employment of sal ammoniac or common salt has this advantage over dilute sulphuric acid, that the expense and trouble of amalgamation may be dispensed with. One other point of interest is that a solution of sal ammoniac in the porous cell with the zinc prevents the battery from freezing. I have submitted a bichromate cell charged in this

Digitized by Google

manner to 20° of frost without any ice being produced. Dilute sulphuric acid freezes very readily. The knowledge of this fact may perhaps be useful where bichromate batteries are employed for telegraph purposes in countries liable to frost.

I notice also that Prof. Dolbear claims having discovered the advantage of sal ammoniac. A glance through the patents for galvanic batteries during the last two years would show that he was not the first to employ it.—Yours, &c.,

Derby, Oct. 27, 1885. R. FREDERICK YORKE.

INFORMATION WANTED.

TO THE EDITOR OF THE ELECTRICIAN.

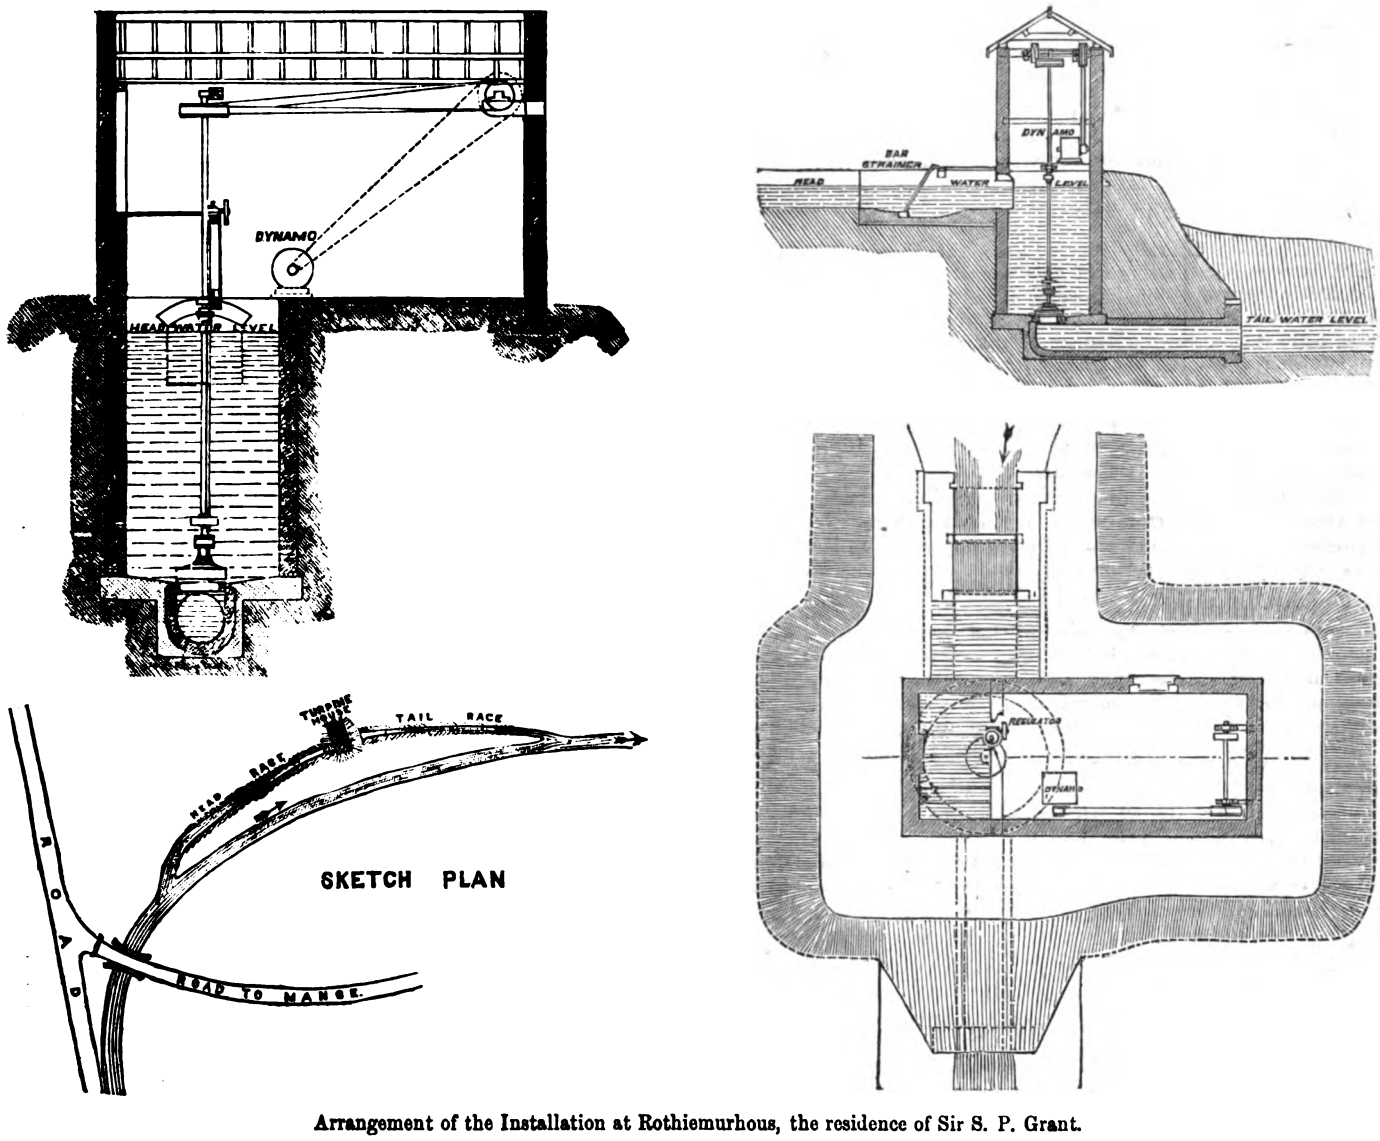
SIR: Would you do me the great favour of inserting in your valuable paper the following query?

Can you or any of your correspondents supply me with any information concerning a new Hungarian invention, which one of our leading electricians considers is to supersede all the present systems of electric lighting?—Yours, &c.,

ELECTRICIAN.

ELECTRIC LIGHTING IN THE HIGHLANDS.

We herewith illustrate the arrangement of the apparatus employed to light the residence of Sir S. P. Grant, of Rothiemurhous, situated on the Spey, near the foot of the Grampians. This installation has lately been carried out by the firm of Messrs. Craven and Elworthy. The power is obtained from a stream some three-quarters of a mile from the mansion, and is utilised by a turbine constructed by Mr. Hett, the well-known turbine builder, of Brigg. The motion is communicated to a counter-shaft and thence to the dynamo by means of belts, so that, no gearing being employed, the driving is very smooth and silent. The dynamo is of the Phœnix type, built by Messrs. Paterson and Cooper, and is, together with a switch-board and a set of 25 accumulators, placed in a suitable house over the turbine flume. The current is conveyed from the dynamo house to the mansion house by six wires. The stream which works the machinery also supplies the house with water through a 4in. pipe, and this is used as a return, thus reducing the initial outlay on the electric light mains. The number of lamps throughout the house is 80, which are of the ordinary Swan type.



Arrangement of the Installation at Rothiemurhous, the residence of Sir S. P. Grant.

The practical advantages of a turbine have been satisfactorily demonstrated, while the economy of water leaves nothing to be desired. The lights have been run direct from the dynamo without the intervention of the accumulators as an experiment, and the light remained perfectly steady. The plant above mentioned is in charge of a man who has had no previous experience of electric lighting, and as it has given satisfaction it is a convincing proof that no great obstacle is to be encountered in lighting country houses, and especially is this so where water-power can be obtained.

ELECTRICAL ENGINEERING.

A LAMENT FOR THE ELECTRICIAN.

The profession of "Electrician" is fast assuming the unfortunate garb of too many of our trades and professions. It is already, like these, filling the advertising columns of not only its own scientific journals with situations and appointments wanted, but has found a level amongst the clerks and commercial agents seeking any suitable employment rather than find themselves without home or food. What a dreadful come-down, indeed! A profession ranking side by side and carrying the same importance as that of a civil engineer; a profession requiring a wide and varied scientific knowledge, coupled with a mathematical and inventive brain power; a profession considered perfectly suitable, and, indeed, studied by gentlemen of birth and education, to have reached such a depressed state that even those who have made its mysteries a life-long study, and taken pleasure in doing their best to advance its infant steps to strides of magnitude, now find their hopes crushed, their energies all but wasted, their livelihood quickly disappearing, and their repeated appeals for electrical appointments utterly disregarded. This not only applies to the junior members of the profession, but it is within our knowledge that men ripe in the theoretical truths of this natural, but seemingly unnatural, agent, and experienced beyond a doubt in its practical applications, past holders of important and responsible posts, are at this moment seeking work to do. Their hands, in the past used to the manipulation of telegraph instruments and other electrical apparatus, are now forcibly obliged to be idle, whilst their ready money is expended in repeatedly advertising their talents and consequent requirements. These advertisements appear and reappear, first in one journal then in another, and latterly it has been literally grieving to see that the daily advertising media have received a share of this unfortunate patronage. Unmistakably the profession has received a terrible blow, a disaster has befallen it so damaging to its young life that it now practically walks on crutches. Such a fate spreads trouble broadcast, as during the last five years the electrical profession has gained such vast importance that the time has been also prolific in the manufacture of students and practical men. These men, as electrical engineers, have found, and still find, their time fully occupied, as they can never finish or neglect to apply themselves constantly to its studies. The scope of these studies involves most engineering subjects, widening almost daily by the importation of new theories and the ever-increasing inventions for its practical applications; indeed, electricians find it impossible to be all-round men, or profess proficiency in every branch, as its thousand and one commercial industries are beyond an individual brain. Employment, time, and experience may presently prove merciful enough to attain such an enviable consummation, but specialists are now the order of the day—specialists for special branches, to the lock-out of intruders. Telegraphy and its partisans can swim along easily and successfully because of its riper years, but the newly-initiated electric light and telephony are suffering much. The telephone is chained hand and foot and hampered against competitive improvement by the iron hand of monopoly; whilst electric lighting has been nipped in its budding life and its earlier successes completely smothered by the overwhelming selfishness of a few untutored adventurers, who sought to, and did, enrich themselves at the expense of the most brilliant of domestic commodities. Necessarily its votaries are the immediate sufferers; its admirers have undoubtedly suffered by loss of money, and the general public are suffering from their general mistake. There are some engineering electricians whose pecuniary means enable them to defy commercial depression, and there are even those amongst them, unfortunately, who at this moment actually gloat over the loaded neck of the half-drowned industry, because it gives them time to advance their particular branch by strides, and to insure, perhaps, a monopoly in the future, or to raise their chances in the electrical resurrection. These find enough work, in the absence of competition, to keep them going at a fairly brisk rate. Not so the less favoured; they may starve or betake themselves into the whirling lottery for other employment. Now, what is the cause of this state of things? What circumstance is it that within this short space of time has so completely overturned the brilliant prospects of a superior profession, and been the means of beggaring many and stultifying others? The answer is—legislation and speculation. And here a short history of the progress of electric lighting up to the present, as viewed from the incidental and personal experience of one behind the scenes, and who has experienced both the bitters and sweets of the profession, will explain the disastrous influences of these two great friends or enemies of commercial progress, and amply illustrate so dire a catastrophe as a dead lock in electric lighting. Yes, truly a catastrophe! as it is not only the professional enthusiasts who are the losers, but the nation—the people. English commerce and competition are ever on the increase; continually some new theoretical problem is being thrashed into workable condition, and mental activity giving birth to new scientific applications. But in electric lighting is found a commodity which, having reached a certain critical point, received a stunning blow, the effects of which will require time and patience to overcome. Some years since American industry lent its fascinating charms to simplify and overcome the difficulties experienced in this country in the manufacture of machinery necessary for the production of the electric current, and also the means for utilising its energy. Other countries also brought assistance, until our English market was enabled to offer a fairly good assortment of dynamo machines, lamps, and apparatus, intended to revolutionise the existing lighting system, with which people had been familiar for the last fifty years. Necessarily a commotion followed. The public mind became a whirlpool, and excitement increased step by step with the advancing strides of this giant illuminating competitor. Gas shares and dividends were scrutinised, whilst its manufacture became a question of general interest for improvement. It was at this time that gentlemen's sons, finding an occupation opening to them compatible with their social standing, and embodying a professional career, sought eagerly for centres of instruction, and paid heavily in order to be first in the field. Several enterprising capitalists immediately lent themselves and their money to this evident source of profit, with the result that more would-be electricians were turned out than were even then necessary. A few *bonâ fide* corporations were hard at work doing their best to render the new scientific industry a commercial success, and employing both time and money in research simultaneously with active work. As the public confidence was yet wanting, few installations were made, and these few were individual and isolated, for the simple reason that customers conld only be found amongst large consumers of gas, and whose calculations taught them that a saving might be effected by the employment of a larger illuminating agent. The manufacturing districts of the midland and northern counties afforded the largest sphere for the efforts of the electrical engineer. Sheffield, for instance, at that time could boast of the greatest use of the electric light. Its enormous iron and kindred works were enabled to continue their work both by day and night; but here it is only fair to say that the commercial value of electrical apparatus was anything but perfect, and consequently its employment in these particular cases was a continual source of professional anxiety. Trained electricians were attached to these individual installations, and, as a matter of fact, found themselves well occupied in constantly adjusting some provoking portion of the circuit whose performances popped here and popped there like the caperings of a jack-in-the-box. The energies, and temper perhaps, of the electrician might well find cause for compulsory rest after a long spell of such care and anxiety daily, from perhaps four o'clock in the afternoon until eight o'clock the next morning during the coldest of winter months, continually watching that no failure placed works and workmen in darkness and danger. Such, indeed, has been experienced, and even a ladder kept ready at any moment to mount and arrange refractory carbons or sticking cut-outs.

With an extraordinary commercial foresight and adaptability, one or two particular companies, obtaining patent rights, and representing the manufacture of a specific system, hurriedly obtained quotations for their shares upon the Stock Exchange, and surprised both the electrical and commercial world by their sudden activity in preaching the surprising merits of their own wares. Enterprise and duplicity were not wanting. No trouble was spared to excite the public mind to a state of frenzy, and undoubtedly such efforts were rewarded, much to the detriment of both people and enterprise. Undoubtedly the public were duped, whilst those behind the scenes, the instigators of so foul a bubble, laughed in their sleeves. Company shares were run up and concessions sold to subsidiary companies, whilst promoters quietly and greedily pocketed a first-rate income. One or two, personally known, could pocket their thousands in a week. The stockbrokers were exceedingly busy, shares continually changed hands, money was lost and money made, until the speculative epidemic seemed to have laid a siege and so bombarded the excitable commercial susceptibilities of the business man that no room was left to listen to the warning voice of the reasoning electrician, who foresaw the imminent evils of such precipitate action. The sequel followed, a review of which commenced with the subsidiary companies being thrown for the first time upon their own resources. To find legs wherewith to stand appeared to be a matter of great difficulty to not a few of them after the vast expenditure entailed in the purchase of the right and its conveyance. Starting with brilliant hopes, excited determination did much to render those in office obdurate to the difficulties before them. Such matters had not been considered, and there was not time now to look at the stern matter-of-fact duties that lay before. In some cases a large amount of capital was spent in building central stations with the idea of supplying householders with domestic electric lighting from the one centre, and upon the same mains as the public lighting of the streets, whilst others wasted their substance in some other imprudent or riotous commencement to their existence. It must have

Digitized by Google

come upon them as a depressing fact that, coincident with their finding out the many difficulties with which they had to contend, arising partly from the incomplete condition and unsuitability of their electrical apparatus, and the want of money, the public enthusiasm seemed to be abating, that the quotation of shares was gradually ebbing out its life, and that the great speculation agitators, finding their game played out, were taking back places and otherwise finding refuge in obscurity. Then, and not till then, came upon these subsidiary companies the realisation of their position ; foundations built on the sand, with not even a pecuniary backbone as a prop ; public enthusiasm dead ; scientifically insufficient and inefficient tools to work with ; a onesided and unworkable Act of Parliament of rights and restrictions, and no money ; a chaos of disasters, being a death blow to any enterprise whatsoever. Failure followed, and, one by one, each found its way into the list of voluntary or compulsory liquidations ; and as a calm always succeeds a storm, so a terrible period of inactivity in the electric lighting commercial industry has proved no exception to the rule. For the last two years the majority of electricians have found their services immensely at a discount, and many have even had difficulty to subsist. Of the public installations, which had been almost considered as permanencies, some have died, and others are gradually disappearing. Even the Thames Embankment falls back upon its old friend and faithful servant, whilst the City lighting has resolved itself into a few straggling and struggling old type, perhaps half-discarded, Brush lamps. Into what a state of collapse has it descended ! Into a bottomless pit ? Well, hardly as far as that. Resuscitation has yet a chance, and will step in ; but when ? is the question.

THE DISTRIBUTION OF ELECTRICITY.*

BY PROF. GEORGE FORBES.

LECTURE II.

(Continued from page 460.)

Multiple Tree System.—I will assume that all lamps are of the same pressure. In this case, the size of conductor per 1,000 amperes being fixed, the engine driver regulates the pressure by telegraphic indications of the potential at the nearest and farthest lamps. Compensated galvanometers may be introduced in the engine house to indicate the potential of distributing boxes, when variable currents are flowing.

Our first tree system extends to a distance of 124 yards ; beyond that we must have a second tree system with feeder mains to a distributing box, from which branches go out to supply a district, no part of which is more than 124 yards from the distributing box, or less than 124 yards from the station. From these distributing boxes a pair of thin wires

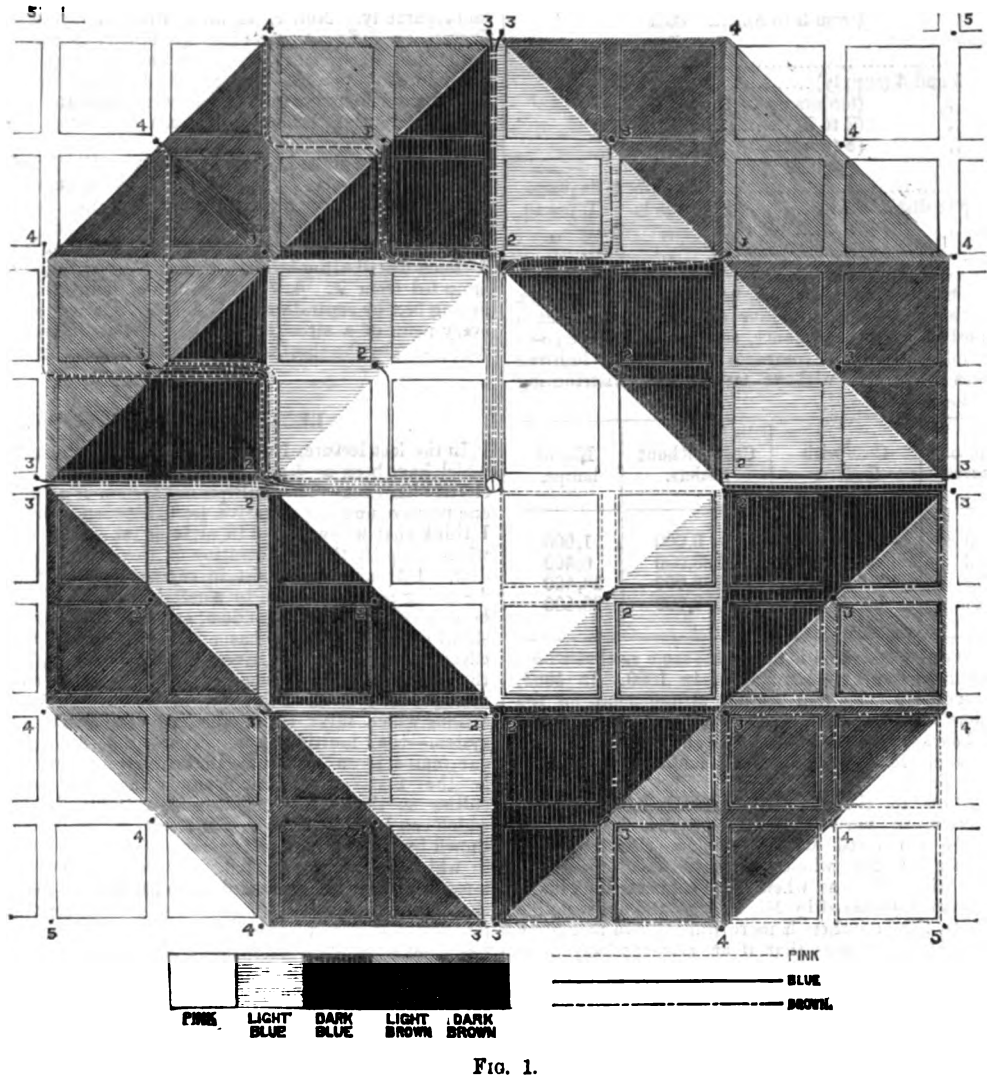

FIG. 1.

124 yards is the limiting length of conductor. Now notice that this is not necessarily the limiting length of conductor from the station, because it does not much matter what the fall of potential from the station to a lamp is ; but it is the limiting length of conductor between the farthest and the nearest lamp, or the difference in length of conductor to the station from the farthest and nearest lamps ; for here the injurious variation of potential comes into play. If the nearest lamp were 124 yards from the central station, there would be a loss of potential of 4 volts in that distance, in order to comply with economical considerations, but that loss of potential would not affect the potential between different lamps, if might go to a voltmeter in the engine house, an end of each wire being attached to the mains in the distributing box. With a similar tell-tale coming from the most distant lamp of the system, the engineer knows exactly what pressure is required. This second district, with feeder mains losing four volts, is generally larger than the first, and will generally require a number of feeder mains, or roots, feeding separate trees. It will be noticed that each root is connected to a separate dynamo. If we extend the distance still further we must put on a new set of roots or feeder mains, each losing eight volts ; and so on up to any distance. The further we go the greater is the cost of mains, but this cost is more nearly in proportion to the distance than to the fourth power of the distance, as in Mr. Kapp's paper (which is not founded on the economical considerations).

I must here put in a warning, necessary from what I have seen of the

* The Cantor Lecture of Professor George Forbes, delivered on February 9th, 1885. From the *Journal of the Society of Arts.*

Digitized by Google

practice of this system here and abroad. The distributing box of a feeder must not be in the centre of the district supplied by that feeder, or you waste all the extra copper going to the lamps nearer to the station than the distributing box. The point of distribution must be the point of the district nearest to the central station, in order that we may have a maximum economy of copper.

Suppose we are lighting a town like Philadelphia or Chicago, which is built in square blocks, and suppose two sides of each square are 124 yards long, we should have a fed centre for each block on the diagram below where 1 is the central station. Within the square indicated by Fig. 1, no feeder mains are required. The distance of all the points 2 from the station is the same if measured along the streets. There are four squares and eight half squares thus supplied, equivalent to eight squares. The first feeder main supplies the district between the squares marked 2 and 3 respectively, equivalent to twenty-four squares ; the second set of feeders supply forty squares, the third fifty-six, and so on. The copper in the service of a block is one-half of the copper in 124 yards of the feeder main for a block, since some supply conductors are short, and others 124 yards long. Thus, to supply twenty-four squares with the first feeder, the latter must have the copper of supply conductors for forty-eight squares. In this way we find the cost of supplying the districts up to 1, 2, 3, &c. Let L be the cost of copper for one square :—

Cost for district 1 is	8L	for 8 squares.
,, between 1 and 2 (supply)	24L	
,, ,, (feeders)	48L	
Cost of district 2.....	80L	for 32 squares.
,, between 2 and 3 (supply)	40L	
,, ,, (feeders up to 2).	80L	
,, ,, (from 2 to 3).....	80L	
Cost of district 3.....	280L	for 72 squares.
,, between 3 and 4 (supply)	56L	
,, ,, (feeders up to 2).	112L	
,, ,, (2 to 3)	112L	
,, ,, (3 to 4)	112L	
Cost of district 4.....	672L	for 128 squares.

Cost of lighting square up to distance.....	124 yards	is	L per sq.
,, ,, ...	2×124 ,,		2·5L ,,
,, ,, ...	3×124 ,,		3·8L ,,
,, ,, ...	4×124 ,,		5·25L ,,

It will be seen, then, that the cost does not, in this system, vary in a proportion even approaching the fourth power of the distance, but is much more nearly proportioned to the distance, especially when we go to great distances. The following table compares the cost of lighting districts of various sizes with and without feeders and distributing centres :—

—	No. of squares.	Cost with feeders.	Cost without feeders.	No. of lamps.
1 district	8	8,000	8,000	1,600
2 districts.....	32	90,000	128,000	6,400
3 districts.....	72	280,000	648,000	14,400
4 districts.....	128	672,000	2,048,000	25,600

The system which I have now described is nearly the same as that which was proposed (in an imperfect form) by Mr. Edison in 1880. In 1883, Mr. R. E. Crompton proposed a somewhat similar arrangement for the Victoria provisional orders (also imperfect). As shown before, telegraph wires from distributing boxes (proposed by Mr. Edison) are unnecessary ; a compound-wound galvanometer attached to the mains in the engine-house serves the same purpose.

I would draw attention to the fact that the ends of the twigs, or the branch conductors, in parts of a district fed by different roots or feeders, may be connected when they are close together, thus making a network of the whole district, the proportions of conductors remaining the same as when not connected. This is a distinction from the network proposed by Mr. Edison, and a distinction necessary for economy. In this case there is more difficulty in managing the potentials, but it has this advantage, that if an accident happens to one feeder main its fed district will, in some cases, be not quite in the dark. Considering the comparatively small chance of accident to feeders, as shown by our experience of gas, I would waive this, and in some cases I might even prefer that each block should be supplied from its distributing box by independent wires to each lamp. The potentials of all lamps are then absolutely constant, and, as shown before, there is less waste of energy in the distant lamps. At Paddington Mr. Gordon uses a modification of the independent wire system by leading a group of wires for a main, and cutting out more or less of them automatically, or by signals from the engine house, according to the proportionate consumption in different parts. This is one example of many devices which the engineer may resort to in special cases, but which are not satisfactory as a general system. The different potentials may be given to the mains in a variety of ways. Edison puts resistances in the feeders. Gordon does the same by cutting out some conductors of the main feeders. I prefer, after getting 100 volts, to add to the pressure by a number of dynamos of large quantity and only two volts pressure. Terminals come to studs, along which feeder contacts slide till the right pressure is attained.

I have not time in three lectures to go into all these details. I must stick to the main question.

Network Mains.—I now come to the network system, and after the care we have bestowed upon the multiple arc system generally there is not much to say. In the form proposed and carried out by Mr. Edison it is not economical, and I shall show you why. He leads his conductors along the face of each block of buildings, and wherever the conductors intersect, the + and − conductors are connected together respectively. Distributing centres are provided with feeders supplying them, and with wires to the engine house to indicate the potential. Resistances are introduced into the feeder circuits to equalise the potentials. This is a beautiful idea, carried out without calculation, and consequently not economical. It is verbally identical with what I have called the tree system, with the branches of separately fed districts connected. The chief practical difference is that Mr. Edison lays his conductors of the same size for a long way. In the tree system the economical size of conductor is chosen in every part. Secondly, Mr. Edison equalises potential by resistances in the mains, which is hostile to economy. The importance of having a large number of feeding boxes and feeders is very great, for two reasons : —1. Repairs are more easily executed with less interference to many people. 2. The equalisation of potentials may be made practically perfect.

The advantages of independent wires from lamps to distributing boxes are enormously increased by the fact that repairs do not affect other lamps. The only consideration to weigh against its advantages is the extra cost of thin insulated wires. This is a matter which it is impossible to touch in a general statement of the problem, but which the engineer must calculate for every special case before finally deciding. The only advantage of connecting separately fed districts is the prevention of darkness in case of accident to a feeder. I prefer to guard against this by splitting each feeder into two. It would rarely happen that both were damaged together, if laid separately. Notice, in all systems of laying mains, the size of conductors in different parts is proportionate to what it would be if a wire came from each lamp by the shortest route. On the wall is a diagram to show you the arrangement proposed by Mr. Edison, where you see separate dynamos connected with separate feeders, going to separate distributing boxes, which are connected to the whole network system.

My object in these lectures is to lay methods before you, not to give opinions, but it may be right that I should state to you my belief that the most satisfactory multiple arc system proposed is as follows :—1. A large number of distributing boxes as follows (the number depending on the type of dynamo, or *vice versâ*). 2. Each box fed by a different feeder. 3. Each distributing box must be nearer to the central station than any lamp fed from it. 4. Small groups of lamps to be fed from the distributing box by separate wires. 5. The relative section of conductor at every point of a street to be the same as if every lamp had a separate wire going by the shortest street route to the central station.

LECTURE III. (Delivered Feb. 16).

In the last lecture, I was engaged in describing the different methods which have been used to apply what is called the multiple arc system of electric lighting. The multiple arc system is a system in which there are one positive and one negative lead, between which the lamps are placed. I think that we succeeded in arriving at several very general conclusions which simplify the consideration of the manner of laying mains a great deal. I think I am right in saying that in the past the practice of designing mains has been to a certain extent haphazard ; the mains have been selected a little at random, and then perhaps afterwards adjusted to a slight extent ; but there has not been that thorough estimating of the effects which could be arrived at by calculation, and in consequence of that there have been some grievous failures in electric lighting on the multiple arc system. I think we arrived at one or two important generalisations which must be accepted as necessary for economy, and in such a system—the multiple arc system—the amount of copper used in our mains is so enormous that everyone must admit that economy is the first consideration, and that all such engineering difficulties as there may be must be met by the engineer as difficulties which can be conquered. The results which we arrived at were clearly shown by the diagram of the city of Chicago, as we chose to call it, in which it was shown that, in order to have good distribution, there must be no great variation of pressure in the mains, electric pressure in the mains corresponding, as you will remember, exactly with hydraulic pressure if it were a service of water ; and in order to prevent our having too great a variation of pressure in different parts of the district, or in the same district at different periods of the night, when the consumption over the district varies, it is necessary, as I showed by means of the diagram, to have a large number of distributing boxes with mains, trunk lines of conductors coming to these distributing boxes and feeding them, and each one of these distributing boxes then serving to light up a certain space, which in the diagram is essentially a triangular space. And I also gave you the rules for determining what is the size of the district which may be lighted up by such a distributing box, and I think everyone here will agree with me that the limit was very confined indeed, compared with the general ideas which have prevailed as to the number of distributing boxes which are required ; that is to say, that upon the assumption upon which we have been working of the size of conductor required to carry a certain current, we concluded it would be necessary to have the distributing boxes so close that no lamp should be at a greater distance than 124 yards from the distributing box. Another important point which has been, I may safely say, altogether neglected in all schemes which have been hitherto issued for distribution of electricity from central stations is this, that the distributing box, the point from which the distribution takes place, must be closer to the central station than any of the lamps which are fed by that distributing box. As a

Digitized by Google

general rule, the distributing box has been put in the centre of the district which it feeds, and that is a mistake; it ought to be nearer the central station than any of the lamps which it feeds. I gave you also in the last lecture some account of the relative cost of different systems of lighting in the multiple arc way, and it was found that by introducing a large number of distributing boxes in this way the cost was very materially reduced; but, at the same time, the cost was very great, even with these distributing boxes. And the cost may be divided into two parts; first, the cost of the supply wires, the conductors which are supplying the electricity from each distributing box to the houses, which are represented by the square lines round each block of buildings; and secondly, there is the expense of the feeders, the conductors going up to the distributing boxes. Now, when we increase the size of our district to any considerable extent, the cost of these feeders, these trunks which carry the electricity to the distributing boxes, is far greater than the cost of the supply system of conductors. If there be a means of reducing the cost in this way—that is to say, any way of cutting out these feeding conductors, that will be a very great economy indeed. This evening I will leave altogether apart the system of multiple arc lighting, which is the system which has been almost universally adopted in the past, and I shall speak this evening about the different systems which have been proposed and carried into effect for using higher pressure in the mains. The work which is done by a certain number of lamps is a perfectly definite amount of work, and it is measured by the product of the pressure of the electricity into the quantity of the electricity which flows. If we increase the pressure, we diminish the quantity of electricity that flows; that is to say, we diminish the current, and if we diminish the current, we can diminish the size of our conductors.

Now a great deal has been talked about the danger of introducing high pressures in electric distribution. I think that I shall find general agreement among competent people when I say that a great deal of what has been talked in this way is pure nonsense, and that high pressures are not in the least more dangerous than our present systems of illumination; that if we have to bring high pressures of electricity through a district those pressures are confined to the wires, and it is only in the case where there is disgraceful negligence of duty, and a disgraceful leakage towards the earth in some part of the system, that it is possible for anybody to receive a dangerous shock from the wires of such a system.

(To be continued.)

LEGAL.

United Telephone Company v. Bassano.

In the Chancery Division, on the 26th inst. (before Mr. Justice North), Mr. ASTON, Q.C., said it had been arranged that the trial of this case should stand over until the appeal had been heard in the case as to which the learned judge had already given judgment, but had not yet stated on what reasons the judgment was founded. This case would stand over until the decision of the ultimate Court of Appeal in the action on the Edison patent. The plaintiffs were to be at liberty to apply to have the case restored to the paper if the appeal was not proceeded with in due time. If, on the ultimate appeal, the learned judge's judgment should be upheld, the defendant's would submit to that judgment on similar terms in respect to the present action. If, however, that judgment should be reversed, the plaintiffs might proceed with this case in the usual course; the existing undertaking not to manufacture, sell, or dispose of the instruments complained of was to be continued until the hearing of the appeal.

The JUDGE said he failed to understand the object of this application; but if the parties had agreed to the arrangement he would not object to it.

Mr. PLUMTRE asked that the stay of execution should be continued.

It transpired, however, that no notice had been given of this application.

Mr. ASTON said he would prefer that no motion of this kind should be heard until after they had been favoured with the grounds of the judgment.

The JUDGE said he could not prevent notice of motion being given.

Ultimately it was arranged that notice of motion should be given by Thursday, the 29th inst.

On Thursday Mr. BIGHAM, Q.C., applied for an order to stay the inquiry as to damages and the taxation of costs in this case pending the appeal.

The JUDGE: What special ground is there for departing from the usual practice?

Mr. BIGHAM said the ground was that there was a *bonâ fide* intention to appeal, which the defendant was prosecuting with all diligence. The appeal was set down on 23rd September, and it was No. 101 on the list, so that it would probably come on within two months. Under those circumstances it was undesirable to have an inquiry at present into the costs.

The JUDGE said it might be convenient if the matter was adjourned, but it was entirely a matter for the decision of the plaintiffs. He saw nothing exceptional in this case. The order would be the common order as to taxation of costs.

Mr. ASTON, Q.C., said it was not necessary to get an order to stay the inquiry into damages in this case.

The JUDGE: You had better draw up no order at all at present; and make the costs of this application costs in the cause.

London and Provincial Electric Light and Power Generating Company (Limited).

Mr. ROMER, Q.C., applied to Mr. Justice Chitty for Mr. Gaminara in this case, which it had been arranged should be taken as a test case, for the removal of his name from the list of shareholders of this company. Mr. Gaminara was a general merchant, living at Upper Norwood, and he applied for and obtained immediately upon the registration of this company in May, 1882, fifty shares in the company of £5 each. He took the shares upon the strength of the statements in the prospectus that the company had acquired the patent rights of the Chertemps arc lamp for the United Kingdom; and of the lamp itself they said it "is well known for its brilliant white light, for its steadiness, and for its simplicity," and "the feed of the lamp is so sensitive that, while giving the maximum amount of light, it follows exactly the consumption of the carbons." The idea conveyed by this was that the lamp did not flicker. The applicant claimed that there were six misrepresentations in the prospectus, but that the one quoted was the principal one, and he had filed an affidavit to the effect that this allegation about the feed was untrue. Affidavits had been made by several electrical engineers, including Mr. G. C. Offor, Mr. A. J. Howes, and Mr. H. F. Joel, saying that the statement in the prospectus was misleading and untrue; that the lamp was fed by clockwork, consequently the consumption of the carbons was irregular; that the lamp varied in intensity, and necessarily flickered. Mr. G. H Redwood, the secretary of the company, had filed an affidavit in reply, saying that by the paragraph in question in the prospectus, "it was meant that, owing to the excellent construction of the lamp, the light thereby generated was, as compared with that generated by that of other companies, of uniform quantity and intensity." This was not how Mr. Gaminara understood it; and he (Mr. Romer) urged that the true meaning was that which Mr. Gaminara attached to it, and which had been proved to be untrue.

Mr. INCE, Q.C., contended that there was no misrepresentation. It was not stated in the prospectus that the lamp would not flicker; but, on the other hand, no evidence had been submitted to show that the lamp did flicker. The allegation in the prospectus was perfectly true; the feed was such as to preserve a uniform distance between the points of the carbon as they were consumed. Even Mr. Offor, in his affidavit, admitted this. The carbons adjusted themselves as the consumption went on.

The JUDGE said this was all only statement by counsel, which was not supported by evidence.

Mr. INCE said it was sufficient to point out the discrepancies in the evidence on the other side, and he read the affidavits in considerable detail. All Mr. Joule said was the feed was not sufficiently sensitive to prevent occasional flickering; the company never said that it would prevent occasional flickering. They only said that the lamp gave a more steady light than one not supplied with the feed. The clockwork responded to the electrical condition of the carbon points.

The JUDGE: Yes, but the other side says that it does not respond quickly enough.

Mr. INCE said this involved no misrepresentation. The company in the prospectus expressed the full belief.

The JUDGE: The remarkable thing is that you give no evidence to show that that statement is true; you do not show that you have tried the lamp and find that it is as you state in the prospectus.

Mr. INCE said his second point was that there had been delay. The application for the shares was made in May, 1882, and the summons was taken out in January, 1883; the applicant had made no statement as to when he discovered the misrepresentation, but in any case he had delayed too long.

The JUDGE said this was the more important point. He had known a delay of six weeks to be fatal in a similar case.

Mr. ROMER said the applicant repudiated the bargain to the secretary of the company at once, and when told the company would proceed against him, he expressed his readiness to receive a writ; but no proceedings were taken.

The JUDGE said it was clear that the alleged shareholder repudiated within a reasonable time. There was no ground for saying that he must fail on the score of delay. It was a case of simple misrepresentation, of an innocent kind so far as fraud was concerned, but sufficient to enable a person who had acted upon it, if it turned out to be untrue, to ask to be relieved from the consequent responsibility. There was no question that the statement in the prospectus was material, and that it induced the present applicant to enter into the contract. The statement was that the feed "follows exactly the consumption of the carbons," and the scientific evidence for the applicant showed that no arc lamp could be so constructed as to accomplish this. He (the Judge) had come to the conclusion that the words, taken in the natural sense, were untrue in point of fact. The applicant's name must therefore be struck off the list of shareholders.

COMPANIES' MEETING.

Brazilian Submarine Telegraph Company.

The twenty-fourth ordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel, on the 29th inst., under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting and the minutes of the last meeting, which were confirmed.

The CHAIRMAN said he would congratulate them and himself on the Company having attained a round dozen of half-yearly meetings, that being their 24th half-yearly meeting, and he hoped that the meetings had been satisfactory on both sides of the table. The report of the Directors contained in itself almost all the information that he could give them if

Digitized by Google

he spoke to them for hours. But there were one or two observations he would like to make. A fault had developed itself in the Madeira-St. Vincent section, but it did not interfere with the execution of the work by the cable. A diminution of insulation had also taken place in the Lisbon-Madeira section, but that was exactly of the same character as the other. Both those faults were in the old cable, which had now been down for a dozen years, and with those exceptions their property was in a perfectly satisfactory state. He regretted to say that their income last half year had been about £7,000 less than that of the preceding half year. That was due to the depression of trade prevailing everywhere, the competition of the West Coast of South America line, and also the adverse rate of exchange, which had affected them in bringing their money from Brazil. It was very satisfactory to say that they had reduced their expenses by £2,077, and notwithstanding the diminution of their income they were still able to pay a dividend of 6 per cent., and carry over a respectable balance for next year. They had to regret the death of Senor Santos Silva, who had been their reprensentative in Lisbon, and under the Articles of Association of the Company they had elected the Duke de Loulé. Those were all the points which it was necessary for him to touch upon connected with their own enterprise. But he would like to allude to a matter affecting cable property generally. They knew, and other companies knew by more disagreeable experience, that cables were constantly stopped in shallow water, sometimes from wilful injury done to them and sometimes from accident. That subject had become the ground of a convention between the Great Powers interested in cable property, and the result had been an agreement entered into by all those Powers for the protection of property of this description, and anybody who now wilfully injured cable property would be liable to be punished. That was something gained certainly, but he thought it would be quite possible to have a convention which would protect their property in time of war, as well as in time of peace, against injury. Of course, no one would for a moment imagine that belligerents would consent to cable operations being carried on in time of war, but he thought the property might be protected if traffic were suspended during warlike operations. He thought that the step which had already been taken was in that direction. He concluded by moving the adoption of the report and accounts and the declaration of a dividend of 3s. a share, making, with the interim dividend, 6 per cent. for the year, free of income tax.

Sir JAMES ANDERSON seconded the motion, and testified to the value of the services which had been rendered to the Company by the late Senor Silva.

In reply to Mr. JOHN NEWTON,

Sir JAMES ANDERSON said that Mr. Fuller had more especially represented the Company at the late Conference at Berlin, but as nothing material had occurred affecting their Company, Mr. Fuller might not perhaps care to reply. He (the speaker), however, might say that a great effort was made to get this Company to reduce their rates, but that did uot appear to be the desire of their friends of the Western and Brazilian Company or of the Brazilian Government, and the rates remained as they were; but the whole tendency of these conventions was to reduce rates. There was one phase of the question which it was just as well the public should know. All the Governments of the world, with two exceptions, had a large deficit in working their telegraphic system; but notwithstanding that Germany was determined to have them made larger deficits still, and that had resulted, so far as the European traffic was concerned, in a reduction of as much as 4 per cent. in the European tariffs. When they began to discuss matters at the Conference, the expression *cables de luxe* was tabooed, but another expression arose, namely, that there were certain cables that were called "the normal way" for telegrams, and it was generally agreed that those cables should be supported, and that the tariff should not be taken for them to the enormous extent proposed. When they first went to Berlin the majority of the States fell in with that view, and the result had been that the Cable Companies had not been obliged to reduce their tariff to anything like the extent which was wished at first, and they had managed to get the rates kept up to a fair amount, particularly if the traffic increased as a consequence of the large reduction which the European States had made in the tariff. At first it appeared as if the Eastern Company, with which he was most concerned, were going to lose £40,000 a year on their European traffic alone. But he did not believe that in the two years they would lose anything, and on the face of it the loss came down to something like £12,000. At the former conferences the feature was that telegraph systems ought to pay, but he regretted that that was not the case now, the feature in the minds of the European States, especially of Germany, being that that was a secondary consideration, and that if the telegraph administration was fused with that of the Post Office they need not care what they lost in one department, because the other would make it up, and they also thought that the indirect advantage derived from the increase of commerce would more than cover any loss they made on the telegraph administration.

Mr. NEWTON said that what had just been stated had confirmed him in the view he had always taken as to the importance of keeping up their reserve fund.

The resolution was then unanimously carried.

On the motion of the CHAIRMAN, seconded by Mr. FREDERICK YOULE, the Duke de Loulé was re-elected a Director, as was also Viscount Monck, on the motion of Sir THOMAS FAIRBAIRN, seconded by the Hon. W. ST. JOHN F. BRODERWICK, M.P.

Messrs. Henry Dever and John Gane were re-elected auditors, and the proceedings terminated with a vote of thanks to the Chairman and Directors.

COMPANIES IN LIQUIDATION.

The following notices appear in the *London Gazette*:—

The Jarman Electrical Company (Limited).—At an extraordinary general meeting of the above-named company, duly convened and held at No. 6, Great Winchester-street Buildings, in the City of London, on the 5th day of October last, the following special resolutions were duly passed; and at a subsequent extraordinary general meeting of the said company, also duly convened and held at the same place on the 22nd day of October last, the following special resolutions were duly confirmed, viz.: 1. "That the company be wound up voluntarily, under the provisions in that behalf of the Companies Acts, 1862-7; 2. That Mr. W. Smith, of 6, Great Winchester-street, E.C., be appointed liquidator for the purpose of winding up the affairs of the company; 3. "That the liquidator be authorised, under the 161st section of the Companies Act, 1862, to carry out the agreement of 31st July, 1885, between the said Jarman Electrical Company (Limited) of the first part, Chainsonovitz Prosper Elieson of the second part, and Edward Spendlove, as trustee for and on behalf of the Electric Locomotive and Power Company (since registered) of the third part, and any confirmatory agreement for the sale to the said Electrical Locomotive and Power Company of the business, property, and effects of the said Jarman Electrical Company."—G. HAMILTON, Chairman.

The Electric Sun Lamp and Power Company (Limited).—The creditors of the above-named Company are required, on or before the 4th day of December, 1885, to send in their names and addresses, and the particulars of their debts or claims, to Messrs. William Perkins, Matthew Inglett Fortescue Brickdale, and Henry de Grelle, the liquidators of the said Company, at 5, Bombay-street, Bermondsey, in the county of Surrey, and if so required by notice, in writing, from the said liquidators, are to come and prove their said debts and claims at such time and place as shall be specified in such notice, or in default thereof they will be excluded from the benefit of any distribution made before such debts are proved.—W. PERKINS, M. I. F. BRICKDALE, HENRY DE GRELLE, liquidators.

The Anglo-Continental Telephone Company (Limited).—Notice is given that a general meeting of the members of the Anglo-Continental Telephone Company will be held at the offices of Messrs. Fox and Greig, No. 22, Austin Friars, London, E.C., on Thursday, the 26th prox., at 3 o'clock, for the purpose of having an account laid before them, showing the manner in which the voluntary winding up has been conducted, and the property of the Company disposed of, and of hearing any explanation that may be given by the liquidator; and also of determining by extraordinary resolution the manner in which the books, accounts, and documents of the Company and of the liquidator thereof shall be disposed of.

NOTES.

NOTICE OF REPAIR.—The cable between Fao and Bushire is repaired.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th ult. amounted to £3,314.

LONDON PLATINO BRAZILIAN COMPANY.—This company have declared an interim dividend of 1s. per share for the half year ended 30th September.

THE WEST AUSTRALIAN TELEGRAPHS.—It is expected that telegraphic communication with Roeburne will be completed by about the 15th of next month.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for October, 1885, amounted to £56,994, and to £53,865 in the corresponding period of 1884.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of October were £1,748, against £1,816 in the corresponding period of last year.

GREAT NORTHERN TELEGRAPH COMPANY.—The receipts of this company for October were £24,400 ; from 1st January to 31st October, £241,640; against in the corresponding months of 1884 £234,680, and 1883, £215,280.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October amounted to £43,986, and to £41,357 for the corresponding period of 1884, showing an increase of £2,629.

THE AUSTRALASIAN CABLE SERVICE.—It has been decided that the New Zealand Government will undertake to continue the Australasian cable service for five years, provided the charge for press messages did not exceed 3d., and for ordinary messages 6d.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th October, were £2,558, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st October are £1,931, as compared with £2,512 in the corresponding period of 1884. The July receipts, estimated at £5,089, realised £5,157.

THE LIGHTING OF PICCADILLY-CIRCUS.—At a recent meeting of the Metropolitan Board of Works a letter from Messrs. Hunter, Harrison, and Co., submitting a scheme for the electric lighting of the large open spaces at Piccadilly-circus, was referred to the Works and General Purposes Committee.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of October was 2,694, estimated to produce £2,100, against 2,589 messages, producing £2,230 in the corresponding month of last year. The traffic receipts for the month of July, estimated at £2,500, realised £2,517.

AWARDS.—Messrs. Walter T. Glover and Co., of Salford, Manchester, have been awarded a gold and silver medal at the International Inventions Exhibition, 1885.—Messrs. Robey and Co., of Globe Works, Lincoln, have received a gold medal for their patent improved Robey mining engine, horizontal fixed engine, and Robey compound semi-fixed engine fitted with electrical regulator.

UNITED TELEPHONE COMPANY.—At the board meeting of this Company, held on the 3rd inst., the directors being satisfied that the position of the company justifies them in making a somewhat larger payment on account of the earnings of the current financial year than heretofore, have determined to pay 4s. on each fully-paid share (part-paid shares receiving in proportion) by way of interim dividend.

TELEGRAPHIC CONFERENCE BETWEEN ENGLAND AND THE EAST.—It is said that the Eastern Telegraph Company has asked the Dutch Government to join in the arrangement between the company and the British Government for the application, from the 1st of the current month, of the provisions drawn up at Berlin for the regulation of telegraphic correspondence between England and the East.

THE ELECTRIC LIGHT IN THE INNER TEMPLE LIBRARY.—The librarian of the Inner Temple library writes as follows to the *Daily News* :—"*Apropos* of your article on the electric light in this library, may I be allowed to say that the success of the installation is mainly due to Mr. John Clerk, Q.C., treasurer of the Inn; Mr. Arthur Cates, the architect; and to Mr. Belshaw, the manager of the Edison-Swan Electric Lighting Company."

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.—The next meeting of this society will be held at the Institution of Civil Engineers, 25, Great George-street, Westminster, S.W., on Thursday, the 12th instant. There will be a council meeting at 7 p.m., and an ordinary general meeting at 8 p.m., when a paper will be read by Major-General Webber, C.B. (Ret.), R.E., past president, upon "The Telegraphs of the Nile Expedition."

THE LIGHTING OF THE CITY.—At a recent meeting of the Commissioners of Sewers, Mr. Pannell asked whether the Streets Committee had had an offer to remove an installation for electric lighting and lay the same in a district of the city for a stipulated sum. Mr. Altman, chairman of the Streets Committee, said they had had an application to remove an installation from some part of the country to London. It was now before the committee, and he hoped soon to bring up a report.

CAUTION.—Those who have visited a Spanish, Italian, or Portuguese port, will have a vivid remembrance of the extraordinary precautions against possible risk of infection taken by the sanitary "visit." The following, however, gravely recounted by a Milan contemporary, beats anything we have seen or heard of. At the time when the cholera broke out in the departments in the north-east of France, a number of Italian telegraph office officials ordered a quarantine of twenty-four hours, with fumigation, to be imposed upon all telegrams coming from the infected districts.

AN APPLICATION.—In the High Court of Justice (Chancery Division) recently, before Mr. Justice Chitty, an application was made by divers shareholders of the London and Provincial Electric Lighting and Power Generating Company for rectification of its list of shareholders by the removal therefrom of the applicants' names. It appeared that the company was incorporated in May, 1882, and was in November, 1883, ordered to be wound up. The ground of the application was that the applicants were induced to take their shares by means of misrepresentations contained in the prospectus issued by the company. Mr. Justice Chitty made the order applied for.

THE ELECTRIC LIGHT IN A LIVERPOOL CLUB.—At the dinner recently given to the Liberal candidates for the Liverpool constituencies at the Junior Reform Club, the dining saloon was lit up for the first time by the electric light, and

Digitized by Google

presented a most pleasing and brilliant effect; the work was carried out in a satisfactory manner by Mr. W. H. Fleming, electrical engineer, of Baliol-chambers, Stanley-street, Liverpool. The motive power for driving the dynamo machine, which was an 8in. Elwell-Parker, was obtained from a gas engine situated in the basement of Baliol-chambers. Fifty Edison-Swan 45-volt 16 candle-power incandescent lamps were used.

THE LALANDE AMPEREMETER.—The new amperemeter of M. F. de Lalande is highly commended by our French contemporaries, who lay great stress upon improvement effected by the substitution of an electro for a permanent magnet. The instrument, roughly, consists of a bundle of soft iron wires placed in the interior of a metallic areometer, which latter is inserted in a gauge full of water surrounded by a coil traversed by the current to be measured. Under the action of the current the bundle of wires is attracted, and the areometer is more or less displaced according to the strength of the current indicating the value of such displacement upon a scale graduated upon the instrument

POOLE SCHOOL OF SCIENCE AND ART.—The following have obtained prizes at the above science school:—W. Bartlett, 2nd class elementary certificate for electricity; A. R. Curtiss, 1st class elementary certificate for electricity and local prize for electricity; F. B. Daniel, 2nd class advanced certificate for electricity; L. F. Davis, 1st class elementary certificate for electricity, local prize for electricity; Mrs. Gilbert, 1st class elementary certificate for electricity, local prize for electricity; A. Reed, 1st class advanced certificate and prize for electricity and local prize for same; W. Sedgfield, 2nd class elementary certificate for electricity; R. Smith, 1st class elementary certificate for electricity and local prize for electricity; E. J. Wilkins, 1st class elementary certificate for electricity and local prize for ditto.

TARDY TELEGRAMS. — A correspondent of the *Standard* writes as follows:—"I do not know what may be the experience of other people; but after three weeks of sixpenny messages I find most of them rather dear at the money. I live in a London suburb, twenty-five minutes by train from Ludgate-hill, three-quarters of an hour by cab from Ludgate-circus, and my house is so near the Post Office that I can walk to it in seven minutes. Yet it is rare that a telegram from Ludgate-circus reaches me within forty minutes, and I have received one at forty-four minutes past six which was handed in at four minutes past five. It therefore took one hour and forty minutes to travel a distance which a cab can cover in three-quarters of an hour. To my finite intelligence this looks absurd. Is the office overworked or undermanned, or is the young lady operator becoming careless?"

THE "MAGNETIC UMBRELLA."—Mr. Sprague, in a letter to us, mentions this subject as follows:—"I may say that the late accounts published of the mysterious 'magnetic umbrella' somewhat amuse me, as I possessed one myself a long while ago. When the first experiments with the Gramme machine were made in the Westminster Bridge-road, I was leaning close to it on my umbrella, and the machine being suddenly turned on the umbrella was torn out of my hand, and ranged across the field-magnets. It became a powerful magnet and remained so for years. I often puzzled people with it by setting magnetic needles spinning about by merely pointing my finger towards them, and I know that in some cases I caused a good deal of mental tremor by my apparent possession of this unusual 'magnetic moment,' the poor umbrella being of course a mere accident of the moment."

TELEGRAPH AND POSTAL ADDRESSES.—Sixpenny telegrams are already exerting their influence on business ways. The adoption of "telegraph addresses" is likely to become universal among such as carry on a large correspondence in which the use of the telegraph is constantly called in; and hence the necessity of a new or supplementary method of indexing. Messrs. Duncan Campbell and Son, of St. Vincent-street, Glasgow, have been prompt to provide for this want. They have issued a strongly-bound index of "Telegraph and Postal Addresses." One half of the volume is arranged for the alphabetical indexing of "Telegraph Addresses," followed by the names and postal addresses of correspondents. Reversing the book, the order is found reversed; the spaces under each letter are left for names and postal addresses followed by telegraph addresses. The device is ingenious and simple, and may be turned to account for more purposes than one.

ELECTRIC SIGNALLING FROM BALLOONS.—Mr. Bruce, whose experiment at the Albert Palace was noticed in our columns, has written to us to say that he has been carrying out fresh experiments at Chatham, with a view to procuring the adoption of his system for the purpose of military signalling. The official trial of the invention took place on the 19th ult., when the signalling apparatus, the balloon, was sent up four or five miles from Chatham, and allowed to ascend 500ft., a series of sentences being flashed by the Morse system. The officers of the Royal Engineers, who were deputed to inspect the apparatus, have pronounced the experiments eminently satisfactory. It has been suggested that this translucent balloon may be utilised for other military operations besides signalling, such as for a "point light" for concentrating forces by night; and owing to the wide area which is illuminated by the balloon, it has been proposed to use it for lighting working parties.

THE ELECTRIC LIGHT AT TUNSTALL.—In connection with the festivities incident upon the opening of the new town hall at Tunstall, Staffordshire, on Thursday week, a football match was played under the electric light on the Phœnix Park Grounds, a vast assembly of people being present. The grounds were effectively lit up by six Lever arc lamps. The football match was succeeded by a promenade concert in the covered market, which was attended by several thousand people. The Market Hall was illuminated by ten 2,000 candle-power nominal arc lights of the same system, and two lamps were placed outside—one over each entrance. An engine had been provided in the Soho Mills, but Mr. Lever found it desirable to hire a portable engine as well, so that the work was divided between them. This was on the 29th ult. The next night a ball was given in the Town Hall, when the front of the building was illuminated by five arc lamps. The lighting was a great success.

A SAD ACCIDENT.—We regret to have to announce that a sad accident occurred off the mouth of the harbour of St. Thomas on Saturday the 3rd ultimo. Messrs. E. Howes, the second engineer, G. Heath, third engineer, and James Day, jointer, of the cable steamer "Duchess of Marlborough," belonging to the West India and Panama Telegraph Company, were, while boat sailing, caught in a sudden squall, which filled their boat and sank it. Nothing has since been heard of Messrs. Howes and Day, but Mr. Heath was on the following Monday discovered on an island close by, after having sustained an exposure of about thirty-eight hours. Little hope is entertained for the safety of the other unfortunate men, there being every reason to fear that

Digitized by Google

they have fallen victims to the sharks which abound in the waters of St. Thomas. Both leave wives and families to deplore their loss. Mr. Day had only recently left the service of the India Rubber and Gutta Percha Company, at whose works he was employed in the capacity of jointer.

THE FRANKLIN INSTITUTE.—The programme of lectures at this institute for the session 1885-86 has just been issued. It promises to be very interesting. On the 13th inst. Lieut. Bradley A. Fiske, U.S.N., will discourse on "Electricity in Warfare;" Prof. A. E. Dolbear on "Telephone Systems," Dec. 11; Mr. C. J. Kintner, Chief Examiner, Department Electricity, U.S. Patent Office, Washington D.C., on "The United States Patent Office Historical Electrical Apparatus," Jan. 25, 1886; Mr. Carl Hering, of Philadelphia, on "Dynamo-electric Machinery," March 1; and upon the same subject one week after that date; and Capt. Otho Ernst Michaelis, U.S.A., on "The Function of Electricity in the Development of Markmanship, or Electro-Ballistics," March 15. The lectures of the physical course are chiefly upon subjects bearing upon the International Electrical Exhibition of 1884, by gentlemen who were personally engaged in scientific work connected therewith. They have been arranged by Prof. Houston with the object of giving the members of the institute a review of some of the leading features of that important historic event.

CONTINENTAL ITEMS.—The installation recently started at the New Lyceé Louis-le-Grand, Paris, is giving great satisfaction.—The inauguration of the electric light at the Opera House, Paris, will be coincident with the first representation of "The Cid," a new opera by Massenet.—The Société Industrielle of Amiens is offering gold medals for the best designs for a new dynamometric brake and a simple and economical dynamometer. Plans may be forwarded to the president until 30th April prox.—It is said that the Société Générale des Téléphones has decided to add to its other establishments a factory for the manufacture of submarine telegraph cables at one of the principal French ports.—The yacht "Hero," belonging to M. de Rothschild, has, preparatory to her departure for Nice, been equipped with a dozen Trouvé portable incandescent lamps.—There is about to be published at the Librairie Bernard Tignol a new work by M. G. Fournier, entitled "Les Sonneries Electriques, Installation et Entretien." This will form the tenth volume of the "Bibliothéque des Actualités Industrielles."

WELL-DESERVED PUNISHMENT.—A remarkable charge was investigated before the Liverpool Justices on the 3rd instant, when Edwin Mitchell and James Hughes were summoned for having obstructed a telegraph communication of the Exchange Telegraph Company. It was stated that the company conveyed messages by means of a tape, and supplied a number of betting and other clubs with racing information. The defendants took a room above one of the clubs, and carrying the telegraph wire through the window, attached it to a brass water tap, thus stopping the electric current, and preventing the club below from receiving the news of races. Mitchell was found in possession of the room when the wires were tampered with. It is the practice of these clubs to make bets up to within three or four minutes of receiving the result of the race, and the stoppage of the messages complained of would give Mitchell time to back a winner of a race with tolerable certainty at the club where the result of the race by means of his conduct had not been received. The summons against Hughes was withdrawn. Mitchell pleaded guilty, and was fined £10 and £3. 7s. 6d. costs.

CRYSTAL PALACE INDOOR FETES.—These *fêtes* will for the present take place tri-weekly, on Mondays, Thursdays, and Saturdays. The normal lighting of the building, by about 5,000 ordinary gas-burners, and 75 large electric arc lamps, each of a nominal 2,000 candle-power, will be supplemented by 10,000 gas-jets in lamps of various beautiful hues, and 4,000 "bucket" oil lamps. The tinted glass lamps, arranged in festoons and other graceful devices along the girders and at other points of vantage in the building, have been specially manufactured at Stourbridge for the Crystal Palace Company, many of the tints being quite novel. The music will be mainly furnished by military bands, and these will play on an elegant newly-constructed decagonal orchestra in the Centre Transept. This orchestra alone will be lighted by about 2,000 coloured lamps. The electric arc lamps in the centre will be masked, so to speak, by Chinese lamps encircling them, the object being to add picturesqueness to the general scene, and to prevent the milder lights from being overpowered by the electric light. The great stage which forms the background to the scene has been decorated by Mr. F. Fenton, and represents a semi-Oriental interior. This also will be brilliantly lighted. The whole has been designed and executed by the company's staff.

THE SIXPENNY TELEGRAMS.—Although the Post Office authorities are unable at the present moment to furnish a tabulated statement showing in actual figures the working of the sixpenny telegraph system during the few weeks it has been in operation, they have nevertheless had sufficient experience of its working to satisfy the Telegraph Department as to the success that has hitherto attended the cheapened rate, and the still greater success they may fairly anticipate. Taking only the ordinary paid inland telegrams, exclusive of press and other messages of a special character, the increase during the first completed week in October reached 33 per cent., which is 3 per cent. beyond the original estimate for the entire year. During the second completed week the increase was 44 per cent.; but in the third week there was a fall in the percentage of from 44 to 39. This, however, need hardly be regarded as discouraging, inasmuch as, in comparison with the corresponding period of the previous year, the depression then experienced was considerably greater in proportion to the then charges than the slight falling off recently experienced. The average price paid for telegrams during the past month has been about 8d., as contrasted with an average under the 1s. system of 1s. 1d. Of the large number of telegrams transmitted under the reduced rate about forty per cent. are attributable to the sixpenny rate, and there is little doubt that the extra halfpence as between the minimum and the average charge have been contributed to an appreciable extent by those who as yet have had little exercise in the art of condensation. The increase of private telegrams in the metropolis has been really enormous when compared with the general increase throughout the United Kingdom, for whereas the total percentage of increase has fluctuated between thirty-three and forty-four per cent., the increase in London alone has amounted to considerably over sixty per cent. There has been a proportionate increase in several of the largest of our provincial towns, notably Liverpool, Glasgow, and Manchester.

THE PROPOSED ELECTRIC LIGHTING OF BRISTOL.—In October last year an Electrical Committee of the Bristol Corporation was appointed to inquire into the best means of lighting the city by electricity, and to invite such tenders as they might deem advisable for the supply of electricity, or for the execution of any work necessary for the purpose. The committee was also instructed to ascertain the cost to the council of laying and

Digitized by Google

maintaining their own mains. The committee have since applied to Mr. W. H. Preece, F.R.S., who said that, although at present they could not compete in price with gas, yet that the ultimate economy was so marked that it had only to be tried to be proved. He thought the city should contemplate the use of at least 2,000 lamps. Such an installation would, he said, pay its way; and if the lamps were distributed in the best parts of Clifton, it would speedily lead to a demand for the use of electric lighting elsewhere. He had no doubt that plant could be laid down which would work with safety, surety, and economy, and maintain a constant and steady supply; and he hoped the committee would proceed with the work, and be the pioneers of a self-supporting electric light installation. The committee had received a further report from Mr. Preece, dated the 16th ult. He was of opinion that the Electric Lighting Committee of the Bristol Corporation had better apply to the Board of Trade for an extension of time. The committee had applied to the Board of Trade, asking what steps it would be necessary to take in order to obtain such extension. The Board replied to the effect that they could not prolong the time except by a provisional order confirmed by Parliament; but that, in the event of the sanitary authority not laying down mains within the prescribed period, the Board, as then advised, would not be disposed to exercise their powers to revoke the provisional order which the authority had obtained. This being so, their provisional order, and the powers under it, still continued in force. The committee thought it proper at this time to lay before the council what had been done by them, and to submit the present position of the business; also to ask for instructions as to whether they were prepared to provide the money and proceed with the works, either in the compulsory area, or on the basis of Mr. Preece's report of December, 1884, or have an experimental installation on a small area in some other part of the city and county. As an alternative, whether they would wait and see the result of further experiments in other places. The report of the committee will be considered at an early meeting of the Town Council.

The Electric Light in Kendal.—A local contemporary says that Mr. Councillor G. J. M'Kay is to be thanked for the introduction in Kendal of this much admired light in a large and practical way. "We had the pleasure recently of going through his new woollen manufactory and of seeing for ourselves the light working to perfection in all the various departments, including the offices and warehouse. It appears that Mr. M'Kay has given great attention to this light, and before placing his order visited several manufactories and mills lighted up with electricity, and also examined the various makes of dynamos. Having secured sufficient information to satisfy him, it was no longer an experiment but a realised fact that the electric light was not only better in every way for lighting purposes than gas, but had also the advantage of being cheaper than gas charged at 2s. 6d. per thousand feet, after allowing liberal interest for the first outlay and a reasonable allowance for attendance, &c. In the departments where the work was being carried on the light appeared much superior to gas, and from inquiries we made from the workpeople they preferred it to gas. They could also discern the various colours of the yarn and cloth more correctly. The electricity is produced by a Crompton new patent compound wrought-iron dynamo, and is driven by the same engine which provides power for machinery in the mill. This dynamo lights 160 incandescent glow lamps of Swan-Edison's patent, 20 candle-power each, which are spread over the various departments of the manufactory. The dynamo is capable of working 250 lights, and the main wires are laid down large enough for the remaining 90 lights whenever required. The contract has been successfully carried out under the instructions of Mr. Francis Preston, A.M.I.C.E., and M.I.M.E., consulting and electric light engineer, Huddersfield. The installation has been carried out by Mr. Wilson Hartnell, C.E., engineer and electric light contractor, Leeds. Mr. Hartnell has erected over forty installations during the past two seasons, including ironworks, manufactories, warehouses and private mansions. At the present he is lighting with 300 lamps Wentworth Castle, also the private house of Colonel Brooke, J.P., Armitage Bridge, Huddersfield. The introduction of the light into Kendal has also brought a little work into the town, as Mr. Preston has placed an order for a vortex turbine and a large quantity of cast-iron pipes with Messrs. Gilbert Gilkes and Co., of the Canal Iron Works. This turbine and pipes are required for one of Mr. Preston's installations. We are informed that Mr. M'Kay intends inviting many of the townspeople to visit his works, and to inspect the light for themselves."

Electric Tramway Engine.—An Essex contemporary is quite enthusiastic in the praise of the C. P. Elieson's patent electric tramway engine, which has for some time past been tested and run at the works of the North Metropolitan Tramway Company, Union-road, Leytonstone. The engine will be removed in a few days to the Stratford Depôt, whence public trials will be made. It appears that an extension will shortly be made of the tramway from Stratford down the Ilford-road, and that arrangements will be made later on to work this portion entirely by electric engines. Meanwhile an engine of greater power is being constructed, with the view of showing what can be done on a railway. The following special advantages are claimed for the engines, which are of the regular pattern:—1. They can be placed upon any existing line of tramway where horses are employed without interfering in any way with the arrangement of the cars on the permanent way, and the electrically propelled cars can run alternately with horse cars where required. (2.) The cost of an installation of charging station and locomotives to replace horses is considerably less than the cost of the horses, harness, and stabling, while the maintenance is quite forty per cent. less. (3.) The apparatus is perfectly under the control of one attendant, who need not be a skilled electrician. (4.) The cars or carriages can be splendidly illuminated by the same current of electricity that supplies the power to the locomotive, the fraction so used being inappreciable. (5.) The enormous tractive force developed by the special electric locomotives which the Electric Locomotive and Power Company propose to manufacture, enables the traction upon railway lines, where smoke and steam are objectionable and prejudicial to the health of passengers, to be carried out electrically with economy. (6.) The absolute safety of the system, the low tension current employed being perfectly harmless. It may be interesting to state that the maximum of speed developed in the engine under notice is about eight miles an hour, but if necessary an engine can be constructed to run as slow or as fast as may be required for all practical purposes. The power is derived from 50 cells, containing about 280 amperes, and the current used varies from about 60 amperes per hour at starting to about 35 amperes per hour when running. It will therefore be seen that a continuous run of about six hours, at an average of 40 amperes per hour, is secured without exhausting the stored electricity. Great improvements have been, and are being, made in storage cells, and there is not the slightest doubt that in the future cells of greater capacity will be constructed, thus enabling an engine to run for several hundreds of miles without recharging.

THE DETERMINATION OF CURRENTS AND RESISTANCE IN A NETWORK OF CONDUCTORS.

(Concluded from page 469.)

Maxwell's second theorem here quoted is "to determine the capacity of a condenser by means of a Wheatstone bridge."

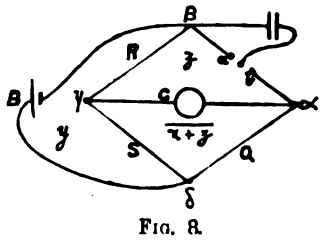

FIG. 8.

Let α, β, γ, δ be the four points of a Wheatstone's bridge, and let the branch between α and β be interrupted at a b, and a Leyden jar or condenser inserted, provided with some rapid commutator, such as a tuning fork, so that whilst one pole of the condenser is kept permanently attached to β the other is alternately joined to a and b.

* * * * * *

Now let the meshes of the network be called $x+z$, z, and y; then x is the current through the galvanometer and y is the current through the battery. When the fork is set in vibration, the commutator and the condenser act together like a resistance, and let through so much electricity per second.

Now, as the condenser gets its charge by electricity flowing into it, it builds up an opposing electromotive force in the z circuit, which at any instant is equal to the value of $\int \frac{z\,dt}{K}$, where K is the capacity of the jar the integral being integrated from the instant when the charging commences up to the instant considered. Now, if the commutator makes n vibrations a second when the steady state is set up, the current z which flows into the jar has a mean value, z; and therefore $\frac{z}{nK}$ is the opposing electromotive force in that branch.

The condenser and associated commutator behave like a resistance in the branch $\alpha\beta$ with a counter E.M.F. in it. Only such a combination differs from an ordinary metallic resistance in this, that its apparent resistance is not constant, but depends on two things—the speed of commutation, or charge and recharge, and the capacity of the condenser; whilst the counter E.M.F. depends not only on n and K, but also on the current z, and therefore on the resistances of the other branches. We require an expression for the E.M.F. charging the condenser. Let the difference of potential between a and b be called e. Then consider the network formed by the five conductors, R, S, Q, G, and B, with the electromotive force in the branch B; write down the net-work equations for this two mesh network

$$(B+R+S)\,y - S\,(x+z) = E$$
$$-Sy + (Q+S+G)(x+z) = 0$$

[The commutator is supposed not to be in action, consequently the branch $\alpha\beta$ is interrupted, and the cycle current z is equal to zero.]

We obtain $$y = \frac{E\,(Q+S+G)}{\delta}$$

and $$x+z = \frac{ES}{\delta}$$

where δ = the determinant.

$$\begin{vmatrix} B+R+S, & -S \\ -S, & Q+S+G \end{vmatrix}$$

which is $$S\,(Q+G) + (R+B)\,(Q+S+G).$$

Now, the difference of potential e between a and b when the condenser is just beginning to be charged is

$$G\,(x+z) + R\,y = e.$$

[This will be seen by writing the network equation for the z cycle with $z=0$.]

$$\therefore e = \frac{E\,S\,G}{\delta} + \frac{E\,R\,(Q+S+G)}{\delta}.$$

Now, if the electromotive force e be employed n times in a second to charge a jar of capacity K, the average current flowing into the jar is $nKe = z$.

Now, to find z we have to consider the distribution of currents when the fork or commutator is in operation, and the condenser allowing a flow of electricity to take place through it.

Let P be the resistance which could equivalently replace the jar and fork—that is, would allow an equal quantity of electricity to pass per second; then since $\frac{z}{nK}$ is the opposing electromotive force in this branch, we have an equation for the three cycles z, $x+z$ and y [which after rearranging becomes]

$$-Sz + (R+S+B)\,y - (R+S)\,z = E$$
$$-Gx - Ry + (P+R)\,z = -\frac{z}{nK}$$
$$(Q+S+G)\,x - S\,y + (Q+S)\,z = 0$$

Now let Δ stand for the determinant

$$\begin{vmatrix} -S, & R+S+B, & -(R+S) \\ -G, & -R, & P+\frac{1}{nK}+R \\ Q+S+G, & -S, & Q+S \end{vmatrix}$$

Then the solutions of the above equations for z and x are

$$z = \frac{E\begin{vmatrix} -G, & -R \\ Q+S+G, & -S \end{vmatrix}}{\Delta}$$

and

$$x = \frac{E\begin{vmatrix} -R, & P+\frac{1}{nK}+R \\ -S, & Q+S \end{vmatrix}}{\Delta}$$

z is the average current flowing through the condenser, and x is the current through the galvanometer. Now, let the resistances R, S, and Q be so varied that the current through the galvanometer is zero, then $x=0$, therefore

$$\begin{vmatrix} -R, & P+\frac{1}{nK}+R \\ -S, & Q+S \end{vmatrix} = 0.$$

Now insert this value for $P+\frac{1}{nK}$ in the determinant Δ above and calculate its value, and we arrive at the expression

$$\Delta = \frac{\{B\,(Q+S)+Q\,(R+S)\}\,\{G\,(R+S)+R\,(Q+S)\}}{S}$$

We have now, by substitution of this value of Δ in the value obtained above for z, an expression for the value of the average current through the condenser when the bridge is balanced, and it is

$$z = \frac{ES\begin{vmatrix} -G, & -R \\ Q+S+G, & -S \end{vmatrix}}{\{B\,(Q+S)+Q\,(R+S)\}\,\{G\,(R+S)+R\,(Q+S)\}}$$

Equating this to the other value for z, namely,

$$z = nKe$$

[and substituting the value of e already found, we get finally]

$$nK = \frac{S\,\{S\,(Q+G)+(R+B)\,(Q+S+G)\}}{\{B\,(Q+S)+Q\,(R+S)\}\,\{G\,(R+S)+R\,(Q+S)\}}$$

which gives us a value for n K in terms of

B, Q, R, S, G.

Now, it is interesting to note that we may otherwise write the above expression for n K,

$$\frac{1}{nK} = \frac{\Delta}{\delta},$$

where Δ is the determinant,

$$\begin{vmatrix} R+B+S, & -S. & -R+S \\ -S, & Q+S+G, & Q+S \\ -R, & -G, & R\left(\frac{Q}{S}+1\right) \end{vmatrix}.$$

And δ is its first minor,

$$\begin{vmatrix} R+B+S, & -S \\ -S & Q+S+G \end{vmatrix},$$

therefore n K is of the dimensions of a resistance.

THE STEAM ENGINE AT THE INVENTORIES.

On Monday next the Inventories will close, the engines will have run their course, and some of the makers will have been glorified; others very much not. Half a year of performance in public has taught engine makers, and those of the public who have cared to learn, a good deal, and many electrical engineers have learned the lesson that has been so freely taught them. There have been many successes and many failures, and electrical engineers are bound to express their sympathy and their gratitude to those who have failed, for the instruction gained in this way is proverbially more indelible than that imparted by success, although no one can congratulate those who have supplied the negative information.

The display of engine power for lighting purposes has been no small thing, for Messrs. Davey, Paxman, and Co. alone supplied over thirteen hundred horse-power, and besides their engines there are, as our readers well know, various engines of different kinds, mostly of small size, and a large proportion of them high-speed engines. A few of the small engines, those of the double acting type, have been doing very well; but the number of high-speed engines that have done well, we regret to say, is for some reason very small. We regret this because a really efficient engine, capable of running long periods at a stretch at high speed is a very desirable accompaniment of a dynamo. To be able to dispense with gearing of all kinds would be a very great boon if it could be done without accompanying losses in efficiency and economy.

We have on several occasions dwelt on the relative efficiency of high and moderate speed engines as proved by their behaviour when doing the work required by the electrical engineer on large installations and running long periods. Three or four years ago, before the very extensive trial had been made of engines in a competitive manner, there seemed reason for hoping that high-class design and workmanship would place the high-speed engine amongst those which the electrical engineer could employ without any question of efficiency and satisfactory working. Expectations have not been fully realised—far from it. He, as a rule, only uses the high-speed engine where he has not sufficient room for a moderate speed engine and its driving belt, rope, or friction gear. Large numbers of high-speed engines have been put into steamships, but the highest speeds are not now generally adopted, although on board large ships engines may be expected to be watched and nursed as much as is necessary. This fact explains to some extent the continued use of small high-speed engines at sea, but at the same time it must be admitted that skilful attention to details and material has done a good deal towards improving their staying power. The experience of all ship-lighting engineers is not the same, and hence it is clear that the high speeds have not been as impracticable as providing more room in some ships. We are, however, here concerned more immediately with the results of a half-year's working of the engines at the Inventories. Here there has been no restriction as to the amount of supervision or of labour expended in keeping the engines in order, while that comparison which is said to be sufficiently objectionable to be stimulating to any who have reason to fear it has done all it could do. The result is the same, the palm for trustworthiness belongs to the moderate speeds.

Engines which would be on the scrap heap in a month if run at four hundred revolutions per minute will success fully run for years if run at one hundred. Many of the engines which caused a great deal of trouble at the Inventories by failure at four or five hundred revolutions per minute would probably run five years without costing five pounds for repairs if their speed had been from 150 to 200 revolutions per minute. The strains that are imposed upon the parts of small engines by these very high speeds are very great as compared with what is generally supposed. The connecting rod, for instance, in a single acting engine is supposed to have a tolerably comfortable time, because its compressive strength alone is brought into play. This, however, is not the case. The transverse strength is severely tested, and not only so, but it takes a good many pounds of steam per hour to do it.

If we suppose an engine to have an 18in. stroke, and to run at 250 revolutions per minute, the crank end of the connecting rod will make 500 strokes of 18in. in the plane of the crank pin path—that is to say, the connecting rod makes 500 angular traverses per minute; so that it is stopped and started 1,000 times per minute. The speed of the crank will be 1,175ft. per minute, and this speed is acquired by the big end of the connecting rod in the period of a quarter of a revolution, or in one thousandth of a minute; or a speed of 196ft. per second is acquired in 0·06 of a second.

If we suppose the engine to have a horizontal cylinder, so that the rod moves up and down in a vertical plane, it is obvious that gravity comes into play in both the up and down movement, in the former increasing and in the latter decreasing the strain due to the inertia of rest of the rod, which is over-

THE INTERNATIONAL INVENTIONS EXHIBITION.

The Inventions will not fail to be somewhat more interesting electrically in that various modified forms of the Gramme machine are exhibited. Among the largest exhibitors of this class of dynamo are Messrs. Elwell-Parker, who show eleven dynamos of various powers from 1,500 watts to 50,000 watts, and one six horse-power motor. The largest machine is of the four-pole type, and thus not distinctly on the Gramme lines. Fig. 1 gives a perspective view of this machine. The armature has a core 16in. diameter, 36in. long, and 2in. thick, wound with 186 turns of ·12 wire. At a speed of 450 revolutions per minute the external E.M.F is 110 volts. The exciting coils of the field-magnet are 14in. long, and each is wound with some 2 cwt., giving a little over 3,400 turns of ·058 wire, and has a resistance of 72 ohms. The arms are coupled parallel. They can of course be so coupled as to make both poles above the centre line N or S, and both below it S or N, when the machine works like an ordinary two polar dynamo. The armatures of all Elwell-Parker machines are similarly constructed. Figs. 2 and 3 show the method for coiling the core.

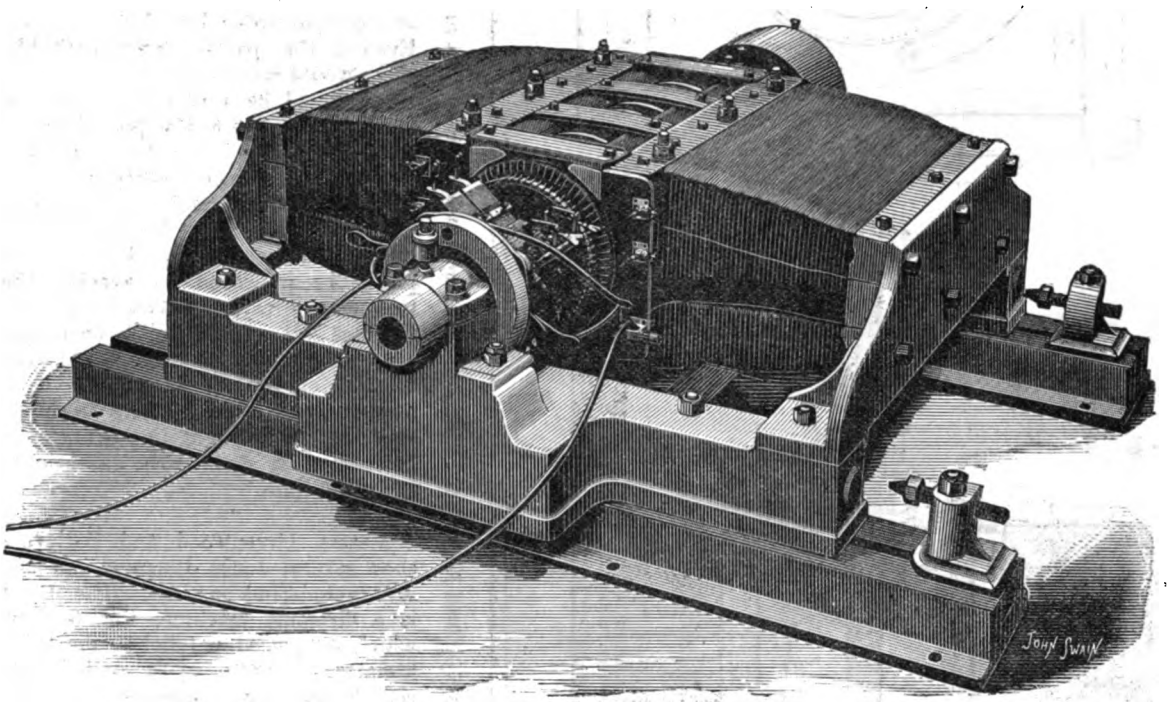

Fig. 1.—Elwell-Parker Four Pole Machine

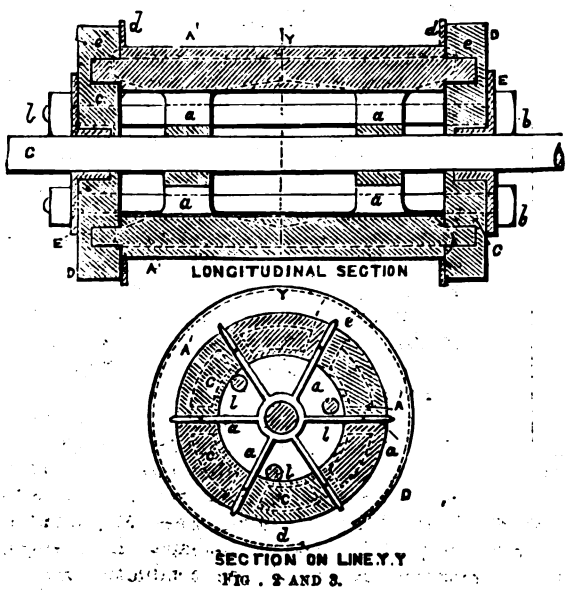

Fig. 2 and 3.

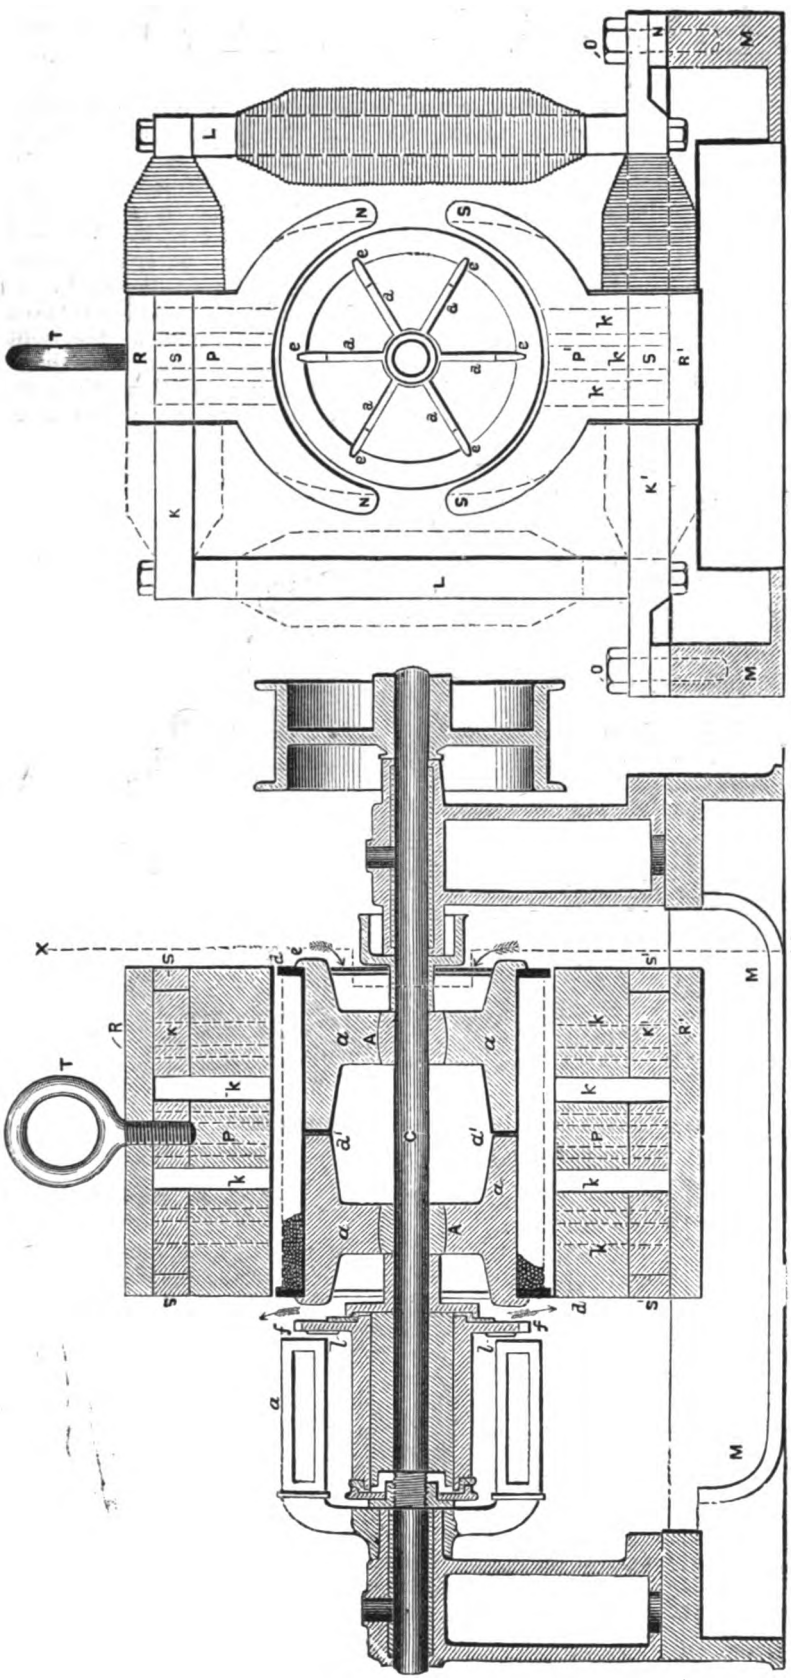
The supporting arms *a a* are keyed to the spindle C, and after having been insulated with tape and fibre—the latter to prevent metallic contact between the core and the arms—the wood blocks A^1 are inserted and held in place by discs D D, into which they are mortised. Three bolts, *b*, keep the whole frame together. To prevent the small lugs or projections *e* coming in metallic contact with the iron of the core, washers, *d d*, of vulcanised fibre are placed one at each end, and the space between them is now completely filled with iron wire coiled on as evenly as possible. In the process of coiling a bituminous compound is applied, which is intended to insulate to a certain extent the wires from each other. After a few layers of wire are coiled on, the surface is tested, and if found out of truth a cut is taken over it. We need hardly mention that the depth of a cut never equals the diameter of the wire, and usually is only a fraction of it. A few more layers are then coiled, and if necessary a cut is taken again, and so on until the core is completed to the right radial depth. In this way a true cylindrical core is obtained. After removing the blocks of wood and insulating the core, it is wound with double silk-covered copper wire in the usual Gramme fashion, but only one layer of wire is used on the out side of the core.

Mr. Kapp, writing of these machines, so far as regards the armature wire, says:—"Most of the modern dynamos contain only one layer of wire on the armature; the Crompton, Edison-Hopkinson, Mather and Platt, and several other machines are constructed in this way; but Messrs. Elwell-Parker have pushed the principle to its utmost limit by making this layer exceptionally thin—in other words, by allowing a high density of current in their armature coils. Most makers regard 3,000 amperes per square inch of conductor a sufficient strain, but in the dynamos under consideration the density is frequently as high as 6,000 amperes. Roughly speaking, we may say that the thickness of the single layer in the Elwell-Parker machine is about one half that found in other dynamos, and in this sense the firm have pushed the single layer principle further than other makers. They maintain that by making the core of small radial depth, so that even the inner coils do not completely fill two layers, the carrying capacity of the wire is considerably increased. The interior of the core is not ventilated, but by a peculiar arrangement on the commutator a current of air is kept flowing into the cavity of the armature at the pulley end, and out between the wires which join the armature to the commutator. This serves to cool the inner wires, whilst the

Digitized by Google

outer turns are kept cool by being whirled through the surrounding air with considerable speed.

"Figs. 4 and 5 show a longitudinal section and an end view of a 6,000-watt machine driven by a Willans engine. The supporting arms, or 'spiders,' are keyed to the spindle C by the hubs A A. Part only of the core is shown, and the armature coils are left out for clearness of illustration. The dark lines represent the insulation between the arms and core. The field-magnets consist of flat wrought iron slabs, K L, bolted together in the shape of a rectangle, with cast iron pole pieces pinned on in the middle of the top and bottom slabs. A large number of pins, K K, are used, these pins being driven tightly into holes bored out in the pole pieces so as to be in close contact with the metal. By this arrangement it is intended to obtain the magnetic conductivity of wrought iron whilst still retaining the cheaper material, viz., cast iron, for the bulk of the pole pieces. In small machines the frame M M is made of Parker's metal, but in larger machines it is made of cast iron, and packing pieces of non-magnetic metal are inserted between frame and field-magnets. It is of interest to note that the thickness of these pieces need not be very great; at any rate, much less than would be required in an Edison machine of equal size. In the latter the pole pieces themselves have to be kept off the frame by non-magnetic packing, and since the free magnetism is greatest at the poles the magnetic insulation must be correspondingly high. In the Elwell-Parker machine, however, the two portions of the field-magnets which come nearest the frame both belong to the lower pole, and are therefore magnetically at a comparatively low difference of potential. Even if the packing were omitted the machine would still continue to work. The only effect would be a very slight drop of electromotive force, due to the partial muffling of the two lower half coils by direct contact with the frame. The rest of the magnetic circuit would, however, not be altered. The arrangement of magnets adopted by Messrs. Elwell-Parker is certainly very compact, but I think that it might be improved by keeping the vertical magnets a greater distance from the polar extensions N S. As is well known, magnetism is always densest at the corners, and a considerable number of lines of force must be wasted by leakage from these corners to the core of the magnet. Some slight improvement might also be effected by shaping the extensions as shown in dotted lines."

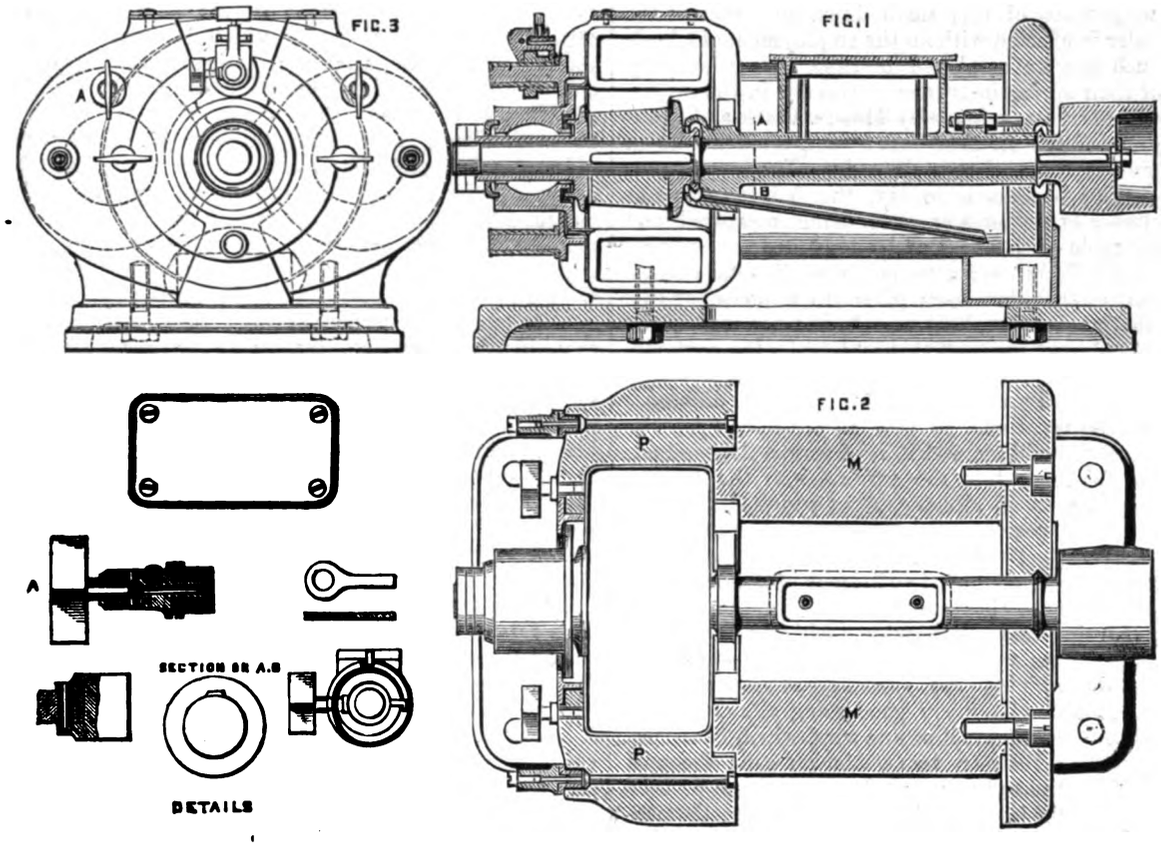


FIGS. 4 AND 5.—Elwell-Parker 6,000 Watt Machine—longitudinal section and end view.

Messrs. Greenwood and Batley, of Leeds, show several Jones dynamos and a number of Armington-Sims engines. The Jones dynamo is a Gramme machine, the field-magnets of which are placed parallel to the spindle. The armature consists of a cylindrical Gramme ring having a core composed of charcoal iron wire insulated by a single covering of cotton, and wound on a flanged mandril, the length being twice the radial depth. It is supported by a number of flat U-shaped webs or arms pushed over from the inside, the inner edge of the arms being taper, and let into grooves on a central hub of fibre. They are held in place longitudinally by being pressed tightly between two gun-metal discs insulated by fibre rings. The webs are stamped out of sheet iron, and it is claimed that they assist in reinforcing the magnetic field. A very good point in the armature is the perfect insulation of the core from the shaft. The armature conductor is a copper ribbon laid on flatwise. The winding is commenced by placing the middle of the total length of ribbon intended for one section against the inside of the core inclined at a slight angle to the axis, so that when the two halves are brought over the outside of the core they miss each other by a small distance, forming two turns side by side on the external periphery. In some cases Mr. Jones inserts troughs consisting of a series of U-shaped iron wires, into which the external layers of the conductor are placed. The coils are connected up amongst each other and with a commutator in the usual manner. Connection with the

Digitized by Google

latter is made by a series of L-shaped copper pieces, one end of which is soldered to the radial part of each coil, whilst the other is soldered to the corresponding plate of the commutator. The plates, which against each other are insulated by mica, are made of phosphor bronze, and are arched out internally to reduce their weight. They are held together by two rings of fibre, which are clamped by means of a screw between two flanged discs of gunmetal. The commutator being on the extremity of the shaft is very accessible. The brushes are mounted on insulated ferrules which are fixed to a brass ring capable of being set to any angular position on another brass ring, which at the same time serves as a connecting piece between the two cast-iron pole pieces P P. A salient feature of the machine is the manner in which the spindle is supported. The armature is overhanging, and there is only one bearing of Mitstand metal, the length of it being about 9 diameters. Since the pole pieces partly enclose the armature on its two radial faces, it is extremely important that it should be firmly held in a longitudinal direction, and, if need be, that an adjustment can be made in that direction. For this purpose the yoke end of the bearing is provided with a flange and



adjusting screws, S, by which the whole shaft and armature can be set, so that the clearance on either side of the armature is equal. The magnet cores are two cylindrical bars parallel to the spindle, and joined by a cast-iron yoke. In the machine we illustrate the magnets are placed to the right and left of the spindle, but in larger machines they are placed above and below it. The base of the machine is a plate of zinc.

"We have received permission," says *The Engineer*, to "publish the electrical data of Mr. Jones's 100-light machines, which are as follow:—Current, 64 amperes; electromotive force 100 volts at terminals; speed, 950 revolutions. The armature is wound with flat tape ·22in. by ·07in., or ·0154 square inch, and the density of current is about 2,100 amperes. The core is 14·5in. diameter, 6·5in. long, and 2·75in. deep, giving an effective area of 17·8 square inches. There are fifty-two sections in the commutator and eight turns of conductor to each section, making in all 416 turns counted all round the armature. The perimeter of armature coils is about 22in., giving a total of 250 yards of conductor. Thus at a speed of 950 revolutions 2½ yards of wire produce 1 volt. The calculated resistance of the armature is ·106 ohm, consequently the loss of potential in the armature is 6·85 volts. The cores of the field-magnets are 15·25in. long and 5·75in. diameter, giving an effective area of 26 square inches. Since the lines of force which flow through the armature on both sides of the ring must all come through one magnet core, it follows that the density of lines in armature and magnets is in the proportion of $\frac{26}{2 \times 17{\cdot}8} = {\cdot}73$; hence, if one square inch of armature core carries seventy-three lines, one square inch of magnet core carries 100 lines. The core of the armature is, however, not solid iron, but a number of iron wires placed close together. If we assume that they are arranged on true vertical and horizontal lines, the proportion between gross area of core and area actually occupied by iron is as $4 : \pi$; and consequently the area offered for the accommodation of lines in the core is only ·78 of the gross area, that is, nearly that of the magnet cores. The magnets are compound wound, viz., one layer of ·200 square wire, and twenty-four layers of ·042 round wire. There are sixty-nine turns of main wire on each magnet and the total length of wire on both magnets is 72 yards; resistance, ·043 ohm; density of current in main coils, 1,600 amperes; loss of potential, 2·8 volts. The twenty-four layers of shunt wire have a total length of 7,800 yards and a total resistance of 144 ohms; current through shunt, ·7 ampere; density of current, 500 amperes. From these data we can calculate the electrical efficiency of the machine as follows:—Internal electrical energy, $64{\cdot}7 \times 109{\cdot}65 = 7{,}100$ watts; external electrical energy, $64 \times 100 = 6{,}400$ watts; therefore efficiency $\frac{64}{71} = 90$ per cent. The maximum exciting power of main coils is 7,800 ampere-turns; that of the shunt coils is 8,700; total, 16,500 ampere-turns. The calculated weight of copper on this machine is:—Armature, 43lb.; main wire, 34lb.; series wire, 124lb.; total, 201lb. At 1,000 revolutions per minute the output of this machine would be about 6,800 watts, or about 34 watts for every pound of copper.

This figure might be somewhat increased by allowing a greater density than 500 amperes in the shunt wire. The total weight of the machine is 10cwt.

Among the apparatus exhibited by Messrs. Latimer Clark, Muirhead, and Co., of Westminster, are some of the electric measuring instruments invented by Profs. Ayrton and Perry, as well as their electric motors. The measuring instruments consist of ammeters, voltmeters, and ergmeters. In the former is employed their "magnifying spring," shaped something like a long, narrow, curled-up wooden shaving, and having the property that if one of the ends be fixed while the other is pulled so as to stretch the spring the latter end rotates through a large angle. This peculiar behaviour, which, of course, does not occur with ordinary spiral springs, arises partly from the way in which the spring is coiled up, and partly from the special dimensions given to the various parts, and formed the subject of a communication to the Royal Society. The spring is stretched by a very thin soft iron cylinder (to which its free end is attached) being pulled into a solenoid wound with wide copper strip in the case of the ammeters, and with fine copper wire in the case of the voltmeters, and although the cylinder is pulled but a short distance into the coil, the pointer moves over some 270° ; hence the instrument is very sensitive. For example, a 20-ampere ammeter will read the 1-10th of an ampere, and a 200-volt voltmeter to one volt. And as the magnifying of this small downward suck of the thin iron cylinder is effected without the employment of wheels and pinions, such as were employed by these inventors in the earlier form of their spring instruments, there is in these magnifying spring instruments made by Messrs. Clark and Muirhead an absence of the friction that accompanies the use of wheels and pinions even when well made. The instruments are "direct-reading,"—that is to say, the pointer points at once to the number of amperes or volts being measured, and no constant nor table of values need be employed.

Profs. Ayrton and Perry's ergmeter measures the total amount of electric energy that has been given to a house, or to a room, during the previous week or month, and not merely the number of coulombs, which is all that is done by the coulomb-meters of Edison, Ferranti, &c.—that is to say, the ergmeter takes account of variations in the potential difference maintained between the mains as well as in the current supplied to the room or building, and it is of course the products of the potential difference into the current into the time, or simply the total quantity of electric energy supplied, that the householder ought to pay for, and not simply the number of coulombs of electricity. The ergmeter can be very conveniently employed in the measurement of the efficiency of accumulators, since the variations in the electromotive forces of the accumulators during charging and discharging—which, of course, is taken into account by the ergmeter in its indications—must not be neglected in determining the efficiency of accumulators. The instrument consists of a fairly good-going clock, the pendulum of which consists of a coil of fine wire, which is a shunt to the house, swinging between two stationary coils of copper strip, through which the main current flows. And the retardations of the clock, as the inventors have shown both mathematically and experimentally, by observations lasting over many months, are directly proportioned to the total quantity of electric energy supplied to the house. When the house is using no electric power, as for example during the day, the ergmeter should go like an ordinary good clock, so that its accuracy can at any time be tested by the user by comparing its rate of going, when no electric power is being used in the house for lighting or other purposes, with that of any decent watch or clock. On the other hand, when electric power is being used in the house the ergmeter loses, and the ergmeters are now so wound that a loss of one minute corresponds with one Board of Trade unit supplied to the house. Hence the user, or the electrical inspector, has merely to multiply the number of minutes the ergmeter is slow by the price agreed on for a Board of Trade unit to settle how much the electric bill should be for the past month or quarter. It does, then, for electricity what a gas meter does for gas; but it does something more—it takes into account, as already explained, variations in the pressure, which no ordinary gas meter does, and hence a similar unfairness in the electric bills cannot be made as was made a year or two ago in the gas bills by the gas companies varying the pressure without reference to the consumers.

This firm are also exhibiting Winter's excellent block instruments, manufactured by them. Neither of the instruments can be put to "clear" or "danger" without the independent action of both signalmen. Should the plunger at either station be depressed by accident, it only strengthens the power which holds the indicator over to the last position.

Mance's submarine telegraph apparatus is also exhibited, and the testing apparatus of Sir Henry Mance, C.I.E., of which this firm are the manufacturers.

The exhibit of the Globe Electrical and Engineering Company, of 20, Dartmouth-street, Westminster, consists of an almost complete display of Mr. Killingworth Hedges' inventions. We have already described his fusible cut-outs, which are of the same pattern as exhibited at the Philadelphia Exhibition last year. A new form of automatic cut-out is now shown, consisting of a weighted lever, which is released by a tripping gear, actuated by an electro-magnet in shunt circuit. A portion of the current is diverted in shunt circuit through a high resistance magnet, which is connected to some part of the line, and gives such a difference of potential as to allow $\frac{1}{3}$ ampere to flow through its coils. Directly the current in the main circuit exceeds a certain amount, the excess which has passed through the shunt attracts the armature, releases the tripping lever, and thus allows the contact piece to be quickly withdrawn, and opens the main circuit, which cannot be established until the current flowing through is reduced. This plan has an advantage over some other kinds of cut-outs, in that, the electro-magnet being placed in shunt circuit, a trifling amount of current, which never exceeds in practice half an ampere, is enough to put in action the tripping gear, and thus control any number of lamps. The same arrangement is also exhibited applied to a duplex cut-out, in which it automatically inserts a spare mica foil for that fused. The Hedges fuses or mica foils exhibited show improvement on the original design, in which they were too delicate, and occasionally gave way by being roughly handled. They are now made as follows:—The foil, coloured black, composed of pure tin for the small currents and also metal—an alloy of aluminium and tin—for the large, is held between pieces of mica, which allow for its expansion when heated. One piece of mica passing under the contact piece serves to stiffen the foil and protects it from rough usage. Another simple pattern of cut-out is also shown. The mica foils have eyelets, through which a binding screw passes. This arrangement, which admits of a spare fuse being quickly substituted for that melted, was specially designed for Mr. W. H. Preece, electrician to the General Post-Office, who has used it in his house for some time, and who has found it answer its purpose admirably. A special form of connector cut-out, used for uniting the main leads to branch wire without cutting the cable, is worthy of notice. A fusible plug can be inserted by any person, as no screws have to be undone.

Passing from the electrical to a more mechanical exhibit of the Globe Electrical Company, we find Mr. Hedges' most recent invention, namely, a hydraulic speed gauge. The instrument is a removable glass tube, revolving in a metallic case, furnished on the outside with a sliding ring. The tube being partly filled with water when revolved, the water has a tendency to creep up the side of the glass and imprison the air therein, and continues, carrying it down in a parabolic form, which is elongated as the speed increases. The bottom of the bubble gives the speed, which is easily ascertained by getting two fine wires of the sliding ring in a line, the revolutions being marked on the case. This instrument has been investigated mathematically, and a formula has been devised, by which the angular velocity of the water, which causes the depression, can be ascertained without experiment, as the depression is always proportional to the speed, so that the calibration of the instrument is simpler than many other forms of speed indicators. Mr. Hedges' instrument should prove of great utility for registering the speed of locomotives, and may perhaps be adapted for ship work. One of these indicators is at work in the electric light shed on the stand of Messrs. Goolden and Trotter.

Digitized by Google

come at so high a velocity. The velocity of 196ft. per second is acquired while the big end is falling 9in, or 0·75ft. For a fall of 0·75ft. gravity would give a velocity of 7ft. per second, so that the transverse stress on the rod due to inertia is proportionate to the difference between 7 and 196, and is thus enormously greater than is usually supposed. It may also be observed that as a question of work these very high speeds come injuriously into play. The work done in putting a piston and connecting rod into motion is given out again on the crank at the other end of the stroke, but the work done by gravity on the rising and falling connecting rod is not only not balanced as the crank tends to leave the rod behind it, but it is very insignificant as compared with the work done by the crank in moving it up and down. As above mentioned, the velocity given to the rod is 196ft. per second, while the velocity due to gravity in 0·06 second is but 1·53ft. per second. The crank has thus to pull the rod down as well as raise it. The stroke assumed, 18in., is perhaps large for most of these high speeds, but the speed, 250, is much less than is common, and the strains increase rapidly with the speed, and the lost work also increases.

This is only one detail; but strains cannot be brought to bear on one part alone, and what we have said is merely an example of the extent to which inertia comes into play with high speeds, causing heavy strains on material and wearing surfaces, and representing beside this not a little lost work. There is much to be done yet in these engines, but until better results are forthcoming electrical engineers will no doubt cling to moderate speeds wherever they can be used. At the Inventories, the large engines of this class have run without a hitch, while the high-speed engines have almost all caused delay and annoyance by break down of some kind. The moral is obvious, but the improvements which have been made permit us to indulge in the hope of more.

CORRESPONDENCE.

A PHENOMENON OF CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As Mr. E. A. Williams (p. 472) now explains his object and ideas, it would appear that the first thing to be determined is a question of fact rather than an explanation. Facts are preferably ascertained by experiment rather than by evolution from the inner consciousness, or by the old metaphysical processes. Mr. Williams says he believes "in a stronger primary current when the secondary wire is closed as lying at the foot of the matter." Now, as the subject interests him, I would suggest that he should ascertain, first, whether this increased current does really occur, and then reason from that fact; the experiment is worth making, because it involves some important principles. It is also a very easy one to make. It only requires the primary circuit to be broken mechanically by an independent break instead of by the magnetism of the core. A toothed wheel, driven by clockwork, will answer, or a mechanism which I have used myself. This is an ordinary brake, the vibrating spring of which is provided with two screw contacts insulated from each other. The spring is connected to the zinc of two distinct batteries:—1. A Daniell cell, to give perfect constancy, passes its current to one screw-point, and through it to the electromagnet, which actuates the brake. 2. The battery, which through the other screw, works the coil, of which the usual brake is screwed down and fixed. If the current of this battery also passes through a galvanometer, any changes due to opening or closing the secondary circuit will be visible at once.

Now, I will venture to prophecy that the primary current will be *reduced* when the secondary circuit is closed, and I will explain why. We are afflicted with a great many words in electricity, names not of things or phenomena, but of theoretical conceptions—mere artificialities. "Self-induction," of which we hear a good deal, and as to which there are some suggestive remarks (p. 468), is, in my opinion, one of those words which conveys an erroneous idea as to the facts; it implies, what is in fact often stated, that the current passing in the various turns of a coil of wire reacts upon itself, and *induces in its own wire* a reverse E.M.F., or, as is sometimes asserted, a reverse current—the so-called "extra current" of closing circuit. I do not believe any such counter E.M.F. or current exists at all; the facts which lead to this interpretation are merely one result of a general law, operating in many other ways, but apt to be forgotten in the isolating of each of its actions, and the creation of a name and a separate theory for each of them.

Every molecule of matter is what it is, and is placed as it is, under the action and equilibrium of many forces, and any new force coming into action involves a motion of either the masses or molecules of matter within its scope.

The production of an electric current is the evidence of the action of such new forces, and involves a disturbance of the equilibrium of the molecules, not only of its conductor, but of all surrounding matter, in which it sets up the magnetic state, as well as the condition of static electric stress. These conditions involve an expenditure of energy, stored up in the rearranged molecules, by action against the previously existing forces. These forces give up this stored energy, when the molecules return to their first condition, under their influence, on the removal of the disturbing force.

I consider that what is called "self-induction" is simply this absorption of energy in setting up the magnetic charge—that is to say, it is an effect of the coils of wire, *not upon each other, but upon the enclosed air*, &c. As a certain fact, it varies in the same coil with the nature of the material contained in such a coil. It is this energy, stored in the magnetism of the core of a coil, reacting upon the wire of the secondary circuit (itself also having had its molecular arrangement disturbed by the presence of the current in the primary), which generates current in both primary and secondary at moment of "break."

I think a little consideration will show Mr. Williams that the reasoning of the latter part of his letter does not take all the facts into account. Thus, he thinks "the secondary circuit, when not complete, is *not* a circuit; but we know that it *is* a circuit, as a spark crosses. It is a circuit of which part is "inductive," and only transmits current when the E.M.F. created is capable of breaking through the resistance. That is what I meant when I said the energy is engaged in setting up E.M.F., for that exists whether current is actually generated or not. But this inductive element exists in both primary and secondary circuit, and in each it is alike manifested by the presence of the spark. The whole question, as I have before said, is the proportionate division of the energy between the two circuits, and its power of developing in each an E.M F. proportioned to the resistances. This latter is very great in the secondary; and great as is the wire resistance of the latter, it is trifling compared to the external R_1 under ordinary conditions. When this is eliminated by closing the wire circuit, the secondary resistance is probably a trifle compared to that of the primary, with its air space. Hence with the high E.M.F. set up in the secondary, I say that under these conditions nearly the whole of the energy passes to the secondary wire. There it develops an infinitesimal current, which has but a small reaction upon the core, which is at once demagnetised, while the energy is transformed into heat in the secondary wire.

I may go a step further, and say that it is probable that the closing of the secondary circuit will reduce the primary current. In fact, if we can build up the coil by degrees, while the intermittent current is sent into the primary wire mechanically, as before described, we should have four separate causes of diminution of current—each a distinct "retardation" due to energy abstracted in producing molecular stresses (magnetism or E.M.F.).

Digitized by Google

1. Let the primary consist of two wires, side by side, and wound upon a cylinder, connected so as to reverse the direction of the current, thus neutralising magnetising actions or so-called "self-induction;" we should have the normal current due to the time during which the brake remains closed, and a very trifling spark, if any.

2. Connect the two wires so as to carry current in one direction; we should have a lessened current. The air and tube are now magnetically and electrically charged, taking up energy. This action may be measured as, or called, either a counter E.M.F. or an added resistance. It is *work to be done by the current*, which is therefore retarded, and in consequence diminished during the time of closure.

3. Slip on the secondary with circuit open.

4. Close this circuit.

In each we give further work to do, in 3 we charge the wire, in 4 we produce an actual current in it.

All this is, in fact, worked out (p. 275) of my "Electricity" (second edition), and the experiments there described are, in principle, the same as the one just supposed, but worked out in a different manner.—Yours, &c., J. T. SPRAGUE.

THE IDENTITY OF STATICAL AND CURRENT INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The unorthodox view on Current Induction which I ventured to suggest in your issue of Oct. 23 being not altogether unimportant in its consequences, especially in its deadly antagonism to the *rationale*, not to the facts, of Lenz's law, will you permit me to bring it before your readers in a more forcible and persuasive manner.

A statement at variance with sanctioned theories has little claim upon our consideration unless supported by cogent arguments; and, indeed, I feel that I owe a great many apologies in presenting to your readers so new a departure in electrical theory, which at the very outset represents an induced current as flowing at one part of its course in a direction contrary to that which has been assigned to it, and as flowing there, ignored by electricians, under circumstances when no current is supposed to exist.

Perhaps the following investigation may help to explain my inclination towards an unusual view. It is an observed fact that a primary current in A B, as shown, induces by its present influence a momentary current from *a* to *c* and from *c* to *b*. What takes place in *a d b* is, as far as I am aware, mere hypothesis, and not the result of any kind of observation. Thus all that we can with certainty infer from the actual facts observed is, that the influence of the primary has been such as to cause high potential at *a* and low potential, relatively, at *b*. Let us, for clearness sake, deal with one of these extremities singly, say *a*. Now, I can only conceive of two ways in which the electric potential at any point of a body can be affected. One is by importing a *charge*, positive or negative; the other is by constraining or expanding the electric *capacity* at that point. Accordingly there are only two ways in which the potential at *a* can have been raised. The first of these supposes the influence of the primary, acting through the dielectric, to consist, as it were, in a backward *wafting* of electricity from *b* to *a*. This would be raising the potential by *importation of charge*. The other way in which the potential at *a* might be raised is by *diminishing the capacity* of the conductor at that part; and if this really were the nature of the influence exercised by the primary, having in view the decline of potential therein, then current induction and statical induction would be identified as one and the same physical process, which is surely a happy conclusion to arrive at. We need not, however, base the argument upon the happiness of its conclusion; it is easy to see how to make our choice between the two possible processes of disturbed equilibrium. If the influence of the primary consisted somehow in a backward wafting of electricity from *b* to *a*, the secondary current would flow on continuously, which is not the case. If the influence consists in modifying the capacity of the neighbouring conductor, as in statical induction, then the decline of potential along the primary wire would be accompanied in the other wire by a less and less constrained capacity from *a* towards *b* throughout the portion subject to influence. The declining slope of potential resulting from this unequal capacity would be adjusted, once for all, by a momentary flow of electricity from *a* to *b*, whether by *a d b* alone, or also by the channel *a c b*, when the secondary wire is a complete circuit; and this theoretical result is in accordance with the observed facts.—Yours, &c., E. ALDRED WILLIAMS.

37, Burlington-road, W., Oct 31, 1885.

CORRECTION.—In Mr. A. Bernstein's letter, published in our last issue, the date of the patent should be *1882* and not *188-* as printed.

THE DISTRIBUTION OF ELECTRICITY.

BY PROF. GEORGE FORBES.

LECTURE III. *(Concluded from page 477.)*

The wires which conduct the electricity into a house of any of these high potential schemes can never have a greater difference of pressure between them than what is required for the lamp; that is, in the present state of affairs, something like 100 volts. We will say that is the highest pressure there can exist between the two wires, and it seems almost incredible that there should ever be allowed to be a leak in the system so great that when a person touches one of the wires he should have a high current flowing through his person which would be dangerous. If we are to abolish the idea of using high potentials simply because of this vague notion that some time a shock might be experienced, we might as well abolish the whole system of gas lighting because it is possible that people can go into rooms where there is a leakage of gas with a lighted candle. The danger from gas is infinitely greater than that which can ever come from high potential electricity, and the difficulty of detecting a leakage of gas is likewise infinitely greater than the difficulty of detecting a leakage of electricity. A properly organised system of distribution of electricity at high potential would render a severe shock to any person absolutely impossible, and that is the point which needs to be dealt on very strongly at present, because so much has been talked—and so much nonsense has been talked—about the dangers of high potentials.

I have often found a great convenience in describing the effects of electricity and the systems of distribution by reverting to the analogy of water pressure, and I think those of you here who are not deeply conversant with the subject of electrical engineering will perhaps be assisted by a few words of reference to the analogy of water pressures.

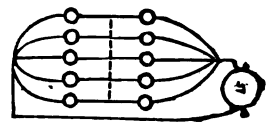

FIG. 1.—Multiple Series.

At present we see through different parts of London pipes being laid for supplying power by means of water at high pressure. This water is utilised in motors or turbines, through which the water passes. The water pressure is remarkably analogous to the pressure of the electricity in our mains; the turbines or other motors which are used to develop the power have remarkable analogy to the incandescent lamps or the arc lamps, or the electric motors which may be used with a system of distribution. Now, in the manner of laying pipes for water-power which we have all observed in the streets in London, all these turbines or water engines are connected directly on to the same set of pipes; in other words, they are all connected in multiple arc, as we would say in electric language. But it would be quite possible to conceive of two turbines connected together in series; that is to say, with a very high pressure in the mains first driving through one of these turbines, and then the outflow of water from that turbine still admitting of considerable high pressure to a second turbine, which it would work with the superabundant pressure which would exist. This is exactly analogous also to the electric system of distribution in series; and this will be clear by examination of the diagram (Fig. 1), where this circle represents the dynamo machine with the two leads coming from it, and here are a number of circuits, each circuit having two lamps in series. This is exactly equivalent to a main to come along here, split into a number of water pipes, with two turbines put in series. It follows that the pressure of water required to drive these two turbines is double the pressure required to drive the one. So it is exactly the same in electric distribution. We simply have to increase the pressure when we put a large number of lamps in series.

Now, there are several different ways in which high potentials can be used effectively and with economy. I will begin with mentioning the probable future which there may be in the application of secondary batteries. We often hear it remarked that the present systems of electric distribution are weak in some points, and that if only a system of secondary batteries were introduced everything would be clear; and there is no doubt that by introducing secondary batteries a great deal of facility is

Digitized by Google

given to the scheme. In the first place you can have a much smaller engine power, much smaller dynamo power, because your dynamos can be working the whole day charging these accumulators, and only used for supply when it is required. In the second place, you can put your secondary batteries all in series over a large district, and charge them all up in series, and then discharge them each to its local district, a small number at a time, and a small number at one place. In this way, by using high potentials, of course we should use small currents. In the hydraulic analogy, by using high pressures we require a smaller volume to flow, and therefore we should require smaller conductors, and consequently there would be a saving in laying down our copper. This is perfectly true, and there is not the slightest doubt a secondary battery system is of the utmost value, and would help us enormously. But at the present moment there are several difficulties in the way of introducing secondary batteries like this, and the first is, perhaps, the most fatal one, and that is that we have no secondary battery. I do not mean to say that much has not been done in the last four years in improving secondary batteries; but at the present time we have not sufficient confidence in the length of life and economy of secondary batteries to justify any engineer in depending upon them in designing a scheme of distribution. But I must say that there is a great probability of something being done in this direction, because there is such a vast amount of intellect in the whole world being devoted to this particular line, trying to perfect it, and already I have seen such enormous improvements in secondary batteries of late, that I cannot help thinking that very likely soon we shall arrive at something much more near perfection; and for this very reason I consider it is of the utmost importance that engineers should consider all such schemes which enable them to use high potentials, because, even though at the present time such a scheme as that introduced is imperfect to a certain extent, those schemes which lay down small wires for using with high potentials are the very schemes which will become applicable when the secondary battery is really a commercial thing in our possession; and, therefore, any person who has at the present moment to lay down a large system of lighting with the multiple arc system, would perhaps find, in the course of a year or two, that the whole of this enormous cost of copper he had laid down would be utterly wasted, because some discovery which had been made would enable him to use smaller conductors. For this reason I consider in designing a scheme of electrical distribution an engineer should consider the great importance of probable discovery in the way of secondary batteries.

There has been one large experiment in the way of secondary batteries made at Colchester, and I have got diagrams here showing schemes of electrical distribution. With respect to the diagram at the other end of the room, which was referred to in the first lecture, I would simply say if you have troughs, or good-sized channels, in which your conductors are laid, there is very little difficulty about your insulation; with a good trench and plenty of room, the engineering difficulties are comparatively trivial, so long as you will remember the facts which I pointed out in my first lecture, that you are not to trust your insulating material as the support for the conductor. Your conductor must be supported by a substance capable of supporting it, not by a bituminous compound through which the conductor will sink in the course of years. But there are no engineering difficulties if you are able to have a dry trough for conducting your wires, and I am perfectly of opinion that if you have the mains laid down in that way you can use your 5,000 volts with perfect facility, and there will be no danger; and with proper tests regularly made such a system would not only be possible, but perfectly safe. The following arrangements are made at Colchester by the South Eastern Brush Company for distributing their electricity. The dynamos with the charging mains act through what is called a rocking switch into the secondary batteries. Now in this supply system, first we have charging mains coming to the secondary batteries situated in different districts through the town, and then from the secondary batteries we have service mains going away to different houses which are to be supplied, and this rocking switch is controlled by what is called a master cell, which is simply a cell with a diaphragm, so that when the ebullition of gas becomes too great, and the diaphragm is raised and the contact is made—which switches over this rocking switch, and the cells then being considered to be thoroughly charged, are transferred from the charging system of mains to the service system of mains. This is the arrangement which was adopted there.

One of the cells which are used there is shown here—one of the Consolidated Company's cells—which I have lately had the opportunity of testing very carefully, and which seem to give fair results; and I have upon the tables below two plates, a positive and a negative plate, and you can examine them and see how they are constructed. Let me put in a word here in parenthesis. I do hope that those who are electricians will not allow the term negative to be applied to what ought to be positive, and the term positive to what ought to be negative. I cannot understand why, since secondary batteries have been introduced, the whole language which electricians have been accustomed and got habituated to should be utterly reversed, and if certain companies who make these batteries persist in calling the plates in that way I do not see why electricians should adopt them, and why they should not stick to the terms they have been accustomed to use. I only hope a word said in season here and there will lead to electricians insisting on proper terms being given to these plates. Here, also, I have some plates well worthy of examination kindly lent me by the Electrical Power Storage Company. I may say that I had the good fortune to look through the work they have been doing of late, and I have been very much struck by the enormous progress they seem to have made in the practice of the construction of cells, and the maintenance of them in good order, and the prevention of the sulphating of these plates, which has been a source of very great trouble; and one of the chief things I was shown was the way in which these negative plates are kept in good condition, and how it is apparently impossible to injure them by overchargiug. I believe I am right in pointing to this one [indicating a cell on the table] as one which has been persistently overcharged with the idea of trying to damage it, trying to make it worse, and if you look at it you will see as good a plate as you ever saw in your life in any secondary battery, the material perfectly sound and excellent. It really seems to show that one of the chief difficulties that has been met with is charging with too weak a current, and allowing the battery to degenerate, and not keeping it thoroughly charged up.

Next, I wish to draw your attention to a system of supply with high potentials which has been introduced by means of secondary induction currents. It is a very old idea to use induction currents in order to use a high potential current in the mains, and a low potential current in the supply service. I believe that the first patent which I have come across taken out in connection with this was by Mr. Harrison, in the year 1857, and since then it has been patented over and over again, and here is a general idea of it shown in diagram (Fig. 2), where there are supposed to be rods of iron surrounded by coils of the main wire; here is the main wire coiling around one end of these iron bars. The lamps, then, have their terminals connected by a wire which coils around the iron bar also, an alternate current is used to pass through these main coils, and it sets up alternate magnetisation in opposite directions by these iron bars, and the magnetisation induces electric currents in this wire which is connected with the lamp, and, consequently, we are able to magnetise this bar by the main wires with any potential that we please, and we are able to draw off, by these induced currents, a current of any potential that we please. In this way different lamps in different parts of the circuit can be fed with a current of whatever pressure you please, although the main exciting current is of very high pressure indeed; but, mark this, there is absolutely no danger in this system, because the charging current is in a closed circuit which never goes near the rooms where the lamps are actually at work; a lamp thus never has over the potential which is required for that lamp, and the high pressures which are used in the mains are confined simply to a closed circuit of wire; therefore there is absolutely no danger in such a system so far as the conduction of electricity to any person is concerned. I may say that, owing to the construction of such apparatus, it acts as a condenser, and so might give a severe shock. But this danger can be reduced to limits of safety, and tested for safety by ordinary electrical methods. I have said that this is a very old system. The idea is very

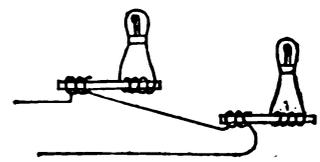

FIG. 2.

old; but it is only in the last few years that it has been worked out practically and with confidence, with a confidence that does honour to M. Goulard, I may say, for the way in which he has attacked this problem; he was confident from the very first. I think it was three or four years ago when we first saw his apparatus in the Westminster Aquarium; since then he has been improving it, and has brought it to a practical issue. Since then I have not myself had the opportunity of experimenting upon the apparatus, but I simply draw my conclusions from the reports, in the first place, made by Dr. Hopkinson and others; and I have not the slightest doubt that from these secondary generators it is possible to get a return of 90 per cent. in the lamp circuits. This is a result which is very remarkable, and is worthy of far more serious consideration than it has received up to the present time from most people, though of course many advanced electricians have been looking with eager interest at the result of these experiments. During the course of the last summer experiments were being made, as most of you are aware, at the Electrical Exhibition at Turin, and I have on the wall a plan of the scheme which was used there, and of the way in which the wires were used. Altogether the circuit had a length of about fifty miles; and we have evidence of the large number of different kinds of lamps used upon that circuit—a large number of Bernstein, Swan, Siemens, and Edison lamps, arc lamps and glow lamps—a large number of different lamps of different pressures, all worked from that central station over that great distance, so that the matter of distance is apparently overcome; these distances were of course much greater than they need be in any town distribution. I do not think I will say anything more about the system just now, except this, that if there is no difficulty about the expense, it is well worthy of far more attention than has been given to it up to the present. I had the pleasure of looking at the installation which is being commenced at the Grosvenor Gallery the other day, and I see there is no doubt we shall have an opportunity very soon of seeing a very large installation there, and at the Inventions Exhibition there is going to be a considerable amount of work done by the same system. After those two experiments we shall be in a position to judge whether economically it is good. In every other point, except perhaps the induced currents which the alternate current machines may create in telegraph wires and other circuits, there really seems to be no objection to the system. It is true there is a great objection to alternate current machines, but when we come to examine it there is very little ground for these objections; if the leading and return wires are brought very close together, induction in neighbouring telegraph

Digitized by Google

wires is small, and I really think that we ought to look—all electrical engineers ought to look—very closely into these experiments which are being made just now, for they really promise well.

Now let us go on to the other systems, and which are more analogous to those which we have been describing previously; and first, let us speak of the multiple series system. Here is a system, which I have alluded to, of multiple series on which there are two lamps on every series (Fig. 1). Now the trouble of that was, when it was first introduced, that if one of those lamps went out, the other in the series went out. In order to prevent that, it was suggested to bring a wire connecting the intermediate position to all the lamps in the circuit. Then if one goes out, the other does not, because it is fed by the current coming from the other lamps. The sketch shows that very well by the dotted line. Another example shows it in a different manner. There we go through successive pairs of lamps, the pressure gradually falling as we go along, and pass through the nine different series connected up. I do not know when this system was first proposed; it is very old, I believe. The first time that it was practically seen in action was, I believe, at the Paris Exhibition of 1881, when Mr. Edmunds lighted the Congress Salon by Swan lamps, the lamps all being fitted in multiple series in this manner. After that the most important experiments made were those by Mr. Preece, at Wimbledon, last year, when, in some experiments he made for the Commissioners of Sewers, he lighted up a large part of Wimbledon with incandescent lamps, all on the multiple series system; and quite lately we have had brought before our notice by Mr. Kierzkowski-Steuart an admirable account of the lighting of Temesvar, in Hungary, by means of a multiple series system like this. Now, the multiple series system is one which is admirably adapted to Temesvar, in Hungary, because it is only used there for street lighting, and the lights are always all required at the same time. But it is not suitable for house-to-house distribution, simply for the reason that if some of the lamps are put out, then the other lamps on the circuit have too much current. [Experiment to show this effect.] Now it would be intolerable, in a general supply of electricity, that when one house in a block of buildings was using rather less current than usual, other persons in that block should get far too much current; and that the next block of houses should receive so little current as was shown by these lamps in the experiment would also be intolerable. Various devices have been proposed for getting over these difficulties. I will deal with one or two. The first system which I shall speak of is one which has already been put into practice, and it is undoubtedly a most ingenious principle. That is what is called the three-wire system, which Dr. Hopkinson originated. There we have two dynamos at the central station working in series, working through each other; that is to say, in the hydraulic analogy two pumps working in series, so as to send the water from the pumps at a very high pressure, if such a thing could be introduced into hydraulic engineering. The supply mains come from the extremities of two wires, but there is a third supply main which comes from the intermediate point and connected between the two dynamos, and the lamps are attached to branches which may come from the first main to the intermediate, or, as it has been called, the compensating main, and some of the lamps are attached to branches which are connected with the last main and the compensating main in the middle. We are able to use twice the pressure by using the dynamos in this way. Of course, a great difficulty, as I have mentioned, would occur were it not for this central connection of the compensating wire; if there are more lamps in use in the first series than in the second series, then it would be necessary to drive the first dynamo so as to give a greater current than the second dynamo is giving, and then by adjusting the pressure of the two dynamos we are able to give a constant supply to both sets of lamps, and at the same time to work them in series. This line on the diagram is supposed to represent a point of very large consumption, such as a theatre, when the wires come, some from the first main and the compensating conductor, and some from the second main and the compensating conductor, but in about an equal number, so that if the lights of the theatre be put out of a sudden, the disturbance in one series of mains will be the same as in the other, and there will not be that change in the light shown you just now.

Now, as to the economy of this system. In the first place you will notice that, as I have arranged it here, which is the manner in which Edison has used it, the fall of potential is at the same rate as it is with the ordinary multiple arc distribution; therefore, according to this way, in which lamps are led off from two pairs of mains at every part, the distance to which these mains can extend is still limited, as it was in the multiple arc system, to 124 yards. But it would be equally possible to use only the first main and the compensating main, up to a distance of 124 yards, and then to use the compensating main and the second, the lower potential main for another 124 yards. Now, as to the economy. A great deal of exaggeration has been introduced in America into the accounts of economy in this system. It has been said that since you are using only half the current when you double the number of dynamos, therefore you halve the size of mains. But then you have three mains instead of four; therefore, they say, you have a gain of 25 per cent. for that reason. But then they also say you have got twice the pressure you had before, and, again, you may halve your mains, and, altogether, they tell you, you can make a saving of copper of 62½ per cent. Now, this may suit American financiers, but it is not electrical engineering. As a matter of fact, in the two cases, with an equal number of lamps, in place of having one dynamo and one pair of mains, I introduce two dynamos and three mains. I have half the current passing through that wire, and, therefore, I may have half the section of it, but there is no further reduction possible. I assume that I may take it for granted that the axiom which we worked out in the first lecture must be accepted as an axiom in all future time—that is, that to get economy in our mains we must use the most economical size of conductor possible. In that case the size of conductor is approximately proportionate to the current it has to carry; therefore, the total amount of copper you have to lay down is simply three-fourths of the mass of copper which would be laid down in an ordinary multiple arc system. At a meeting of gentlemen interested in electricity lately this subject was broached, and I ventured to mention this point then simply because the originator was present, and I may say that Dr. Hopkinson thoroughly coincided with me in the views I have given you, so that the erroneous notion is evidently purely an American idea. If we increase the number of wires from three to a larger number, then we increase the economy; but if all the wires are of the same size, then the limit of economy, the maximum economy, would be to reduce the copper by one-half. But it is possible to reduce the compensating wire, and I should think it might be reduced to one-half, and in that case the limit will be one-fourth; that is to say, when you put a large number of series you will have about one-fourth of the copper which you have otherwise in a multiple arc system. However, if we wanted to be absolutely certain that our lamps would be in perfect working order, and that our conductors would be of suitable size, perhaps it would be right that all these three conductors should be of the same size, because such a consumption might arise. I am not of this opinion; but suppose we say that then would come the question whether it is not possible to devise some other means of reducing the thickness of these intermediate wires—these compensating wires. And this is what Mr. Edison has accomplished, on paper at least. In a very interesting patent which he took out in 1883, he has described a means of switching over the lamps from one pair of mains to the other. Now, I believe there is a great deal in this, and I believe it is possible in this way to make the householders themselves regulate their supply to a great extent. Just think what you do with your own gas. When you first light your gas, if your burners are as bad as burners usually are, your light flares, and you have to turn it down; after a time, when everybody else is using the gas, you have to turn it up again; then, late at night, when everybody has gone to bed and you are hard at work, you require again to lower it. If every householder had a switch, so that he could switch his own lamps on to one pair of mains or the other, when he found his light dull, he would fiddle away with his switch, and in that case he would not only make his own light better, but everybody's else, and every person in the district would be helping the others to acquire the right potential. No knowledge of electricity is required; no householder has to know what he is doing; he has simply to follow the natural instinct which a householder has of fiddling with his gas jet until he gets it to work the best way possible, and thus it is just possible that to some extent that may be of use. Mr. Edison proposed to use this system of switches with the three-wire system in combination with it, so that he will not get a perfect compensation by either the one or the other; by the combination of the two he will get a perfect system and a perfect compensation. He has also proposed, in the same patent, to introduce automatic switches, switches which may be influenced by the pressure of these mains locally, or switches which may be influenced by the person in charge at the engine house, so that wherever there is a deficiency of potential, lamps may be switched over. It is very probable that some development on this line may lead to important results. I have myself tried to extend the system a little, not in connection with the three-wire system, but in connection with the simple two-wire system. I feel pretty certain that the lighting of a town from a central station must be done on some multiple series system until secondary batteries are so economical as to permit the general introduction of such a system as that in use at Colchester. The chief difficulty lies in the fact that each section receives the same current whatever be the number of lamps in use. To obviate the excess of current, we might introduce conductors in those sections where it is required to carry off the excess of current. Thus, we should save the lamps at the expense of energy. These conductors might be in the form of adjustible resistances, acting automatically. This system is wasteful, but there are many cases where, at the present time, it is the most economical. Another plan is to introduce in each section a secondary battery of low resistance, which shall act as a regulator. But secondary batteries are still rather expensive. I have shown a diagram of multiple series arrangement in which two wires go round the circuit with breaks occurring alternately in the two wires. If we alter the position of these breaks we can always have the same number of lamps on each section, and so avoid all excess of current and all waste of energy. [Experiment shown.]

Now, the time has come when we must conclude this course of lectures, and, in conclusion, I have only to say that I think you will all agree with me that when we attack the problem of electrical distribution in a serious vein, we find that it is rather simpler than it seems at the first blush. It has been well said by one of our most distinguished electricians that in the past the distribution of electricity has been the *crux* of electric lighting; it has been there that the difficulty has been. Undoubtedly the Electric Lighting Act has done an enormous deal to hinder electric lighting, but every electrician must admit that there has been a difficulty in the question of distribution; and I think you will all agree that the further we get into it, the simpler are the rules which guide us, and it is only that when schemes have generally been commenced in a slightly haphazard fashion that difficulties of a serious character have seemed to present themselves. In every special district the engineer must use his discretion as to the kind of distribution which he is going to employ. But even in large districts, I think you will all agree that the consideration we have given to it shows that it is a possibility to lay mains on economical principles which shall suffice for lighting large districts, if no undue hindrance is put in the way of enterprising undertakers by the authorities that are in power. The past history of electric lighting has chiefly dealt with the system which I first spoke of in my last lecture, the multiple arc system, but I do not hesitate to say that the future of electric lighting, on a large scale, will deal almost entirely with the systems which have been touched upon to-day. And especially I

Digitized by Google

would draw attention to these different schemes and their value, for the reason which I have already mentioned, that in the future we may have inventions in secondary batteries, or we may have other inventions; but whatever invention there is favouring electric lighting, it will be of a natnre suitable for using the thinner conductors which we should naturally lay down with any high potential system which I have spoken of this evening. Therefore the engineer, in designing a system of mains, would have a natural bias towards such thin conductors, such high potential mains; for that reason he would advise it, as well as for other reasons. When we are able to use, as I confidently believe we shall, a pressure of 5,000 volts, we can diminish the thickness of our conductors to one-fiftieth part, and for a district of 50,000 lights we should only require a conductor of about an inch section of copper. When we are leaving the idea of masses of copper of the size of a man's body, and coming down to masses of copper an inch or even two inches in diameter, I think we are really coming to the question of practical electric lighting. And all this has been done—is not merely theoretical; it has been done to a considerable extent already, and that is the direction in which progress is being made at the present time.

I can only say that I hope the parliamentary difficulties which have partly stood in the way of electric lighting in the past will soon be entirely removed, and that others will prosecute the question of electric distribution, so that we may be all thoroughly ready for it when we have greater facilities for electric lighting in the future, because there is not the slightest doubt that the question of distribution had not been sufficiently developed when the Electric Lighting Act was passed; and if we are ready in the future, when those great concessions which must be granted by this or a succeeding Government—because it is simple justice—when those concessions have been granted, let us trust that engineers will be ready, and be able to supply a scheme which is perfectly satisfactory.

COMPANIES' MEETINGS & REPORTS.

Direct Spanish Telegraph Company (Limited).

The twenty-fourth ordinary general meeting of this Company was held at the City Terminus Hotel, Cannon-street, on Friday, the 30th ult., under the presidency of Sir James Anderson.

The MANAGER (Mr. Chas. Gerhardi) read the notice convening the meeting and the minutes of the previous meeting, which were confirmed and signed by the Chairman as correct.

The CHAIRMAN then said: Gentlemen, before moving the adoption of the report, I will, as usual, make a few observations in my own way. All that will be new in them will be with respect to the Telegraph Conference, because I find, looking at what I said last April, that if I repeated now what I said then it would answer, perhaps, quite as well. I observed on that occasion that we were trying all that we could to get a wire through Spain to Carthagena, and a better wire between Madrid and Bilbao; that a commercial treaty was apparently about to be concluded between Great Britain and Spain, and that our traffic had been interfered with owing to the cholera. Now, the Spanish treaty has not come off, neither did we get the line to Carthagena, although, as I told you, we had the greatest influence possible brought to bear on the matter, and spent some money in trying to get it. The cholera also has prevailed ever since, and still worse than before; so that we have not got to any satisfactory point as regards the traffic. In addition to these prevailing misfortunes trade has been very much depressed, as we all know, and our cable broke the other day. I am happy, however, to say that our ship arrived on the spot this morning. She is a very fine vessel, and with an experienced captain and crew. I am in hopes that we shall effect a speedy repair, although the cable is broken in 2,000 fathoms of water. These are the bad sides of the story. We are very sorry for the breaking of this cable, which is perfectly unaccountable unless we assume some convulsion at the bottom of the ocean. It was a new cable, and unfortunately it broke at the very time when traffic was growing. I do not think we have seen such evidence of growth for many years as there has been in Spain for the last few weeks previous to the cable breaking, and, in fact, I do not know any other outcome for this Company than to look forward to growth of traffic. I do not think it is any use beating about the bush, and trying to make the position look pleasanter and nicer than it is. That growth of traffic will come I have great hopes, but if not we shall not pay dividends in a hurry. Mr. Gerhardi and I have been to the Berlin Conference, where we were five or six weeks, and you will naturally ask what was done there. When we went to Berlin the outlook was as gloomy as possible. It seemed that if the tariffs were arranged as Germany and Austria wished, the Direct Spanish Company would have been wiped out, and there was a wide feeling amongst some of the delegates against submarine cables. There was an idea that a great many of the cables were luxuries, and not of very much use—that a few might be, but not many of them. However, that idea ceased to have any great weight in the course of a fortnight or so. They began to find that for external commerce cables were not only not a luxury but were indispensable, so much so that they had to be termed and were termed the "normal routes." This country, which has practically all its commerce outside the limits of these islands, has, speaking off-hand, 75 per cent. of the whole telegraphs of the world—I mean the external telegraphs—and therefore we are dependent more than any other country which connects its shores with the shores of other States. We received the cordial support of Mr. Patey, who represented the Post Office; of Colonel Champain, who represented India; and of all those States, such as Spain, France, Turkey and Greece, and others, where private cables are landed, and they insisted on almost all cables being considered as normal routes, because of the frequent interruptions of the land lines, and because—seeing that these cables are worked by private hands, and under the ocean, not traversing a number of States speaking different languages—our cables are the most reliable, with the fewest errors. There therefore came to be a better feeling towards us (because the delegates were business men) as we mingled among them. And I must speak in praise of the assiduity of Mr. Gerhardi, who speaks several languages, and who mixed among them in the most genial way, getting more out of them I think than any other Manager at the conference. In order to make the cables pay, those States in which the cables were landed had to raise their rates so as to give them something, and they did so in such a way as to make us very little, if any, the worse for what was done. All through the published records of the receipts of the different telegraph administrations there is nothing but deficits, except in the case of a few States. One country loses £210,000, and there are other countries losing £50,000 to £60,000, and five of the larger States have fused their postal and telegraph receipts so that no one can can tell how much they are losing on the telegraph returns, and they cannot be called in question by their own taxpayers. There is this peculiarity in the Direct Spanish Company and with the European cables of the Eastern Company, that we are opposed to Governments who not only have monopolies, but can afford to lose money, or think they can do so, on their telegraph administration. At all the conferences I have been at in the last fifteen years the governing principle as regards telegraph administrations was that the revenue must pay the expenses, and upon that basis the tariffs were adjusted. But Germany has insisted for some years—and especially at this conference—that that should not be the governing principle. The desire, in fact, of all European States, as you know, arising from the colonial fever, is to extend commerce outside their own limits, and, by bringing down telegraph tariffs to a minimum, to increase the facilities for supporting that commerce between distant colonies, and outside countries and centres from which manufacturers and emigrating populations arise. It was therefore the great aim and effort on the part of Germany and Austria, and some of the other States, to disregard the tariffs of almost everyone, and to bring down the cost of telegrams to a price which they, however, soon saw, when it came to be discussed, would not allow those cables to be maintained, and the result happily was that they recognised that principle, and the tariffs were so adjusted that I do not think this Company will lose much, if anything. The whole aggregate loss that we can see is about £1,400. Notwithstanding all that these States are losing, they are still prepared to lose 40 per cent. more, because that is what the present tariffs amount to; and, assuming that these low tariffs will increase the number of telegrams, I do not think we shall lose anything on the whole. Our tariff will now be 4½d. instead of 6d. a word to Spain. That is the position in which we stand with regard to the Telegraph Convention. I really do not see, as I have said, anything to improve this Company without an increase of traffic to a large extent. We can carry four or five times as much traffic as I have yet seen, so that we have plenty of carrying power. With these remarks I now move the adoption of the report. I do not think I have anything to add unless you ask me questions which may induce me to say something further.

Mr. EDMUND ETLINGER seconded the motion.

In answer to Mr. DYETT, who asked when the old cable might be expected to be at work,

The CHAIRMAN said that they must proceed cautiously, and not be in a hurry to spend a lot of money on what might prove not worth repairing. The Eastern Company lost an excellent ship last year, which the Directors would have employed on this work, but he had not thought it proper or wise to recommend his colleagues to spend money in chartering another vessel to send out for the purpose of repairing the cable. The captain of the vessel had great doubts of its being repaired, and he (the Chairman) would not like to attempt it now, being winter time; and until the summer came he desired not to make any promises in respect to the subject.

Mr. BEARD thought the sooner they dropped the old cable the better.

The CHAIRMAN: I do not think we are prepared to do that.

Mr. COCHRANE asked—what he said he had done at the previous meeting—whether the Chairman would submit the precise opinion upon which the Board had decided not to pay the preference dividend. He complained of the lack of interest in the Company shown by the shareholders, as was evidenced by the paucity of the attendance. The proxies, he went on to say, showed that they were in the hands of the Eastern Company—a very excellent company—but he ventured to submit it was rather a precarious thing to have two representatives of the Eastern Company on their Board, and only one gentleman representing the Direct Spanish shareholders. He thought the time had come when there ought to be some change in the constitution of the Board. As to employing a ship belonging to the Eastern Company to repair their cable, if he was not in error, by the constitution of the Company Directors who were also members of other companies were precluded from voting on such a question, and how, therefore, could a majority of the Board vote on it? It seemed to him that the only hope for the Company was to be absorbed by the Eastern Company. He confessed his amazement that the Eastern Company should hold something like £100,000 of their capital, and that no steps had been taken by the old Board to better protect the shareholders from being so utterly bound over. They could never, he thought, pay a dividend to the common shareholders until their capital was made intact, which could only be effected in two ways—either by replacing their broken cable, or reducing their capital. He was strongly of opinion that a committee should be appointed to meet the Directors and consider the whole question.

The CHAIRMAN, in reply, said that for his own part he would be very glad to be turned out of his seat. He did not go on the Board willingly, or for any purpose of his own. As for the ship, he was quite certain that the Eastern Company did not wish to give them a ship; and if it were

not that they were so largely interested in the prosperity of the Direct Spanish Company, they would not get the ship at the price they were getting her for or for anything like it. Anyone with the slightest experience of shipping might see at a glance that the same terms could not be offered by any Company making money out of its ships. The Eastern Company made no money out of the Direct Spanish. The former, as he had said at the last meeting, had an object in buying shares in the latter, and that was an object which, if realised, would have been the making of the Direct Spanish Company. If they had twenty committees matters could not be mended. If the Eastern Company could have taken one of their cables to Carthagena, to connect it with Bilbao, it would have been the saving of the Company, and he was in hopes of doing it yet. No one else could do it but the Eastern Company; and, moreover, it would pay no other Company to do it. They got Sir Robert Morier to exert himself on their behalf, and that gentleman was authorised to do so by our own Government. If the shareholders wished to get a committee to manage the Company he was willing to resign, and unless he were patted on the back he would rather not be on the Board. The only way of making money for the Company was by developing traffic in some way. He could not take any blame to himself for contracts of the old Board. The old cable was far too overladen with capital. It was not represented by that, and never was. He would not move a finger to be kept on the Board. The Directors were doing the best they could, and he defied anyone to do better. He had no personal interest to serve by remaining on it.

Mr. ETLINGER, as a member of the old Board, said that the interests of the Company were looked after by the two gentlemen connected with the other company in a much better way than any one else could do, on account of their experience in such matters. They had power to help the Company, and they were willing to exercise it. He quite agreed with the Chairman that a committee would not improve the position.

Mr. DYETT said he would be very sorry to lose the services of the Chairman. It seemed to him that the Directors were doing their very best for the Company.

Mr. BEARD expressed a wish to see the Company taken over altogether by the Eastern Company.

The CHAIRMAN replied that it could not be done at the price the shareholders of the Direct Spanish would want.

Mr. COCHRANE repeated his question as to the opinion on which it was decided not to pay the preference dividends.

The SOLICITOR (Mr. Blunt) read the substance of the opinion of Mr. Horace Davey, Q.C., to the effect that the Directors could not properly pay a dividend on any of the shares, including preference shares, until they had either put the original cable into a proper state of repair and working order or abandoned it altogether, and taken the necessary legal steps to write off the capital represented by that cable as lost capital unrepresented by available assets.

The CHAIRMAN said that this subject had engaged the attention of the Directors a great deal. They had been enjoined against paying dividends. Anyone could buy a share in the market, and could hold the Board personally liable for the payment of dividends. This had been the case in the Anglo-American Company, where the Directors had tried to defy such a view, but had been obliged to give in. They had taken counsel's opinion, and no Director would, in the face of such an opinion as they got (which was only one of a number), take the personal responsibility of being liable to pay back dividends which had been distributed.

The SOLICITOR here pointed out that Mr. Davey had also said that no valid distinction could be made between preference and ordinary shareholders.

Mr. COCHRANE remarked that he asked the question because at the last meeting and since some of the shareholders thought that if the extra capital were called up the Directors were released from that liability.

The CHAIRMAN pointed out that they had only £12,000 to call up, which he did not think could be used for any other purpose than that of laying land lines in Spain.

The motion was then put, and carried unanimously.

Mr. DYETT urged the Board to exercise all the economy they could under the circumstances in which the Company is placed, and suggested that in future the Company's meetings should be held at their own offices.

The CHAIRMAN said the Directors had themselves made the same remark before the meeting, but on this occasion they expected a larger attendance of shareholders anxious to hear what the conference had done.

Mr. STOKES proposed and Mr. DYETT seconded a vote of thanks to the Chairman, which was cordially agreed to, and

The CHAIRMAN having briefly replied, the proceedings terminated.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

Report and accounts of the Directors for the half year ended 30th June last, to be presented to the twenty-fourth ordinary general meeting, to be held at the Cannon-street Hotel, on the 10th inst., at two o'clock:—

The gross receipts, inclusive of Government subsidies, have amounted during that period to £259,476. 9s., against £237,672. 11s. 5d. for the corresponding period of 1884, showing an increase of £21,803. 17s. 7d. The working and other expenses, including £23,406. 15s. 6d. for cost of repairs and renewals of cables and expenses of ships, absorb £74,418. 6s. 9d., against £66,658. 18s. 9d. for the corresponding half year of 1884, leaving a balance of £185,058. 2s. 3d. From this is deducted £3,104. 15s. 4d. for income tax, and £41,595 for interest on debentures and contributions to sinking funds, leaving £140,358. 6s. 11d. as the net profit for the half year, against £127,415. 15s. 8d. for the corresponding period of 1884. Against this the Directors have charged a further sum of £20,000 on account of the partial renewal of the Singapore Saigon and Penang-Rangoon cables. The cost of the operations will be shown in the accounts for the current half year, the whole of the cable not having been picked up before the 30th June. One quarterly interim dividend of 1½ per cent., amounting to £31,250, has been paid during the half year, and another of like amount, together with a bonus of 2s. per share, was distributed on the 15th ultimo, making a total payment of 3½ per cent. for the half year, leaving £32,858. 6s. 11d. to be carried forward. In accordance with the provisions of the trust deed, dated 10th May, 1879, 239 Five per cent. Australian Government Subsidy Debentures were drawn on the 29th April last for payment at par on the 1st July. A new cable steamer, "Recorder," has been built for the Company by Messrs. R. Napier and Sons, to replace the ss. "Magneta." She is now fitting out in the Thames, and will shortly be despatched to Singapore. No serious interruptions have occurred during the half year, although the Company's ships have been employed on various repairs. They have also been employed on charter to the Telegraph Construction and Maintenance Company for a considerable period, as shown in Abstract C. At the same time, 322 knots of cable, taken principally from the Company's stock at Singapore, were sold to that Company. The latter transaction will appear in the current half year's accounts. All the Company's cables are now in good working order. At the International Telegraph Conference recently held at Berlin, several important questions were discussed affecting the telegraphing public, but the principal changes made in the existing convention were in the direction of cheapening the European tariffs. The new convention will come into force on the 1st July, 1886. The question of reduction of rates has been under the consideration of your Board for some considerable time, and at the conference it was agreed to make certain reductions to Australia and China on condition that the Indian and South Australian Governments reduced their transit rates. The South Australian Government have agreed to bear their share of the reduction, and negotiations with the same object are proceeding with the Indian Government. The land line between Port Darwin and Adelaide, belonging to the South Australian Government, has, as usual, worked well during the half year under review.
